Administration of Quinine in Malaria.—According to M. JACCOUD, there is a great and important difference between the apparent and the real onset of an attack of intermittent fever. The real onset begins several hours before the chill, and consists in an increase of the urea in the urine. Chronologically speaking, then, the first phenomenon in intermittent fever is not the chill, nor the elevation of temperature, but the greater or less increase of urea in the urine. This increase takes place at different times in the various forms of malarial fever. In the tertian it is six or eight hours earlier than the chill; in the quartan type it may be twelve, fifteen, or eighteen hours earlier. Thus the proper time for administering quinine is fixed by the nature of the disease, its action being felt six hours after the remedy has been given. It will be perceived that in the quotidian type of intermittent fever a dose of quinine given six hours before the chill has not time to modify it, because the real onset occurs two hours before this outward manifestation—the chill—and, therefore, to be effective, the drug must be given eight hours before this is expected. In tertian fevers the proper time for giving quinine is twelve hours before the chill, and in quartan fever it is eighteen hours. Large single doses are most effective, because the drug is rapidly eliminated by the urine. Small and repeated doses never produce the action of the whole amount prescribed. When any gastric disturbances make small doses necessary, the whole dose should be given in such fashion that it is disposed of in one hour or less.—*New York Medical Journal*, March 15, 1890.

Medical Treatment of Dysmenorrhœa.—DR. E. W. MITCHELL writes as follows upon the medical treatment of dysmenorrhœa:

Remedial measures naturally divide themselves into those of relief and those of cure. Of the former, opiates occupy the first place in their power to relieve and in their power for ultimate evil; but once used, the danger of the opium-habit is great. The bromides, chloral, tincture of cannabis indica, hyoscyamus, belladonna, are all valuable. In plethoric women with scanty flow he has often found the bromides, combined with belladonna or hyoscyamus, promptly effective in affording relief. Sometimes the pain may be arrested by beginning their administration a day or two preceding the flow. Cannabis indica is useful in certain spasmodic cases and in cases with a free flow.

Antipyrine is a valuable addition to our means of allaying pain, and will give temporary relief in a large majority of cases, whatever the diseased condition; but the author has not been able to observe any curative effect. Caution should be exercised in its administration, since in too large doses dangerous symptoms may arise, especially in anæmic women. Dr. Palmer speaks highly of concentrated tincture of cimicifuga and of tincture of pulsatilla. Dr. Mundé also recommends pulsatilla in the neuralgic form. The physician may very wisely give his patients (and especially the anxious mothers) a warning against overdosing and oversoaking. Rest in bed, the application of dry or moist heat, an occasional hot sitz bath, the moderate drinking of hot fluids, are domestic measures which will afford a certain amount of relief. The dosing with gin or whiskey, with tansy tea, etc., should be discouraged. With cannabis indica in cases in which the flow is free; belladonna or hyoscyamus in spasmodic cases; antipyrine, possibly oxalate of cerium, pulsatilla, etc., we have a list of remedies for relief which are safe and usually effective for the time.

Bromides in congestive cases, used occasionally or for short periods of time, may be valuable, but their prolonged administration disorders the stomach and favors anæmia. Chloral should be used with circumspection on account of the liability to the establishment of the chloral habit. —*American Journal of Obstetrics*, March, 1890.

Treatment of Morphinism.—In a valuable paper upon morphinism (*Dublin Journal of Medical Science*, December, 1889), DR. ARTHUR WYNNE FOOT writes that it is easier to cure a morphine-eater of his craving than a morphine-injector. The probability of a cure may be estimated by attending to the following points: (1) The *duration* of the habit. Cases of short existence are more successfully treated than those in which the habit, of long standing, has exercised a deleterious influence on mind and body. (2) The persistence or not of the *condition which gave rise* to the exhibition of the drug. If this condition be irremovable, a cure is scarcely to be expected. (3) The physical and nervous *constitution* of the patient. Bad effects follow the withdrawal of morphine in cases of weakly individuals, or in those of specially nervous temperament. The magnitude of the

dose does not much affect the prognosis, except in so far as the larger doses indicate chronicity of the habit. It is a hopeful consideration that, in most cases, to break the habit means to get well, because, unlike alcoholism, the morphine-habit does not entail structural lesions of any vital organ. Relapses, however, are very frequent, being more common in men than in women. So great is the tendency to relapse that Jäckel does not consider a cure to be accomplished by the mere suppression of the morphine-hunger, but considers the continuance of control over the patient in a proper institution of the greatest importance. Dr. Wynne Foot's practical remarks on the treatment of morphinism may be summarized as follows: The process of cure requires a degree of moral and physical courage seldom at the disposal of a morphine *habitué*. His abject mental state calls for firmness, gentleness, and tact on the part of the physician and the attendants. Neither the intensity of his craving nor the reality of his sufferings should be underrated or disputed. Four methods of treatment have been tried: (1) the *deceptive* plan; (2) the *substitution* plan; (3) the *tapering-off* plan; (4) the *abrupt withdrawal* plan. The deceptive and the substitution plans are not worthy of serious consideration in the management of confirmed morphinism; the latter simply handing the sufferer over from one enemy to another. Not only is the substitution of cocaine for morphine dangerous, but there is a risk of developing a cocaine-habit which is worse than morphinism. As to the tapering-off plan and the abrupt withdrawal plan, there seems to be no unanimity of opinion as to which mode of treatment should be employed. The first-named plan consists in the gradual reduction of the dose, until none of the drug is required. Dr. B. W. Richardson considers it better to reduce the dose at each administration than merely to lessen the number of injections in the twenty-four hours. The abrupt discontinuance of the drug is attended in all cases by indescribable sufferings, and in many by serious dangers. When morphine is suddenly cut off in those accustomed to its use a remarkable group of severe and alarming symptoms ensue, called the *Abstinenz-symptome* or reactionary effects. These comprise acute diarrhœa, insomnia, great excitement, amounting at times to mania dangerous to those around, and particularly to the physician; hallucinations, and collapse. Great care is needed in the case of pregnant women addicted to opium, because incautious attempts to withdraw the habitual drug are, according to some authorities, almost certain to be followed by premature labor.—*Practitioner*, February, 1890.

Treatment of Sycosis.—Brooke considers that sycosis is always a contagious disease, and that there is no non-parasitic sycosis (*British Journal of Dermatology*). Sycosis, like true barber's itch, affects, almost exclusively, those who frequent the lower class barber-shops. Three or four days after being shaved, the patient notices a localized redness, followed by the formation of small points of pus, the commonest seat being just below the lower lip. The treatment Brooke recommends is, should there be much inflammation or eczema, the application of a lukewarm poultice of an antiseptic starch paste (made from starch powder 1 ounce, boric acid 30 grains), to be changed three times daily. This helps to soothe the inflammatory condition, to clean the skin from crusts and scabs, and to soften and empty the pustules. As soon as possible, epilation and shaving must be begun. The ointment which he finds generally effectual is composed as follows:

R.—Oleate of mercury (2 per cent.)		1 ounce.
Ichthyol	. . . . .	20 minims.
Salicylic acid	. . . .	10 grains.
Oil of lavender	. . .	2 drops.—Mix.

This should be kept applied on strips of lint or linen. It is by no means absolutely necessary to shave frequently, but the stubbly condition of the hair produced by infrequent shaving seems the most irritating to the follicles and most provocative of relapses. Hence the full growth of the hair is the next best alternative to regular daily shaving. External influences have not infrequently a distinct modifying effect on the disease; thus the sudden advent of cold wet weather, to which the patient may have been exposed, and internal causes, such as dyspepsia, nervous depression, anæmia, and struma, are apparently answerable, in some cases, for sudden relapses or very prolonged duration.—*Edinburgh Medical Journal*, March, 1890.

The Prevention of Urethral Fever.—Dr. C. G. Buchanan Klophel contributes a valuable paper on urethral fever to the *Therapeutic Gazette*, March 15, 1890, and in the prophylaxis of the disease lays stress upon the following points:

1. In operations for the relief and cure of chronic retention of urine, the complete evacuation of the urine at first should not be permitted, but rather the withdrawal of only a few ounces, and the immediate injection of a solution of boric acid or other mild antiseptic, in volume equal to one-half the quantity of urine withdrawn, lessening with each succeeding injection the quantity of fluid thrown in, and increasing the amount of urine withdrawn. As a result, we have less shock, if, indeed, any; no suppression of urine; no hæmorrhage from the urinary organs; and slight, if any, so-called urine fever.

2. Tight strictures of the membranous urethra are more successfully, and hence more safely, dealt with by perineal section. When associated with strictures of the pendulous urethra, the combination of internal and external urethrotomy is undoubtedly the best treatment.

3. The decomposition of blood, urine, and other organic matter in the bladder or urethra, may give rise to the phenomena of urethral fever through the production of ptomaines; hence the necessity for antiseptic treatment, generally and locally.

4. The disease is more common among those who are predisposed to it by a peculiar nervous temperament.

5. In view of the fact that more or less shock attends all urethral operations, especially the forcible and rapid dilatation of old strictures with sounds; and as sudden death has followed even the gentle insertion of a sound, the calibre of which was less than that of the stricture, it is hence important that all practicable antiseptic precautions should be observed in every case of dilatation of a urethral stricture or strictures, with a view to avoiding, so far as possible, such effects, which are more likely to follow the rapid dilatation of old strictures when not preceded by internal urethrotomy.

6. It is also important to ascertain the condition of the bladder, urine, and kidneys before operating for stricture of any degree, and when these two organs are found extensively diseased, the greatest skill, gentleness, and patience are necessarily called for in the treatment of strictures. Further, when these organs are diseased, and we have to deal, in a given case, with several strictures of very small calibre of the pendulous urethra, two courses compatible with safety are presented, viz.: gradual dilatation alone, or internal and external urethrotomy, leaving a few days between the internal and external operation, the latter being done first.

7. Quinine, in any quantity, exerts no manifest influence over the course of urethral fever.

8. Boric acid, internally, by its resolvent and antiseptic action, doubtless does exert a favorable influence upon the disease, and will prove a prophylactic if given some days before operating.

9. With a further view to prophylaxis, both before and after all operations upon the urethra—even simple catheterism—the canal should be injected with some mild antiseptic. This is more essential after each act of micturition subsequent to internal urethrotomy.

10. When urine fever persists despite all treatment, or should it, after any operative interference with the urethra, jeopardize the patient's life, perineal section should certainly be done.

Treatment of Delirium Tremens.—In discussing the treatment of delirium tremens (*Journal of Nervous and Mental Diseases*, March, 1890), DR. E. P. HURD says that in most cases alcohol should be withdrawn at once, though in a few the gradual "tapering-off" method is preferable. Again, there are other patients in whom symptoms of cardiac weakness make the stimulation of alcohol necessary. Sleep is undoubtedly the great restorative, and, to procure this, recourse must be had to the hypnotics, of which the author prefers chloral. In some cases he combines ½ grain of morphine with 20 grains of chloral. Capsicum is also a useful drug, stimulating, as it does, the gastric branches of the vagi, and indirectly the nerve-centres. Dr. Kinnear, of England, at one time gave 20-grain boluses of powdered capsicum, the patient falling into a quiet sleep within an hour after taking the dose.

Lately a new treatment of delirium tremens by large doses of strychnine has been recommended. To Laton, of Rheims, we are indebted for this therapeutic novelty. Laton advised doses of 5 milligrammes ($\frac{1}{12}$ grain) by hypodermic injection or by mouth; these doses to be repeated two or three times a day. Dujardin-Beaumetz has repeated the hospital experiments of Laton with uniformly good success. By experiments on animals, Beaumetz has found "that there exists within certain limits a real antagonism between the action of alcohol and strychnine." Drs. Journet and Bounard also report favorable results from a series of trials in private practice of this remedy in delirium tremens, and in a number of the *Bulletin Générale de Thérapeutique* for 1888 appears an article by a Brazilian physician, Ramos, "On the Employment of Strychnine in Delirium Tremens," in which he extols the effects of this remedy. He declares strychnine superior to all other remedies, morphine, chloral, paraldehyde, etc., in controlling the disordered manifestations of alcoholism. Ramos would give large doses, hypodermic injections of $\frac{1}{12}$ grain, repeated every four or five hours, till the insomnia, agitation, and delirium are mitigated or disappear. In some cases, he does not hesitate to give as much as 1 grain in the twenty-four hours.

Mixture for Epilepsy. — According to the *American Druggist*, BROWN-SÉQUARD'S mixture for epilepsy is composed as follows:

R.—Sodium bromide, Potassium bromide, Ammonium bromide	of each	180 grains.
Potassium iodide, Ammonium iodide	of each	90 "
Ammonium carbonate		60 "
Tincture of calumba		1½ fl. ounces.
Water, sufficient to make		8 " "

Prescription for the Fever of Phthisis.—The *Revue de Thérapeutique* quotes the following prescription, which is said to be used by LIEBERMEISTER in the hectic fever of phthisis:

R.—Sulphate of quinine		30 grains.
Pulverized digitalis		7½ "
Extract of gentian—sufficient quantity.		

Mix, and divide into forty pills, of which from six to ten may be taken daily.

Prescription for Acne.—The following is quoted in the *Centralblatt für die Gesammte Therapie*, March, 1890:

R.—Salicylic acid, Sodium borate	of each	52 grains.
Boric acid		40 "
Alcohol, Glycerin	of each	1½ ounces.
Oil of bergamot		5 drops.

To be used as a wash three times daily.

Prescription for Eczema.—According to the *Centralblatt für die Gesammte Therapie*, SAALFELD uses the following ointment in cases of pustular eczema:

R.—Potassium carbonate		15 grains.
Salol		75 "
Olive oil		150 minims.
Sulphur		1½ drachms.
Zinc oxide, Starch	of each	3½ "
Lanolin, sufficient to make		6 ounces.—M.

Removal of Warts by Electrolysis.—DR. PATRZEK, of Oppeln, describes, in the *Deutsche medicinische Zeitung*, his method for removing warts by electricity. The wart is first thoroughly moistened with a warm solution of salt. Both needles are then thrust through it just above the surface of the skin, and the current turned on, one element after another being added until pain is felt. Five cells are sufficient. With most cases two sittings of five minutes each are sufficient to destroy the growth, which gradually dries up and falls away, leaving a surface at first slightly reddened, but which later assumes the appearance of normal skin.—*Weekly Medical Review*, March 15, 1890.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author.

ARSENIC AND BICHLORIDE OF MERCURY IN THE TREATMENT OF ANÆMIA.

ALTHOUGH it is perfectly true that we have almost no knowledge of the manner in which alteratives act in instances of disease where, through morbid functional activity, enlarged glands or growths appear, it is evident that they must act upon the trophic nerves or directly upon the nourishment of the affected parts. If they are used in large quantities they act as depressants to the normal nutrition of the body, producing primarily a decrease in the vitality of morbid growths, so that they melt down and disappear, and they may finally so reduce the condition of the healthy tissues as to cause sloughs and ulcerations. Whether these changes are due to the over-stimulation of nutrition—that is, to an excessive trophic change—or whether they depend upon actual lowering of the tone of the parts, we know not. One thing we do know, however, and that is, that small doses of most of the so called alterative drugs act as very distinct stimulants to the development of normal structures, and in no instance do we find this more typically represented than the effect which they exert on the blood. Quite a number of years ago Keyes, of New York, emphasized the value of minute doses of mercury bichloride in syphilitic and other anæmias, and abundant clinical observation has certainly confirmed his views. The dose of bichloride of mercury in anæmia should be about one-fortieth of a grain. Not only will minute doses of the bichloride of mercury act in this way, but small amounts of calomel or mercury itself will have such an effect.

Inunctions of very small amounts of mercurial ointment, once a day, or every other day, in adults and children, will increase the fulness and redness of the cheeks and lips, and the number of the corpuscles; the piece of ointment used being no larger than the half of a very small pea. This treatment will be found of service in cases not dependent upon specific taint or scrofula. The marked increase in the nutrition of children of a syphilitic taint, who are suffering from marasmus, under the use of gray powder and inunctions, gives further evidence of this fact.

Arsenic also is of value in anæmic conditions, and may be employed in comparatively larger doses than mercury; but, nevertheless, smaller amounts than are usually given in chorea and similar states. Osler has shown the value of the drug in anæmia, and so has Barton, of University College, in England. Any one of the preparations may be employed, but not more than one-sixtieth of a grain of arsenious acid should be taken in a day, although more has been used with no less benefit to the patient. Most of the drug under these circumstances is in excess and is cast off in the urine and fæces unused and wasted, and strains and irritates the emunctories of the body during its passage through them.

TREATMENT OF DYSENTERY BY ENEMATA OF CORROSIVE SUBLIMATE, ETC.

IT is now generally recognized that certain morbid conditions of the intestinal tract may be favorably modified by various drugs belonging to the class of antiseptics, among which the chief are calomel, bismuth, naphthalin, and thymol. It is a noteworthy fact that these substances are all insoluble, and it is in virtue of this property that they are enabled to run the gauntlet of the absorbents and exert their specific action upon the intestinal contents. The best of all antiseptics—corrosive sublimate—has thus far been of little use for the purpose mentioned, because it was supposed that no benefit could be exerted by any but a lethal dose. While this may be true of its administration *per os*, it is shown by G. LEMOINE (*Bulletin général de Thérapeutique*, January, 1890) to be a mistake so far as concerns administration *per rectum*.

Lemoine has treated fifty-four cases of dysentery by enemata of corrosive sublimate and with the happiest results. The strength of the solution was one to five thousand, of which, two hundred grammes were at first administered three times a day; later, two hundred grammes of a solution of one to three thousand were injected twice daily. Improvement showed itself, as a rule, after the first injection, the first symptoms to disappear being the tormina and tenesmus. In a certain number of cases the tenesmus was so great that the enema could not be administered without a preliminary treatment, which consisted in painting the sphincter with a five per cent. solution of cocaine.

In the acute cases, a cure resulted from this treatment in from three to four days; whereas, in the more chronic cases which presented themselves for treatment on account of an acute exacerbation, a cure was effected, as a rule, in one day. The latter statement is somewhat startling in view of the well-known fact that chronic dysentery is decidedly rebellious to all the usual modes of treatment.

In no case was there any sign of systemic poisoning. It is probable, Lemoine believes, that the mercury is not absorbed when thus employed in dysentery. In five cases he tested the urine for mercury, and in every instance with negative results. This fact seems to stand in marked contradiction with the well-known absorbent power of the large intestine, and is probably due to the intensity of the inflammation of which it was the seat.

Lemoine's cases were all treated in Algiers, and many of them were of a severe type. In view of the infectious character of dysentery, the treatment is eminently rational, and the demonstration that our most powerful germicide can be used with impunity as an intestinal antiseptic is of decided value. At the same time, in view of the accidents that have followed the employment of resorcin in lavage of the stomach, we would recommend the greatest caution in the use *per enema* of the more poisonous corrosive sublimate.

REVIEWS.

Outlines of the History of Medicine and the Medical Profession. By Joh. Hermann Baas, M.D. Translated, and in Conjunction with the Author Revised and Enlarged. By H. E. Handerson, A.M., M.D. New York: J. H. Vail & Co., 1889.

This is one of the most valuable books which has appeared for a number of years, representing a class of medical literature of a standard equal to Hirsch's well-known book on *Geographical Pathology*. At the present time students, in graduating from medical colleges, leave with the idea that everything in medicine has been acquired within the last fifty years, and that everything which occurred before that period is absolutely useless in their daily life. In reality, a little knowledge of what our ancestors have done before us when defending themselves against disease would often save much useless repetition, and on certain occasions a large amount of chagrin, when a remedy brought forward as new is proved by wiser heads to have been used hundreds of years before. One of the best instances of such a state of affairs is represented by Bergeon's treatment of phthisis, which depended entirely for any therapeutic effect which it might possess upon the sulphur which it contained. Hundreds of years ago it was discovered by the medical men of the period that the influence of sulphur was exceedingly useful when applied to certain diseases affecting the mucous membranes, yet it remained for Bergeon to bring forward as a new idea the rectal injection of this remedy in the disease known as tuberculosis of the lung. A little knowledge at the time Bergeon first brought this method to notice would have saved a vast amount of experimentation and a still greater amount of expense to those who in their desire to aid in a discovery hastened to buy the necessary apparatus.

It is impossible for us in this brief review to do more than call attention to the great thoroughness with which the author and translator have carried out their work. No point has been left uncovered, and yet the book is so arranged that it can either be used as a work of reference or be enjoyed as interesting reading.

The American publishers have thought best to leave out a large number of the references which the German author placed in the original book, and this cannot but be regretted as an unfortunate decision. At the same time we readily recognize the fact that these additions would have very materially increased the cost and consequently the price of the work, and might have placed it far beyond the reach of many of those who might desire to possess it.

In conclusion, we wish to urge upon the profession in general the necessity for obtaining some such work and of glancing over its pages before attempting to foist upon their unsuspecting brethren a remedy which in reality may be as startlingly old as they believe it to be novel.

A Text-book of Obstetrics, including the Pathology and Therapeutics of the Puerperal State: Designed for Practitioners and Students of Medicine. By F. Winckel, M.D. Translated from the First German Edition with the Permission of the Author. By J. Clifton Edgar, M.D. Ninety illustrations. Philadelphia: P. Blakiston, Son & Co., 1890.

Notwithstanding the fact that American obstetricians have not been at all backward in providing students and their professional brethren with text-books upon midwifery, it is perhaps well that some of the prominent teachers of the United States in studying foreign authors have concluded to place before Americans the views which they find so useful in their utterances to their students.

There can be little doubt that the differences which exist in the methods of treatment in different portions of the world depend upon two great causes. The first of these is the geographical position of the persons among whom the author practises his profession, and the other is the mental tendencies which are peculiar to certain races. For this reason it is very frequently useful to place German, French, English, and American ideas side by side, and by a process of mental boiling down to separate the good grain from the practice of each nation, with a result which surpasses in every detail the methods of any one country.

It is useless for us to attempt to criticise a work of which Professor Winckel is the author. His practical experience and laborious researches in the literature of the subject have qualified him to place before the profession a book which is certainly of great value, and we desire to compliment Dr. Edgar upon his foresight and admirable work in the preparation of the American translation. One of the useful things about the work is that bibliographies accompany the articles upon each special subject, while the illustrations seem to us to be almost entirely original, which is but natural when we consider the enormous amount of material from which the author may obtain figures. The work of the American publisher has been well carried out, as is usual under these circumstances, and we venture to say the translation is put before the profession of this country in much better form than the German publishers placed the original before the physicians of the Fatherland.

SOCIETY PROCEEDINGS.

NEW YORK COUNTY MEDICAL SOCIETY.

Stated Meeting, February 24, 1890.

EYE-STRAIN, AND AN EASY METHOD FOR ITS DETECTION.

Dr. Francis Valk believes that the peripheral irritation caused by eye strain, either when the extrinsic or intrinsic muscles are involved, tends to cause various nervous phenomena, and may even be the exciting cause of the manifestations of functional chorea and epilepsy. He called attention to a recent monograph by Dr. J. H. Woodward, of Vermont, in which it is stated that out of one hundred and fifty cases of headache, vertigo, lachrymation, nausea, epileptiform convulsions, migraine, neuralgia, and similar troubles, at least eighty-five per cent. were relieved by the use of suitable glasses; sixteen per cent. were not benefited; while in the remaining cases either the patients refused to follow advice or the results were unknown. All of these cases had refractive errors, which, Dr. Valk said, could have been recognized by the method which he advocated in his paper.

The author showed that hyperopia was the most serious refractive error giving rise to eye-strain, because perfect vision was only possible by the continued action of nervous impulses which control the ciliary muscles. In the opposite condition, or myopia, there may be no eye-strain, except under special circumstances, such as the use of too powerful glasses. In the astigmatic eye, in order to counteract the effect of the unequal curvature, there must be unequal contraction of the ciliary muscle in the different meridians, with consequent strain and irritation.

When the intrinsic muscles of the eye are affected, the subjective symptoms which may be present are: headache, usually frontal and about the eyes; pain in the eyeballs, and a feeling of strain after reading; burning, lachrymation, floating specks before the eyes, slight stickiness of the eyelids in the morning, dizziness and vertigo.

When the extrinsic muscles are the seat of the difficulty, there will usually be occipital headache, or pain referred to the back of the neck.

During the last two years or more, the author has made frequent use of the simple and important diagnostic test known as "retinoscopy." In this method, as he practised it, the observer does not watch the movements of any shadow, but simply the movements of the illuminated portion of the retina across the pupillary space. If the pupils be widely dilated, it may also be noticed that the refraction at the periphery of the cornea is different from that in the centre, giving rise to two apparent shadows. If these appear to move in opposite directions, the condition present is one of hyperopia in the centre, and myopia at the periphery.

The instrument requisite for the performance of this simple test is readily extemporized by taking an oblong piece of looking-glass, 3 x 1½ inches, and covering it with paper. About one inch from the end, and on the face of this glass, cut away the paper so as to expose a clear circular portion of the mirror about 1¼ inches in diameter, and on the back of the mirror, at a point corresponding to the centre of this circle, remove the paper and the quicksilver, so as to leave an area of clear glass one-eighth of an inch in diameter.

Any perforated plane mirror will of course answer the purpose equally well. The room should be darkened, and a good light placed above and a little behind the person to be examined, who is seated in front of the examiner about forty inches distant from him. Placing the instrument before the right eye, and looking through the central aperture, the reflected pencil of light from the mirror is projected into the patient's eye. If the right eye is to be examined, the patient is directed to look beyond and just to one side of the right ear of the examiner. If the room be properly darkened, the pupil will be sufficiently dilated to make the examination easy; but if not, a very weak solution of atropine may be used, or a few drops of a two per cent. solution of cocaine may be instilled into the eye about fifteen minutes previous to the examination. The pupillary space appears of a beautiful orange-red color, with some indistinct apparent shadows at the edge of the pupil as the mirror is moved. The mirror is now slightly and rapidly rotated on its vertical or horizontal axis, being careful not to move the head. If there be any error of refraction, the bright illuminated part of the retina will be noticed to move across the pupillary space followed by what appears to be a dark shadow, but which is really a portion of the retina not illuminated. It is the movement of this bright area that will indicate any error of refraction that may exist. If the mirror be turned to the right on the vertical axis, and the illuminated area is seen to move in the same direction, then the eye must be hyperopic, or shortened in its antero-posterior diameter, and the image seen is a virtual image of the illuminated part of the

retina. Again, if with the same rotation of the mirror, this movement of the bright area is in the opposite direction, or toward the left, then the eye must be myopic, or increased in its antero-posterior diameter, and the image seen is a real inverted image of the illuminated part of the retina. If these two movements of the reflex are very rapid and uncertain, very bright, filling the entire pupillary space, the eye is almost if not fully emmetropic, or, in other words, there is no existing error of refraction. If astigmatism be present, there will be a difference in the movements of the retinal reflex. If, on rotating the mirror, the movements of the reflex in the vertical meridian are in the same direction, the refraction in that meridian is hyperopic; and if the movement in the horizontal meridian is in an opposite direction, the refraction of this meridian must be myopic, and the condition present is known as mixed astigmatism. Should the movements of this reflex be distinct, either with or against the rotation of the mirror in any one meridian—vertical or horizontal—and stationary in the meridian at right angles to that, then this meridian would be emmetropic, and the condition present is known as simple astigmatism — myopic or hyperopic according to the movements of the reflex in each principal meridian. If this astigmatism be at the meridian on the arc of the circle other than that of the vertical or horizontal axes, it will be at once shown by the direction in which the retinal reflex moves, without regard to the rotation of the mirror, at the same time showing the error of refraction.

This test may also be practised with the concave mirror found on the ophthalmoscope, but with this mirror it must be remembered that all the movements of the retinal reflex will be reversed, viz., in myopia the movements will be with the rotation of the mirror, and in hypermetropia they will be in the opposite direction.

This method of retinoscopy was first intoduced to the profession from France, and since then has been largely adopted by the English; but it seems to have met with distinct disfavor among the Germans, one of their professors calling it "the lazy English method;" nor is it yet very generally adopted in this country. Dr. Valk considers it one of the simplest methods for the diagnosis of all errors of refraction, and says that when fully carried out in all its details, it is one of the most exact methods in the hands of the ophthalmologist. In his experience, it has almost invariably agreed with the results obtained by examinations made under atropine with trial glasses and with the ophthalmoscope.

One of the great advantages of the method is that it is not dependent upon subjective statements, but is practically an objective method with positive results, and consequently can be used to determine the refractive condition of children, illiterate persons, and in eyes deficient in visual power—the condition known as amblyopia.

The position taken by the author, that retinoscopy was an easy and desirable method adapted to the wants of the general practitioner, did not meet with the approval of ophthalmologists, who unfortunately were the only ones present who participated in the discussion. The general opinion was that the method required considerable practice and skill; while others went still further and denounced the method as one which was unreliable and incapable of yielding accurate results.

DR. O. D. POMEROY said that there might be eye-strain with a perfectly normal eye; and the reason was to be found in the fact that the ciliary muscle was overworked. There was a limit to its powers of endurance, just as there was in the general muscular system. There were also occasionally very puzzling cases, in which, after correcting the errors of refraction by tenotomies and prisms, and securing a perfect muscular balance, the disagreeable symptoms still persisted.

The great objection to retinoscopy was that it was not only difficult to acquire, but demanded constant practice, and, after all, it merely indicated the existence of refractive errors without determining their degree.

DR. EMIL GRUENING was one of those who did not consider retinoscopy a practical test for the general practitioner, although easy for the ophthalmologist; and, moreover, when practised without atropine, the method was faulty. Only a portion of the hyperopia present might be found, and hence it was necessary to relax the accommodation completely. It was also important that the slightest degree of astigmatism should be corrected; for, he had repeatedly seen benefit from correction of only half a dioptre. But such a small degree of astigmatism would most probably be overlooked in an examination by retinoscopy.

DR. LAMBERT had already called attention to an apparatus which he had devised to facilitate the employment of this method. By using atropine, he had been able to detect one-quarter of a dioptre, and had confirmed this result by subsequent tests with trial glasses. The method, moreover, gives the absolute direction in which the cylinders should be applied; for if a little out of the vertical plane, the shadow inclines slightly toward one side or the other. The method, however, is not easily practised, and is particularly tedious.

Dr. Valk replied that he had used this test very carefully with the plane mirror and without any lens, and it had enabled him to detect one-quarter of a dioptre, the result being afterward confirmed by the use of atropine and trial glasses.

Mention had been made of the rarity with which emmetropia was observed by ophthalmologists. He thought this was largely due to the fact that there is rarely occasion for such people to apply for treatment. He considered the normal eye to be really slightly hypermetropic—*i. e.*, about half a dioptre.

CORRESPONDENCE.

ST. LOUIS.

To the Editor of THE MEDICAL NEWS,

SIR: The largest deal, to borrow a commercial expression, that has been made in medical college affairs has just been consummated, by which the St. Louis Post-Graduate School of Medicine ceases to maintain a separate corporate existence, and becomes a department of the Missouri Medical College. The Post-Graduate School building, which is claimed to be the finest structure of its kind in the United States, has been purchased by the Missouri Medical College, and will be used for the senior classes of the under-graduate department and also for post-graduate classes. It is asserted that the clinics of the Post-Graduate School have been altogether

the best in the city. The large clinics at the old Missouri College will also be kept up as heretofore.

The Missouri Medical College adopts next year a three-years' graded course. For this, as for many other important advances the profession has to thank the Illinois State Board of Health.

In absorbing the Post-Graduate School of Medicine the Missouri College not only takes the fine building of that school, but takes into its faculty several additional members, viz.: Dr. Horatio N. Spencer, Professor of Otology; Dr. William C. Glasgow, Professor of Diseases of the Throat and Chest; and Dr. George J. Engelmann, Professor of Gynecology. Besides these, Dr. A. J. Steele is to be Clinical Professor of Orthopædics, and Dr. H. W. Herman, Clinical Professor of Diseases of the Nervous System and Electro-therapeutics. This gives the Missouri Medical College a staff of fourteen professors with a large corps of clinical assistants and demonstrators, and a property estimated at $100,000.

On Sunday morning, February 16th, there died at his residence in this city one of the oldest members of the medical profession here, Dr. C. W. Stevens. He was born at Pompey, Onondaga Co., N. Y., June 16, 1817, and was of Welsh and English descent. Having been educated as a civil engineer, he came west in 1838, but feeling dissatisfied with the prospects of success in that profession, he commenced the study of medicine. He attended lectures in Kemper College—now the Missouri Medical College—and was graduated in 1842. In 1844 he was made Demonstrator of Anatomy in that school, and held the position until 1849, when he took the same place in the St. Louis Medical College. Six years later he was assigned to the chair of General, Special, and Surgical Anatomy in the latter school, which he filled ably for thirteen years. In 1868 he resigned his professorship and gave up his practice to take charge of the St. Louis County Insane Asylum. As Superintendent of that institution he did credit to himself and gained a considerable reputation as an expert in insanity. In 1872 he resigned his office and returned to general practice in the city, though much of his work was in the field of neurology and psychiatry, being often called to testify in medico-legal cases. He was a pronounced Union man during the war, and saw several months of field service as a volunteer surgeon. In 1879 he was elected President of the St. Louis Medical Society. From November, 1883, to July, 1886, he was again Superintendent of the St. Louis Insane Asylum. Since that date he has given his time to private practice. In accordance with his own request, his remains were cremated.

The several medical colleges of this city hold their graduating exercises this month. On the evening of March 4th, the Missouri Medical College held its graduating exercises, and at the same time celebrated the fiftieth anniversary of the founding of the institution by Drs. Joseph Nash McDowell and John F. Moore. The number graduated this year was 101.

On March 13th, the forty-eighth annual commencement exercises of the St. Louis Medical College took place, the number of graduates being 22. This school has always consistently maintained an advanced position with regard to requirements for graduation and for ten years has had a compulsory three-years' course of study.

In connection with these exercises were held those of the graduating class of the Missouri Dental College; the dental graduates numbering 32.

The same evening the Homœopathic Medical College of Missouri graduated a class of 25 members. The position of resident physician to the Children's Hospital (Homœopathic) was secured by Dr. D. M. Gibson.

On Thursday morning, March 13th, died at his home in Kansas City, Missouri, a man of very considerable note as a surgeon in the western part of this State. The name of Dr. J. W. Jackson is preëminent in the annals of railroad surgery in this country. In 1874 he was made surgeon-in-chief of the Missouri Pacific Railway, and five years later organized the first railroad hospital in the United States, at Washington, Missouri. In 1881 the hospital was removed to Sedalia, as being a more central point to the extended system of roads which had then been acquired by the Missouri Pacific.

In 1884 the entire Wabash system west of the Mississippi was added to that of the Missouri Pacific, and Dr. Jackson was chief surgeon to the whole system. In 1885 Dr. Jackson resigned his position and was given complete control of the surgical department of the Wabash system. During his service in this position and through his instrumentality four railroad hospitals have been erected, viz., at Springfield, Illinois; Danville, Illinois, Peru, Indiana, and Kansas City, Missouri. It was during his service on the Missouri Pacific system that the hospital building was erected at Fort Worth, Texas, at a cost of $30,000, then considered the finest railroad hospital in the West.

Dr. Jackson was president of the Missouri State Medical Society in 1855-56, president of the National Association of Railway Surgeons during its first year, 1888-89, and was first vice-president of the American Medical Association at the time of his death.

NEWS ITEMS.

Prosecution of Homœopathic Druggists.—Messrs. Boericke & Tafel have recently been on trial in New York City for alleged violation of the law requiring all apothecaries to be registered and licensed. They have two places of business in the city which are conducted as homœopathic pharmacies. The prosecution against them was brought through the instrumentality of the Board of Pharmacy, whose counsel consented to the dismissal of the case after a brief argument by the defendants to the effect that it would be a hardship to compel a homœopathic chemist to appear before a board of examining pharmacists, and that it would probably result in driving out of the city nearly all homœopathic druggists.

Polyclinic Lecture Course.—The following is a continuation of the course of Tuesday evening lectures which is given by the staff of the Philadelphia Polyclinic at the college building, N. W. corner of Broad and Lombard Streets. The lectures begin at eight o'clock, and are free to members of the profession and to medical students. March 11, Dr. B. F. Baer, Abdominal Surgery; March 18, Dr. Thomas J. Mays, Treatment of Asthma; March 25, Dr. John B. Roberts, The Theory of Antiseptic and Aseptic Surgery; April 1, Dr. Charles K. Mills, Hypnotism; April 8, Dr. Thomas G. Morton, Imperfect Symmetry and Spinal Curvature; April 15, Dr. B. Alex-

ander Randall, The Anatomy of the Labyrinth of the Ear (Illustrated); April 22, Dr. J. Henry C. Simes, Urethrotomy; April 29, Dr. E. P. Davis, Treatment and Prevention of Puerperal Fever; May 6, Dr. Edward Jackson, Heterophoria, or Latent Squint; May 13, Dr. A. B. Hirsh, Newer Methods in Herniotomy; May 20, Dr. C. L. Bower, The Treatment of some common Fractures; May 27, Dr. J. Abbott Cantrell, Scabies—its Symptoms, Diagnosis, and Treatment.

Manitou Springs, Colorado.—Correspondents who have been wintering in the West report a much more agreeable climate at Colorado Springs, "The Saratoga of the West," than at Denver, somewhat further north. The weather in January was glorious. To quote from a letter: "A clear, bright, and balmy sunshine which tempts one to be out in the open air to enjoy it. The winds know how to blow even here, sometimes, although the place is sheltered from the severest of them. We have been walking and driving almost daily, and appetite and ability to sleep have improved greatly. It is a luxury to breathe here for those with lazy lungs." The dryness of the air on the Colorado plateau appears to diminish the sensations alike of heat and cold and almost any degree of winter extremes can be borne without that feeling of chilliness that marks the low temperatures of the East.

Mississippi State Medical Association.—The next annual session of the Mississippi State Medical Association will meet in Jackson, Mississippi, April 16, 1890. Those desiring to report cases or read papers should notify Dr. W. E. Todd, recording secretary, Jackson, Miss.

Cincinnati City Hospital.—At a meeting of the Board of Trustees of the Cincinnati City Hospital, held March 6, 1890, a department for diseases of the throat and nose was created. Dr. E. Sattler and Dr. Max Thorner were elected Laryngologists and Rhinologists to the institution.

Serious Loss by Fire.—The Toronto University with its newly constructed Biological Laboratory was destroyed by fire, February 16th, while it was in the course of preparation for a public reception. The *Lancet* quotes the loss at half a million of dollars, and that the wrecked edifice was the handsomest of its kind in Canada.

Obituary.—The late PROFESSOR KARL WESTPHAL'S thirty years as neurologist in the University of Berlin were marked by many additions to the science of neurology, obtained through earnest work, careful observation, and a conscientious scrutiny of his own results that made unassailable all that he published. His contributions to the study of tabes dorsalis will long be remembered; the loss of the patellar reflex in this disease has been termed "Westphal's symptom," from its discoverer. Some of the other subjects upon which he bestowed special attention were progressive paralysis, epilepsy, paranoia and agoraphobia. The various forms of ophthalmoplegia chiefly interested him during the last few years, and his studies were important not only to the pathology of the affection itself, but also to cerebral anatomy. The combined affections of the spinal cord also engaged his attention, as did the subject of the formation of cavities in the cord, pseudosclerosis, and Thomsen's disease. Most of his papers on the subjects were first published in the *Archives für Psychiatrie*, which he himself edited for almost two decades.

——DR. EDUARD VON WAHL, professor of surgery at the University of Dorpat, and one of the editors of the *St. Petersburger medicinische Wochenschrift*, died January 29th, aged fifty-seven years. He was appointed to the chair of surgery in 1878, following von Bergmann, now of Berlin. He was a fine operator and brilliant teacher, attracting large classes of students to Dorpat and nearly doubling the attendance at the surgical clinic in ten years. He held the rectorship of the University from 1881 to 1885, and devoted much attention to the question of the prevention of the spread of leprosy in Russia, and promoted the establishment of lazar-houses. He urged the clinical study of mental diseases at Dorpat, and he himself bought the ground and buildings necessary for the purpose, and presented them to the University. He lectured in German, but was familiar with several other languages. His death is reported to have been the result of an accident he met with a short time before, by which several of his ribs were fractured.

——MEDICAL DIRECTOR ADRIAN HUDSON, U. S. N., died February 7th, at the Mare Island Hospital, California, from pneumonia, supervening upon influenza. He was a native of Canada and a graduate of the McGill University. He entered the navy in 1861, arriving, after twenty-seven years of varied service in his corps, at the honorable office of Medical Director, in July, 1888. He was in charge of the Mare Island Hospital at the time of his final illness.

——DR. EDWARD L. PLUNKETT, a blind physician ot New York City, who was a successful quiz-master, died January 10th, aged forty-three years. He became totally blind at the age of twenty-three, when a college student, in consequence of purulent conjunctivitis.

——DR. HEYMANN, professor of hygiene at the Carolina Institution, Stockholm, and editor of the Swedish journal, *Hygeia*, died from cardiac disease during the delivery of one of his lectures.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MARCH 18 TO MARCH 24, 1890.

By direction of the Secretary of War, authority is granted for the admission of MARCUS E. TAYLOR, *Captain and Assistant Surgeon*, to the Army and Navy General Hospital, Hot Springs, Arkansas, for treatment therein.—Par. 6, *S. O., A. G. O.*, March 21, 1890.

JARVIS, N. S., *First Lieutenant and Assistant Surgeon.*—Is granted leave of absence for one month, with permission to apply for an extension of fifteen days.—Par. 1, *S. O. 31, Headquarters Department of the Missouri, Fort Leavenworth, Kansas*, March 20, 1890.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

DEGENERATION OF THE SEBACEOUS GLANDS. ALOPECIA AREATA. TINEA CIRCINATA. GENERAL ECZEMA. ERYTHEMATOUS AND VESICULAR ECZEMA OF THE HANDS.

A Clinical Lecture,
delivered at the Hospital of the University of Pennsylvania.

BY LOUIS A. DUHRING, M.D.,
PROFESSOR OF SKIN DISEASES.

GENTLEMEN: The first patient is a man, thirty-five years of age, with an affection which evidently has its seat in the sebaceous glands. The lesions are multiple, perhaps ten or twelve in all, and are disseminated upon the face and neck, and are largest and in the most advanced stage on the cheeks. They are characterized by the formation of adherent sebaceous crusts seated upon a hyperæmic base. The process is chronic and sluggish, and has existed for five or six years. Notice the complexion of the man and the peculiarities of the skin. He is a typical blond, with yellowish hair on scalp and face, and has a remarkably florid, injected, rosy skin, with active sebaceous glands. The disease is multiple degeneration of the sebaceous glands, a condition which is frequently met with in elderly persons, and occasionally in those under forty. Some of the lesions have already begun to break down and are accompanied by slight atrophic degeneration. Without doubt, in time some one of them would develop into pronounced epithelial cancer of a mild type, and it is this observation which is important for the future welfare of the man. The case at present would hardly come under the designation of epithelial cancer, and may be preferably called degeneration of the sebaceous glands.

A similar case which has been under my observation for the past six or eight years, began just as this case, and has developed into an extensive, ulcerative, epithelial cancer at several points, as on the back of the hand and about the ear. It is, therefore, of importance that all the lesions receive treatment, with the view of improving the tone and nutrition of the glands and of arresting epithelial proliferation. Sulphur here will prove useful in the form of an ointment, one or two drachms of precipitated sulphur to the ounce. Vleminckx's solution,[1] diluted with from one to four parts of water, will also be of value, and may be employed alternately with the ointment mentioned. Salicylic acid may be added to the same ointment with benefit, in the strength of from ten to thirty grains to the ounce. The cure will be slow, probably extending over a period of months. Should some of the more advanced lesions prove rebellious, lactic acid may be applied, with the view of its acting as a caustic. In the matter of diagnosis, lupus erythematosus is to be excluded because the hyperæmic base is not so well defined and circumscribed, nor as inflammatory and active, as in that disease.

[1] Lime 1 part, sulphur 2 parts, water 20 parts. Slack the lime, add the sulphur and water and boil to 12 parts.

ALOPECIA AREATA.

The young colored man before us exhibits a marked degree of baldness in the form of areas, or patches, and to such an extent as to cause disfigurement, more than one-half of the scalp being bald. He is a mulatto, and the disease is rarer in the colored than in the white race. The loss of hair has taken place gradually during the past three months, and there is no apparent cause for the disease. The eyebrows are also involved.

Of late, considerable discussion has again arisen, especially in France, concerning the nature of this process, some dermatologists of high standing stating that there are two forms of alopecia areata, one distinctly neurotic, the other parasitic. Our own experience in Philadelphia, extending over a score of years and including many cases, leads us to believe that the disease is neurotic, though by no means always occurring in nervous subjects, or even due to evident nervous shock or allied general conditions of health. The cause seems to be an arrest (often sudden) of nutrition of the hair, generally of the scalp only, but not infrequently of other hairy regions, and sometimes of the whole general surface.

The parasitic theory, that the disease is caused by an invasion of the hair-follicles by a vegetable growth, a fungus, has not been proved, and for the majority of cases is at variance with the clinical history of the affection.

The treatment is, as a rule, unsatisfactory, in many instances the baldness remaining uninfluenced by the remedies used, whether local or internal. It must never be forgotten that in young subjects the disease tends to spontaneous cure, in from three to six months. As a stimulating application, tar, as a tincture or ointment; sulphur as an ointment; salicylic acid as an ointment or with alcohol; resorcin; and carbolic acid, are all useful. Strong preparations are usually well borne, for the scalp lacks its natural tone, being smooth, shrunken, and pale in color.

Internally, arsenious acid, in doses of from one-fiftieth to one-twentieth of a grain, thrice daily, is the most reliable remedy, and in some cases acts curatively, but in other instances it proves valueless. It needs to be used for a period of from two to six months, and never in excessive doses, always remembering that a tonic effect to the peripheral nerves is the object desired. The prognosis should in every case be guarded, for the disease pursues its course in an irregular, capricious way, often defying the most energetic and faithful lines of treatment.

TINEA CIRCINATA.

This patient is a young woman, twenty-five years of age, with an erythematous, diffuse, slightly scaly patch, involving the orbital and temporal regions, and resembling eczema much more than ringworm, but there is another circular, circumscribed, scaly lesion on the side of the neck, the size of a dime, of two weeks' duration, which is characteristic. There is no history of contagion.

The treatment is simple in such cases: any of the well-known parasiticides, such as sulphur and its compounds; naphthol; chrysarobin; corrosive sublimate and white precipitate will usually effect a cure. A lotion of hyposulphite of sodium, one drachm to the ounce of water, applied freely and frequently, is a cleanly, effective, and safe remedy, and one that we often make use of, both in dispensary and private practice, and will be prescribed in this case.

CHRONIC DIFFUSE ECZEMA OF THE GENERAL SURFACE.

This woman, about thirty-five years of age, spare, pale, and ill-nourished, exhibits over the greater part of the general surface, especially upon the face, scalp, forearms, hands, and thighs, a chronic, erythematous, squamous, and fissured eczema, of many years' duration. She is manifestly a great sufferer, and states that she has been both better and worse than at present from time to time, but has never been free from the disease since it began fifteen years ago. There is now but little active inflammation, but the skin is everywhere thickened, and extremely dry, harsh, and rough, and in many places fissured; while the scalp is the seat of a coating of adherent, impacted, whitish scales, suggestive of psoriasis. The flexor surfaces of the elbows are so much fissured as actually to prevent motion of the joint. It is a severe case, and calls for active internal and external treatment.

The nutrition must be improved before cure can be expected. The various functions should be inquired into, the bowels, stomach, and digestion in particular, and everything that will tend to improve the general and the cutaneous nutrition will be advised. Cod-liver oil, abundance of meat and fat, milk, cream, eggs, bread and butter, and malt extract, should have a place in the diet list. Inunctions with a weak tarry ointment, composed of one or two drachms of tar ointment to an ounce of lanolin ointment (six drachms of lanolin and two drachms of lard oil) will probably prove useful, unless the skin rebel against tar. A weak sulphur ointment, twenty or thirty grains to the ounce, may also be mentioned as likely to be of service. The two may further be combined. Ichthyol ointment, from fifteen to thirty grains to the ounce, is sometimes useful; as is also resorcin, in the same strength.

CHRONIC ERYTHEMATOUS AND VESICULAR ECZEMA OF THE HANDS.

The hands of this woman are inflamed, red, and swollen, the skin thickened and boggy, slightly moist and crusted in minute puncta here and there, with subjective symptoms of heat and itching. Tar has been lately applied, but has aggravated the disease, and apparently a good deal of the active inflammation is due to that remedy. For the present a lotion of boric acid, ten grains to the ounce of water, followed by a dusting powder of starch and oxide of zinc, will be ordered; the wash to be used freely for fifteen or twenty minutes three or four times a day. The hands, of course, to be protected with cloths and a muslin roller bandage. In a few days, the oxide of zinc and starch paste, with ten or fifteen grains of salicylic acid to the ounce, may be ordered. In such cases, calomel ointment, twenty or thirty grains to the ounce, often proves valuable.

ERYTHEMATOUS ECZEMA OF THE LEG.

This variety of eczema is observed in the two middle-aged men before us, and is in the form of reddish, slightly scaly, diffuse, not much thickened, patches on the legs. The disease is similar in both cases, though more extensive and chronic in one than in the other, and being subacute, calls for moderately stimulating remedies, as, for example, an ointment of calomel and oxide of zinc ointment, thirty grains to the ounce, or a salicylic acid ointment, fifteen grains to the ounce. Resorcin may also be mentioned as likely to prove useful.

A CASE OF TRAUMATIC DISLOCATION OF THE LENS, ILLUSTRATING THE THEORY OF VISUAL ACCOMMODATION.

A Clinical Lecture.

BY GEORGE C. HARLAN, M.D.,
PROFESSOR OF DISEASES OF THE EYE IN THE PHILADELPHIA POLYCLINIC.

GENTLEMEN: I have asked your special attention to this case as it presents conditions not often met with for observing the effect of dislocation of the lens upon refraction, and for illustrating the generally accepted theory of accommodation.

The patient, a healthy man, twenty-one years of age, states that about two months ago he was struck in the left eye with a piece of wood, that he has never had severe pain, but that vision has been seriously impaired since the accident. He can see much better, however, on looking downward than when his head is erect and his eyes are directed forward. Well-marked oscillation of the iris at once suggests dislocation of the lens, and, after the use of a mydriatic, it is found that the lens is slightly displaced almost directly downward, leaving a narrow space between its upper margin and the edge of the dilated pupil. Through this space a + 12 D. glass gives a distant vision of $\frac{20}{70}$. When the head is thrown well forward and the eye looks down, the lens assumes very nearly its normal position, and No. 1 Sn. can be read with ease at four inches without a glass. The lens is still nearly clear, though oblique illumination shows a slightly increased reflex, and spicula of opacity are forming on its periphery.

The right eye is, in all respects, quite normal, with a distant vision of $\frac{20}{XX}$, and a near point of four inches.

While the lens in the left eye has been completely detached from its suspensory ligament, it is but slightly displaced from its normal position, and has as yet only partially lost its transparency. There is no intra-ocular hæmorrhage, and no additional injury to the eye, such as

is likely to be inflicted by so severe a blow. The fundus can be seen with the ophthalmoscope with sufficient distinctness to determine that it presents no indication of a myopic formation, which is, in addition, disproved by the refraction of light entering through the space above the lens. In other words, we have here the opportunity to observe, almost without complication, the effect upon the lens of eliminating the influence of its suspensory ligament. This effect has been a degree of myopia which corresponds, with remarkable accuracy, to the accommodative power of the other eye. As the myopia was estimated before we knew the near point of the other eye, and by a member of the class who had no theory to support, the record is not open to suspicion.

You are all familiar with the fact of visual accommodation, and appreciate the necessity for some mechanical contrivance to adapt the focus of the eye to varying distances; but perhaps none of you have any idea how many names famous in science are associated with the study of this point in physiological optics, and what a voluminous literature has arisen from its discussion. Kepler, in 1604, first showed that the eye is a camera forming images, in accordance with optical laws, upon the retina; and demonstrated the necessity that exists in this, as in all other optical instruments, for some mechanism by means of which the image can be kept accurately focussed while the position of the object varies. In other words, he established the fact of visual accommodation. The question of the manner in which this function is performed had still several centuries to wait for its elucidation, which cannot even yet be said to have reached the point of positive demonstration. Helmholtz says there is no other point in physiological optics upon which so many contradictory opinions have been maintained. The apparent impossibility of explaining the process drove many distinguished authorities, long after the time of Kepler, to deny the existence of any arrangement in the interior of the eye for changing the focus, while those who admitted its necessity found their ingenuity severely taxed to suggest a plausible theory.

Each of the following theories has had many earnest and famous advocates. Kepler originated the first, which supposes that the lens is moved bodily forward, without change of curvature, like the lens of an opera-glass. Haller first noticed the contraction of the pupil in accommodation, and thought that it sufficed, by shutting off peripheral rays of light and thus diminishing circles of diffusion upon the retina, to account for the accuracy of near vision. Some maintained that there was a change in the curvature of the cornea, and others that the antero-posterior axis of the globe was elongated by pressure of the external muscles. The latter theory had the support of a number of high authorities, including Buffon, Mickel, Henle, and Listing.

Those observers first struck the true scent who attributed the change of focus to increased convexity of the lens, but they were unable to give convincing reasons for the faith that was in them, and their view was not generally adopted. They thought that the lens was a muscular structure (musculus crystallinus) and that its convexity was increased by the contraction of its own fibres. The name of Thomas Young is particularly associated with this theory. He was the first to support it with experimental proofs, though it had been suggested nearly two hundred years before his time, by Descartes.

The fact that accommodation is accomplished by increase in the convexity of the lens was finally brought to mathematical demonstration by observation of the reflected images of the anterior and posterior surfaces of the lens.

Langenbeck (1849) first showed that changes take place in the size and relative position of these images during accommodation, and Cramer and Helmholtz subjected them to accurate measurement, the former by means of a microscope and micrometer and the latter with an instrument constructed on the principle of the heliometer. Knapp completed the demonstration by a calculation proving that the increase of curvature thus shown is sufficient to accomplish the degree of accommodation effected.

You are familiar with these images in connection with the old "catoptric test" for cataract suggested by Purkinje. When a candle flame is held before the eye, three reflected images may be observed; an erect virtual image formed by the convex surface of the cornea, another of the same kind formed by the anterior convex surface of the lens, and a small inverted actual image formed by the concave posterior surface of the lens, or, more exactly, the anterior surface of the vitreous. It was found that during the act of accommodation the corneal image undergoes absolutely no change either in position or size, and the inverted lens image is just perceptibly diminished, while the image formed by the anterior surface of the lens approaches the cornea and decidedly decreases in size. That visual accommodation is the result of a change in the curvature of the lens is, therefore, a demonstrated fact, but we are still dependent upon theory for an explanation of the exact mechanism by means of which this change is accomplished.

Cramer attributed this function to the iris; supposing that a simultaneous contraction of its circular and radiating fibres exerted a pressure upon the periphery of the anterior surface of the lens, and increased its curvature by bulging forward the centre. This theory was quite generally accepted until Helmholtz reported a case of complete paralysis of the iris, and Graefe one of its traumatic loss, in both of which the power of accommodation remained unaffected. This, of course, threw the iris out of count, and narrowed the discussion to the ciliary muscle as the only possible active agent.

Just how the contraction of this muscle increases the curvature of the lens may be considered still an open question, but the theory of the mechanism of accommodation at present almost universally held to be the most satisfactory, is that advocated by Helmholtz. According to this, the elastic capsule that incloses the gelatinous mass of the lens, will tend to approximate it to the circular form. This tendency is opposed by the suspensory ligament, which is also elastic, and, being attached to the capsule at the periphery of the lens, will keep the latter flattened when in a state of tension. This tension of the suspensory ligament is supposed to exist when the eye is in a state of rest—*i. e.*, when it is adapted to distant vision; while in accommodation for a near point the ligament is relaxed, and the lens is given up to the action of its capsule.

The gray band seen just beyond the attached margin of the iris when the cornea and the anterior part of the sclerotic are removed, formerly described by anatomists as the ciliary ligament, was discovered by Bowman and

Brücke to be composed of unstriped muscular fibres, which have their origin in the region of the canal of Schlemm, at the corneo-sclerotic junction, and their insertion in the ciliary processes as far back as the ora serrata. When the ciliary muscle and ciliary processes are removed, a beautiful zone with radiating lines is seen, which is still often designated by its old name of zonula of Zinn. The retention of this name, however, can only lead to confusion in the minds of students, as this structure is the suspensory ligament of the lens, and had better be known by the term that indicates its function. It is an elastic transparent membrane, usually described as a continuation of the hyaloid membrane, which becomes thicker and stronger and more elastic at the ora serrata. The appearance of radiating dark-brown striæ is due to the fact that this membrane is thrown into grooves in which the ciliary processes are received, and when we remove the latter some of their pigment is left behind.

For our present purpose we may consider the ciliary ligament as an elastic membrane stretched between the ora serrata and the margin of the lens, and assume that its traction is relaxed when the ora serrata is drawn forward by the contraction of the ciliary muscle. In the case of our patient, the lens is torn away from the ligament, and the elastic contraction of its capsule is, therefore, unopposed, and we find the eye focussed for a near point which corresponds exactly with that reached by the strongest accommodative effort of the other eye. It may seem somewhat anomalous that an organ should be made to "function" by complete separation from all its anatomical connections, but it is, nevertheless, a well-known fact that a healthy lens becomes more convex when removed, with its capsule intact, from the eye.

ALBUMINURIA IN THE APPARENTLY HEALTHY.[1]

BY W. H. WASHBURN, M.D.,
OF MILWAUKEE.

DURING the past ten or fifteen years great activity has been displayed in investigating the causes and probable results of albuminuria unassociated with those forms of kidney disease to which the name of Bright has been attached. The subject has occupied a considerable portion of the time and attention of the great medical societies on both sides of the Atlantic. At the meeting of the Association of American Physicians held at Washington, D. C., in 1888, Professor Tyson, of Philadelphia, presented a paper entitled "The Relation of Albuminuria to Life Insurance." At the meeting of the British Medical Association held at Leeds, in 1889, Professor Pavy read a paper entitled "A Discussion of the Prognosis of Cases of Albuminuria, with Special Reference to Life Insurance." These papers were fully discussed.

Tyson objects to such terms as normal, physiological, intermittent, cyclical, and alimentary albuminuria, and proposes the term "functional" as meaning "that there is somewhere a functional derangement, as a result of which, without structural alteration in the kidney, albumin transudes through the vessel walls along with the normal urine constituents." For myself, I object to the term "functional disease," believing that there is no perverted *function* without perversion of structure. Dr. George Johnson (*British Medical Journal*, February 2, 1889, p. 225) objects to all these terms and proposes in their stead "latent albuminuria."

We understand by latency that which is hidden, concealed, or inappreciable. Latent heat is the best example we have of latency, and latent heat is absolutely inappreciable, either to the senses or by the thermometer.

The form of albuminuria to which it is proposed to apply this name cannot properly be compared with latency as we are thus acquainted with it, for this albuminuria is as appreciable as that which accompanies grave kidney disease. Hence I believe "albuminuria in the apparently healthy" to be a designation the most free from objection.

Dr. Pye Smith, of London, examiner for an English life insurance company, says he relies upon the heat and nitric acid tests for albumin, and deplores the introduction of new chemical tests on the ground that we will thereby "imperil the clinical results of the past fifty years." The philosopher seeks truth and should care nothing for the effect which the discovery of such truth may have upon the "clinical results of the past fifty years." What we desire to ascertain is, what relation albuminuria in the apparently healthy bears to the expectation of life; and if such expectation is diminished, our business is to investigate as to the best means of checking the appearance of albumin in the urine.

At the present time the balance of opinion is decidedly in favor of the view that there is no such thing as physiological albuminuria, but that it is pathological in every case, even though a mere trace be present. There is danger that "the long-continued filtration of albumin among the gland cells of the convoluted tubes may by degrees so disorganize them as to render them incapable of performing their excretory function." However, Dr. George Johnson has recorded cases of seven, ten, fifteen, and twenty years' standing which have not resulted in serious disease of the kidneys; the case of seven years' duration fully recovering.

While it has been abundantly proven that albumin may be present in the urine in considerable quantity without indicating serious disease of the kidneys, it is also true that serious disease of the kidneys may be present without the appearance of albumin in the urine. Mahomed demonstrated by post-mortem examinations at Guy's Hospital that this may be the case, the only indications pointing to kidney dis-

[1] Read before the Milwaukee Clinical Society, March 11, 1890.

ease being "increased tension of the pulse," a "heaving left ventricle," and increased quantity of urine. These observations have been confirmed by Dieulafoy, and this has been called the pre-albuminuric stage of Bright's disease. Bartels, of Kiel (Ziemssen's *Cyclopædia*, vol. xv. p. 440), relates a case of granular degeneration of the kidneys which was under his care for some time, in which no albumin appeared at any time, and hence the fact that renal disease existed was not discovered during the life of the patient, but was made apparent at the autopsy. This case was remarkable, also, in that the temperature of the patient in the rectum sank to the low point of 83° F., from which condition the patient rallied and lived some weeks. Professor Da Costa relates a case in his work on *Diagnosis* (4th edition), where there was a marked deposit for some time of crystals of oxalate of lime, accompanied by tube-casts of the hyaline and waxy varieties, and yet no albumin was detected either by heat or nitric acid. Under treatment the oxalate of lime crystals disappeared from the urine, also the tube-casts, and there has never since been any indication of degeneration of the kidneys. The question arises here as to whether albumin would not have been found in these cases had some of the later and more delicate tests been applied.

Dr. Posner, quoted by the *American Journal of the Medical Sciences*, July, 1887, p. 236, says that he believes that serum-albumin is normally present in the urine in infinitesimal quantities, but still sufficient, in most cases, to be detected with such delicate tests as picric acid. Normal urine contains 0.00032 per cent. of mucin, and there is often present a much larger quantity, and as picric acid will detect albumin when it is present in the proportion of 0.00015 per cent. it would not be strange if enough albumin were liberated in solution to give the reaction with this delicate test.

In order to verify this opinion of Posner I tested with picric acid by the contact method, and also with the phenic-acetic test, and with a solution of citric acid of a specific gravity of 1008, by the same method, samples of urine from fifty persons in perfect health, all living in good sanitary surroundings, and in easy circumstances. Their ages ranged from fourteen to fifty-five years. In every instance, at the line of contact of the two fluids, the characteristic cloud appeared with more or less distinctness, indicating the presence of an albuminoid.

Grainger Stewart some time ago reported finding albumin in the urine in 31 per cent. of 407 persons examined in apparent good health. These people were all in the lower walks of life and living in unsanitary surroundings. In none of these cases were any other evidences of renal disease found.

Dr. G. R. Shepherd, in a recent paper before the Connecticut Medical Society, reported albumin present in the urine in two per cent. of 35,000 cases collected from various sources; that the percentage was greater among brain-workers than among muscle-workers; and that while in healthy persons it did not appear after meals, in those who suffered from dyspepsia and oxaluria it was very apt to appear.

During the twenty-two months between April 1, 1888, and February 1, 1890, I examined 338 applicants for life insurance, in which an examination of the urine was required. These applicants were all apparently healthy. Albumin was found in the urine in twenty of these cases, being 5.91 per cent. It would, of course, be interesting as well as instructive to be able to follow up all these cases and trace, if possible, the albuminuria to its cause, but this, in the nature of things, could not be done. Nevertheless, I have been fortunate enough to be able to investigate a number of them, and have selected three which are reported in this paper.

Case I.—W. J. A., aged thirty-four years, light complexion; height five feet ten inches: weight 150 pounds. Family and personal history good; habits of life correct; very temperate in the use of alcoholics, in fact almost a teetotaler. He is a brain-worker. Examined, February 27, 1889. Urine: specific gravity 1024, reaction acid, albumin present in sufficient quantity to be shown by the contact method with nitric acid. Specimens of this gentleman's urine were examined, which were passed at different hours of the day, from immediately after rising in the morning to the last thing before going to bed at night. That urine which came first from the bladder was examined separately from that which came last. In every instance the albumin appeared in about the same quantity. The urine was strongly acid in reaction, and ranged in specific gravity from 1010 to 1026, being usually about 1018. No casts were found in the urinary sediment at any time. I had examined the urine of this man several times previous to February 27, 1889, and had found it normal. The fact, therefore, that the specific gravity and amount were normal, and that the microscope revealed oxalate of lime crystals in great abundance in the urinary sediment, and the further fact that he was annoyed by flatulent indigestion, led to the diagnosis of albuminuria, due to the presence in the urine of the sharp and irritating crystals of oxalate of lime. These crystals, moreover, were found in the urine immediately after leaving the bladder, indicating that their presence there was not due to chemical action after the urine was passed. The formation of the oxalate crystals was attributed to digestive disturbances. Nitro-muriatic acid was ordered with each meal, March 16th; on March 20th the urine was free from albumin, and has remained so, the last examination having been made November 29, 1889.

Case II.—J. C. S., aged thirty-one years, foreman in a printing establishment. Good family

and personal history. A year before the date of examination, this man suffered from typhoid fever, was not critically ill, but during the course of the disease had some urinary trouble, the urine being suppressed for nearly two days. September 16, 1889, I examined him for life insurance. The urine was passed at 2 P.M.; specific gravity 1022, reaction acid, albumin present in quite large quantity. On examination of the urinary sediment, the microscope revealed a few crystals of oxalate of lime, epithelial cells, a few leucocytes, cylindroids of mucin, and a few hyaline tube-casts. September 18th, two examinations failed to show any albumin in the urine; the microscopic examination showed only a few leucocytes in the sediment. September 19th, no albumin, the microscope showing only a few epithelial cells and cylindroids of mucin. From September 20th to November 1st repeated examinations failed to show the presence of albumin. Since the time when the patient suffered from typhoid fever, he has noticed that whenever he has a "cold" his urine is passed in smaller quantities and oftener than normal, and such was the condition of affairs when the first examination was made.

Dr. Wilks (*Lancet*, March, 1873, p. 147) says albuminuria may be caused by a "cold," that cold may set up a condition of the urinary tubules similar to that of the bronchial tubes, and that the condition may be only temporary, but that if it continues six months it is apt to become incurable. This case appears to me to be one of this origin, due to temporary catarrh of the urinary tubules.

Case III.—The third case to which I wish to direct attention is that of an attorney, aged twenty-five years, of sedentary habits. His father died of apoplexy, at the age of fifty-eight years, and his mother of consumption, aged thirty-one years. Family history otherwise good. He has never undergone any sickness himself. Height, five feet ten inches, weight 185 pounds. Examined June 8th, when he appeared in robust health, the pulmonary and cardiac sounds being normal. Pulse 76, regular, steady, and soft. Urine passed at 3 P. M., acid, specific gravity 1022, free from sugar. Albumin present in sufficient quantity to be detected by cold nitric acid test. Microscopic examination of sediment entirely negative. From June 8th to November 1, 1889, examinations were made of his urine eight or ten times per month, at all hours of the day. Numerous microscopic examinations were made during this time. There were found at times epithelial cells which I thought were from the bladder; on one occasion crystals of oxalate of lime; sometimes cylindroids of mucin, and, on June 22d and July 1st and 4th, a few hyaline tube-casts. Albumin was found in every specimen of urine, passed at all hours of the day. During all this time the specific gravity was about normal, the lowest being 1014, and that only once, the range being from 1018 to 1026. Every specimen of urine examined was markedly acid. Theorizing, then, that this albuminuria was possibly due to commencing lithæmic nephritis, I prescribed lithia water, and restricted his diet. I afterward tried lithiated hydrangea and a vegetarian diet. The urine continuing to be strongly acid, and the albuminuria persisting, I prescribed phosphate of sodium and then Vichy water. The Vichy water rendered the urine alkaline, but the albuminuria was entirely uninfluenced by the treatment. About November 1st the patient entered a gymnasium, and since that time has devoted, on an average, one hour per day to active exercise; by this means he has reduced his weight to 166 pounds. About the middle of November the albumin disappeared from his urine, and has not been detected since.

Now, it seems to me that—if it be true that the function of renal epithelium (among other things) is to convert albuminous constituents of the blood, not elsewhere converted, into urea and other nitrogenous excreta, as explained by Ralfe—this case admirably illustrates a condition under which the epithelium was unable to discharge thoroughly this function. A young man, of full habit, a good eater, florid complexion, in fact plethoric, leading a sedentary life, the blood containing more albuminous constituents than were converted by the liver and in the muscles of the body, and more than the renal epithelium was able to convert, and hence a certain amount was allowed to filter through into the tubules, and to escape with the urine.

Diet made but very slight difference in the amount of albumin passed in the urine. Medicines produced no effect whatever, but the moment increased muscular activity resulted in the conversion of a larger amount of albuminous blood constituents into urea, so that there was less to be converted by the renal epithelium, albumin disappeared from the urine.

THE CORPUS LUTEUM "OF PREGNANCY" IN NON-PREGNANT WOMEN.

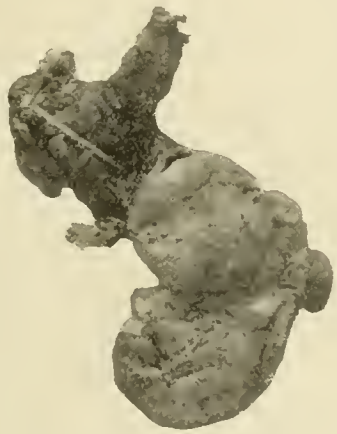
By BARTON COOKE HIRST, M.D.,
of Philadelphia.

In the past year I have seen two cases that might come under this heading: well-developed corpora lutea, exhibiting all the macroscopic appearances of these bodies at the period of greatest development in a pregnant woman, and yet situated in ovaries taken from women, beyond a doubt, not pregnant.

Case I.—Miss S., aged twenty-four, a very small, fragile-looking person, with no mammary development. First menstruated at nineteen; since then her menses have returned at irregular and long intervals. At the menstrual period, although there may be no flow, the girl has intense headaches and disturbances of vision, with an aggravation of pains in the back and left groin, which constantly trouble her to some degree. She has consulted several ophthalmologists, who told her that the eye symptoms were reflex, depending upon some abnormality in the sexual organs. For three months past she has been treated, without success, by a well-

known gynecologist, who finally advised an oöphorectomy. She was sent to me by Dr. Oliver, who was treating her eyes, for examination and treatment. *Examination:* Uterus infantile, scarcely larger than the terminal joint of one's thumb, in good position, and movable. An enlarged ovary, very sensitive, to be felt on left side. I recommended an exploratory incision, and, possibly, an oöphorectomy. The operation was done in April, 1889. Both ovaries, congested and enlarged, were removed. That upon the left side contained a corpus luteum in every way like the same body of pregnancy in its fullest development. It measured three-quarters of an inch in length, a trifle less in breadth, and occupied about half the ovary. (Fig. 1.)

Fig. 1.

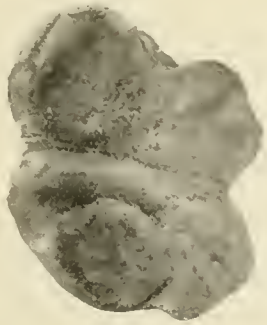


This inequality in development of ovaries and uterus, although observed before, is to me very strange. Ovulation here, no doubt occurred in a regular and vigorous fashion, while menstruation, as a rule, failed to appear. The sexual organs, deprived of their periodic depletion, remained constantly congested, and the individual was made miserable, and incapacitated for work. She is now, a year after the operation, employed as a store-girl, and is almost entirely free from her former symptoms.

Case II.—F. R., aged twenty-three, had her first child fourteen months ago. Since her delivery menstruation has returned but four times. She complains of severe pain in the right lower abdomen, which has disabled her, and compelled her to enter the Philadelphia Hospital for relief. *Examination:* Uterus enlarged, cavity 3½ inches; in fairly good position, partially fixed. In right broad ligament is a large, firm tumor, intimately attached to the uterine wall, and extending out toward the lateral wall of the pelvis. With the idea that a pyosalpinx existed, laparotomy was advised and agreed to. The tumor was found, however, to be an extra-mural fibroma, growing between the layers of the broad ligament, and associated with some pelvic inflammation. Both ovaries were removed. In one a corpus luteum "of pregnancy" was discovered, as illustrated in the accompanying cut taken from a photograph. (Fig. 2.)

It may be claimed that there is an element of doubt in this report, but intra-uterine pregnancy was excluded by the size of the uterus and a long-continued observation of the patient, while interstitial pregnancy was excluded, I think, by the fact

Fig. 2.



that the tube ran above the tumor and was not inserted in the upper, outer corner of it. These two cases illustrate, what is already known, that the corpora lutea "of menstruation" and "of pregnancy" are the result of congestion different in degree and duration, and have nothing to do specifically with the conditions from which they are named. One comes from a temporary hyperæmia of the ovary, associated with rupture of the Graafian follicle; the other from a hyperæmia of higher grade and longer duration. It will be observed that the mere presence of over-grown corpora lutea in the ovaries did not constitute an indication for their removal. This, naturally, it should never do, and yet oöphorectomy has been advocated for "endothelioma of the ovary," which, to my mind, is nothing in the world but the proliferating cells of membranæ granulosæ in ruptured Graafian follicles engaged in the formation of corpora lutea.[1] This, it seems to me, is also the explanation of the tumors described by Dr. Heneage Gibbes,[2] although he distinctly states that corpora lutea can be distinguished from the growths he describes. A careful microscopic study of my specimens will be made by Dr. Piersol, Professor of Histology and Embryology in the University of Pennsylvania, who will prepare a description of their histology.

THE WAKEFULNESS OF NEURASTHENIA AS AFFECTED BY SEASIDE RESIDENCE; ITS SUCCESSFUL MANAGEMENT AND CURE.

By W. H. DALY, M.D.,
of Pittsburg, Pa.

Of all the suffering to which unfortunate humanity is subject, none can compare in its horrible character to the persistent insomnia that is made worse by hypnotics, and especially worse by a residence at the seaside. About twenty-two such cases have fallen under my notice while getting a history of concomitant disease of the upper air-passages, for which they consulted me, during the past three years, and I have been further interested because of a case in which I was peculiarly concerned, and of whose history I have been fully informed.

It is not my purpose, however, to weary the reader with the details of cases, but rather to give the summary of my observations, and earnestly to call attention to the great need for discrimination in the sending of patients afflicted with insomnia to the seaside; and more especially to ask those who are located at seaside resorts, not to allow their honest zeal and enthusiasm for a particular and pet resort to lead them to believe that its air and surroundings will cure anything, from knock-knees to a disposition on the part of children to scratch furniture. The average medical man may make the mistake of sending a neurasthenic patient who has insomnia to the seaside, that would be better at some quiet inland resort, or possibly better at home. but the experienced medical man at the seaside should, in such a case, have the moral courage to say promptly to such a one, who is not likely to be benefited: This is not the place for you to obtain a physiological cure of your insomnia—the only cure worth having, by the way, and the only one, especially, that a medical man, if so afflicted, should ever undertake to accept, since the perilous practice of purchasing sleep by means of hypnotics is one that in *his* hands must sooner or later lead to destruction, permanent and irreparable, if persisted in, as these means, alas for his own welfare, are so readily obtainable by him. Now what shall we do for the sufferer from insomnia? If we find his own home must be abandoned owing to business cares that will occupy his mind and attention if he remains, and if we also find the seaside aggravates the wakefulness, then send him inland far enough to get him away from the ocean's roar, while he will still have the tonic effect of the sea air, if by a brief experience in this he should prove to profit by it. But do not persevere in trying to have your patient *overcome* obstacles that he ought, and you ought to have him, simply to shun, and thereby gain time and comfort for him and hasten his cure. In other words, do not insist too strongly that your patients shall repeatedly and with futility try to adapt their unfortunate conditions to your cast-iron notions of sanitary regimen; but rather adapt your regimen to fit the conditions of the case. This will require no little study on your part, but success will repay the labor of thought in this respect. The patient ought to be encouraged to join quiet friends in quiet amusements, but even this should not be insisted on too strongly. The exercise should be of the quietest kind. I have known eminent neurologists who advised their insomnia patients rather indiscriminately to take horseback exercise. Now I have known the excitement and tension due to this exercise, in many cases, to be followed by wakefulness quite surely and certainly and upon repeated trials. Conversation or cards after supper, or a pleasant short walk before bedtime, and, before retiring, the cold douche to the head or the feet as experience shall dictate. In fact, the regimen in insomnia is largely a matter of experience, and not to be adhered to with unreasonable pertinacity. But absolute quiet is one of the essentials for the wooing of sleep, to the wakeful neurasthenic. The walking over the floor above or some one taking a bath in an adjoining room, or the crowing of a cock, or the gnawing of a mouse, or the rustling of the leaves on the trees beside the window, or the chirping of a cricket will be sufficient to rivet the attention of the insomnia patient and destroy all vestige of sleep, until from utter exhaustion a half hour of partial oblivion may be obtained long after daylight, when there is a lull or period of repose and quiet between the noises of the night and the coming day of bustle and business.

No talk of business or upon business subjects or enterprises should be indulged in, especially in the after-part of the day; this is most certainly fatal to the securing of sleep. Nothing irritating should be said by friends, and all subjects that are known to be distasteful to the wakeful patient should be strictly tabooed, as the wakeful neurasthenic is sensitive to an extreme.

Now that we have said briefly what not to do for this class of patients, it is in order for us to ask what we shall do for their comfort and restoration—for what secures the former is certain, sooner or later, to be followed by the latter. Briefly, it is this: Get along without hypnotics or so-called nerve tonics; the one hundred and one preparations of the phosphates are a fashionable therapeutic fad, that the manufacturer got up for the benefit of his own pocket, and are about as groundless in therapeutics as the statement of the ostensible German savant, which we have all swallowed, more or less, viz., "Without phosphorus there is no thought"—"Ohne Phosphor keine gedank." Now, this is a most thoughtless statement, and cannot be verified,

and the exhibition of the phosphates in any case must act—if they do any good at all, which is questionable—by reason of the other ingredients which render them more or less an elixir and a simple tonic.

The most efficient plan of treatment in the wakeful neurasthenic is a mild alterative and tonic plan, coupled with a close attention to the state of the liver by means of mild mercurial laxatives. I say the liver, but I should also say the stomach, as these two organs are the ones that will reflect their influence upon the brain. A quarter of a grain of calomel at bedtime, with two drachms, more or less, of fluid extract of senna every night, or second or third night as needed, until the yellow stools, nearly always present in the neurasthenic, are tinged with bile. Keep this condition up and keep up the treatment, being careful not to ptyalize. Use wines or whiskey, when they agree, but in the most moderate quantities, and only in those cases where there is no feeling on the part of the patient of a sense of heat in the head or other evidence of cerebral congestion. In congestive cases, four to six leeches applied to the mastoid region at bedtime, and the wounds allowed to bleed until they stop of themselves, will prove of nearly certain benefit, and very often cure. If one trial of the leeches disappoint, repeat it in a night or two, or even take blood from the arm until cerebral congestion is manifestly relieved, and thus enable the distended cerebral vessels to regain their tone, in order that they may assume the needed anæmic condition required for natural slumber. And while you are keeping all this in view, I may assure you without doubt that the practitioner who attends to the condition of the liver, stomach, and secretions from the alterative standpoint is the one who will restore his patients to health again. We have had, and now have, much of so-called restorative medicine; and we follow the fashions of the day as strictly and surely in medicine—shame it is to confess it—as do the fair proprietresses of a dozen bonnets or gowns, and we look to a few leaders who set the styles in our therapeutics and we follow them blindly until we stumble across some new fellow who thinks he knows it all, and, like the hounds who have jumped a new hare, we dash after him until we lose the trail, or rather, lose our patience with a *c*, and sometimes also, lose our patients with a *t*.

Broussais is dead, his doctrines are long since dead and buried; let's look the old fellow up again, and apply some of the hints that he can give as to the physiological doctrine of the liver; put some of the old therapeutics in force with reference to the liver in your wakeful neurasthenics. Do it gently, however; do not try to coax it into action by means of trifling placebos, but put the spur gently to the old laggard and see that its rowel is deftly covered with an amalgam, and this with rest, coupled with quiet and reasonable time, proper food, and mild tonics, will do more, and do it permanently, than all of the so-called nerve foods and brain foods and other swindles with which the credulous doctor and more credulous patient are commonly at the present day carried along with that hope deferred which always maketh the heart sick.

THE OPERATIVE TREATMENT OF HIP DISEASE.[1]

By De Forest Willard, M.D.,
Clinical Professor of Orthopædic Surgery in the University of Pennsylvania, Surgeon to Presbyterian Hospital, etc.

I trust that it will not be inferred from the title of this paper that I look upon the operative treatment of hip disease as the chief element in the management of this affection; on the contrary I regard mechanical and hygienic measures as of the greatest importance, and acknowledge that operative procedures are, like amputations, confessions of defeat; yet operative measures are necessary in a considerable number of cases.

It may, perhaps, be very justly claimed that there are two classes of orthopædic surgeons; the one, viewing apparatus alone as the chief element in the cure of all malformations and deformities; the other class regarding orthopædic surgery as a branch of general surgery demanding the highest degree of general surgical knowledge and skill, yet insisting in addition that mechanical measures and the various forms of apparatus, both before and after operation, are of just as much importance as is a splint after the reduction of a fracture, the necessary reduction and adjustment of the fragments being but a small part of the cure.

Relapses and poor results will occur in the hands of the most careful orthopædic surgeons from neglect and ignorance on the part of the patient, but the worst and most frequent failures are found in the cases where the surgeon, by his words and acts, gives rise to the assumption that he has cured the disease by operation alone. I acknowledge that my predilections and surgical training render me partial to the speedy results of the knife; yet, I value in the highest degree mechanical measures both before and after operation, and am also especially careful to put the system in the best possible condition to resist the tuberculous process.

A wise decision as to the class of cases of hip disease requiring operative means is an exceedingly important one. I must confess that I am often puzzled in regard to fixing an absolute line beyond which it becomes imperative to interfere. I should be exceedingly glad if the American Orthopædic Association could agree upon absolute rules in regard

[1] Read before the American Orthopædic Association, at Boston, September, 1889.

to cases that should, or should not, receive operation; but from my knowledge of the practice and teaching of the several members composing this body, I am sure that there would be a great diversity of ideas and of practice; from those, on the one hand, who never operate, to those on the other who practically make excision their rule of practice.

Cases concerning which there is the least doubt are those in the third stage, with multiple sinuses pouring out unhealthy pus, which drain is rapidly exhausting the patient and threatening dissolution. Yet certain surgeons contend that cases in the late suppurative stage are only suitable for drainage, not for excision. Other cases demanding interference are those showing undoubted evidences of extensive degeneration of tissue with great flexion and adduction, as are also those extremely painful cases of caries sicca, where, without suppuration, the patient sinks, and all forms of mechanical treatment fail to give relief. Albuminuric cases and those showing evidences of commencing waxy changes can often also be benefited by operation, but all these cases have for years been looked upon as at least justifiable ones for interference.

With increased knowledge, however, and especially with increased facilities for operation, due to the greatly diminished risk secured by the use of antiseptics, we ought to advance our lines and rescue a larger number from the tedious delay and crippling results which are so common in this disease. These cases deserve at our hands the most careful attention and skill that can be given them, and American surgery, quick to embrace successful practice, no matter from whence it originates, should give no uncertain sound.

As to the necessity of operation, much will depend upon the condition and surroundings of the patient. It is very justly claimed that in many cases operative means are unnecessary, and there are many surgeons who hold that excision is never necessary. Personally, I can say, as regards the value of careful attention to detail and the application of strict mechanical control, that I consider them so valuable that I have never yet excised a hip-joint in private practice where the individual has been under my care from the inception of the disease. I believe that it is very rarely required under such circumstances, but there come to all of us a great mass of cases with hips riddled with sinuses, pouring out quantities of pus, whom we cannot treat with any certainty that a single instruction will be thoroughly followed, and, with the almost absolute certainty that the disease will rapidly progress or that death will follow. This class of cases stands upon an entirely different basis and must be treated in the way that will give the best results in the shortest time, and we cannot hope to accomplish even that little unless they are received into the wards of a hospital. Instructions that are disobeyed, apparatus that is misapplied, can never give good results.

Before operating it is important that we consider three questions:

1. Is life saved?
2. Is time gained?
3. Is the resulting limb more useful?

1. Is life saved? To answer this question properly would require a careful study of what may be called the natural death-rate from hip disease practically untreated, and secondly, when carefully treated with the utmost attention to every detail, and by various forms of mechanical appliances. It is exceedingly difficult to classify the statistics upon this point, because there are only a few cases in which a certain form of treatment is not instituted; and secondly, even with apparatus there is the greatest diversity of methods. In the large majority of cases, moreover, treatment is interrupted by the patient being placed in the care of some other physician, and thus the course of the case in its entirety is lost and it becomes valueless as regards statistical importance. This is true more frequently as regards hip disease than of other conditions, for the reason that treatment of these cases extends over several years, and there is, therefore, greater opportunity for such change.

Judging from Thomas's statement, we would consider that all cases, even suppurative ones, are curable without deformity, while Hueter takes the gloomy view that only 5 per cent. of suppurative cases, with flexion, adduction, and internal rotation, heal; in fact, he looks upon tuberculous suppurative cases as practically hopeless.

Gibney in eighty cured cases found that forty-eight, at least, had had abscesses. Yale gives the death-rate of conservatively treated cases, without operation, as 31 per cent.; Gibney, 12 per cent.; Clinical Society of London, 33 per cent.; Taylor, 2½ per cent.—the latter all in private practice.

In cases not operated upon one-half are suppurative and 50 per cent. recover without serious loss of motion.

In 837 cases of excision 19 per cent. of the deaths following operation were from rapid miliary tuberculosis.

In 144 cases Sack gives the death-rate as 25; 13 of which were from tuberculosis.

Frosch reports 166 excisions, with 33 per cent. of deaths, one-half of which were from tuberculosis.

Croft reports that 30 per cent. of deaths are from tuberculosis. Under antisepsis the death-rate has diminished, after excision, from 33 to 15 per cent.

Marsh gives 401 cases of hip disease treated without operation, of which 31 per cent. did not suppurate. Of suppurative cases 42 per cent. were cured, and of non-suppurative cases 69 per cent. In suppurative cases treated without operation 33 per cent.

died, as against 10 per cent. in non-suppurative; 9 per cent. of the latter recovered with useful limbs, and only 10 per cent. died, of which deaths 9 per cent. were from tuberculosis.

The percentage of deaths in suppurative cases which occurred from albuminuria, waxy degeneration, and exhaustion could probably have been saved by early excision. Of late excisions 69 per cent. re-suppurated.

In Marsh's collection of 614 cases treated by prolonged rest the mortality was 6 per cent., but it is not proper that the mortality of these cases, which probably were suppurative in a minor degree, should be compared with the 20 per cent. of deaths from excision, as the circumstances of the cases were entirely different. In late excisions 10 per cent. died, and from 20 to 30 per cent. showed no improvement. In the first stage the mortality is, as we know, from 6 to 8 per cent. In the late stage of suppurative cases with amyloid degeneration, the mortality rises from 30 to 50 per cent. By thorough rest the mortality has been reduced in the Alexandria Hospital from 30 to 5 per cent., while 70 per cent. recover with slight loss of motion.

Croft puts the general mortality of hip disease as 35 per cent. Although one of the arguments in favor of early excision is the prevention of tubercular infection, yet, as eighteen or nineteen escape this danger in the natural course of the disease to one that becomes infected, this one does not justify the deforming results of early operation; especially if, as in the early stage, it is impossible to diagnose the exact number of foci of disease that are present, or that may exist in other portions of the body.

The effect of operation upon the mortality from tuberculous infection seems to be very slight.

My own estimate of the natural death-rate in this country would certainly not fix it above 15 to 20 per cent., while in private practice the result would be below 5 per cent.

The death-rate from excision, like that of the normal death-rate above referred to, varies exceedingly, and gives rise to as great a diversity of opinion. Leisrinks gives 63 per cent, Sayre 34 per cent., Culbertson 41 per cent., London Clinical Society Report 37, Caumont, before the use of antisepsis, 66, after its introduction, 41 (11 per cent. died from the operation). Wright, out of 1700 collected cases, makes it 33 per cent., which seems a fair deduction.

Wright states (*British Medical Journal*, December 15, 1888) that incision has not given him any better results than excision; consequently we may, for the present line of argument, practically consider them as one operation.

The saving of life is, of course, the most important consideration of the surgeon, but, if the question were to be considered from this standpoint alone, we should at once join the ranks of those who advise early excision, since the risk from operation at that stage would not be great with asepsis, and in many cases of tubercular infection death would be avoided. Carrying out this line of reasoning, we should arrive at the *reductio ad absurdum* that all cases of hip inflammation should be excised so early that there would be no possibility of the disease being more than a local difficulty.

But even if the saving of life is a prime consideration, other objects must not be overlooked. A large percentage of operative cases die from lardaceous degeneration, of exhaustion from suppuration, or from tuberculous conditions—few from the operation itself.

It would be obviously unfair, however, to compare the results of excision with the results of all classes of cases dying from what may be called the natural results of hip disease, since operative cases, as a rule, are selected from the very worst. The only just method of comparison would be to compare 1000 cases of excision with 1000 equally serious ones, which did not require operative treatment. Could such a comparison be instituted, I believe that the operative course of treatment would yield a less percentage of deaths than the more conservative plan; while at present it occupies a higher place. Were we to compare early resection with similar cases where rigid rest has been secured to the articulation during treatment, doubtless lives would be saved and time gained by the former plan; but as regards locomotive powers, the balance would be in favor of rest.

2. Is time gained? With the practice of antisepsis, which favors rapid healing, we frequently obtain speedy closure of the wound. If any one wishes to have excellent statistics, let him report all cases about the sixth week "perfectly healed." But wait a few weeks more; a small sinus appears, a long period of suppuration follows, and the patient either finally dies, or is cured at the end of possibly a little shorter period than would have been occupied by a natural cure, but the limb is less useful as a walking member.

Even Croft, who favors early excision, acknowledges that the majority of his cases require close watching from one to two years after excision—one-half of them two years, and that ultimate suppuration is very likely to appear.

Wright acknowledges that only 17 per cent. of cases of excision are satisfactory in their results; that 25 per cent. were absolute failures, and that nearly 60 per cent. were suppurating a year after operation, making over 80 per cent. with unsatisfactory results. The cases reported within a few weeks or even a few months after the operation are

not relapses: the disease has continued uninterruptedly in spite of operation, but, as in non-operative cases, the pus has been slow in coming to the surface. True relapses are so common in apparently cured cases as to warn us against too great enthusiasm. I am at the present time treating five cases of relapsed hip disease that have returned after forty-five, nineteen, sixteen, ten, and six years respectively.

In removal of diseased bone-tissue either by excision or by erasion, the underlying layer of bone-cells is necessarily injured, and the inflammation thus set up causes caries with opening of the sinuses and suppuration for a certain period of time. To minimize this element of failure, the scoop should be very sharp and all fragments should be washed out immediately.

Excision in the later stage will undoubtedly yield from 8 to 10 per cent. of deaths within the first few weeks after operation, and fully three-fourths of the cases may be expected to relapse. In probably one-third of the cases improvement is favorable at the beginning, but the return of the disease in the next few months is to be confidently expected. When tubercle has again inoculated the soft tissues a vigorous scraping and cutting out of sinuses may hasten closure.

In cases of great deformity, with marked shortening of the limb and great adduction across its fellow, decided gain in position may be secured by excision, although if these cases are progressing favorably they may be permitted to ankylose when subsequent osteotomy will bring them into good position. In suppurative cases tubercular infection of the system is to be expected in from 5 to 8 per cent. In non-suppurative cases the percentage is still less.

3. Is the limb after excision as useful as the one which nature, assisted by the surgeon's care, is capable of securing? In the large majority of cases, unquestionably no! The loss of the bone, even in one of the worst cases of disintegrated tissue, is seldom as great as in complete excision where the trochanter major is sacrificed. Even in suppurative cases, where there has been absolutely no operative interference, where the joint has been thoroughly fixed, and even although ankylosis has followed, the result is an excellent walking member, and the vertebral column (especially in a child) gives wonderfully compensatory movements. For the working man or woman a stiff joint is incomparably better than one in which the pelvis is insecurely steadied upon the femur, while extensive resection in early childhood may, by the removal of the epiphysis, so interfere with the growth of the member that the limb may be rendered almost useless as a functionating part of the body. The report of the London Clinical Society was decidedly of the opinion that the result was less useful, and I must confess that my results after excision have not been satisfactory, even when treated with care, with rigid antisepsis, and with subsequent attention to fixation of the joint for one or two years. A large majority of cases, six months after leaving the hospital, have been found to be suppurating. I speak of hospital cases, as, under proper care, operation is seldom necessitated in private practice.

It is sometimes argued that the most direful results obtained are those seen in the hands of the best hospital surgeons, which is undoubtedly true, from the fact that hospitals receive the very worst class of cases. Frequently the case when brought to the institution is already in the advanced stage of suppuration with involvement of both femur and innominate. Few dispensary out-patients can receive the close attention that is so essential to cure, and without it even ordinary measures will fail for want of attention to detail at the hands of ignorant mothers.

Yet, looking at hip disease in the light of present pathological knowledge as a local bone tuberculosis, the most rational method is to rid ourselves of the dangerous material if possible, before the general system becomes infected. Is it possible to do this? In the present state of our knowledge we must frankly answer we do not know. First, because we cannot be certain as to the exact number of foci that exist; and, secondly, we cannot fix the time at which general infection commences. We know that the most common point is near the epiphyseal line, but as to the rapidity of either local or systemic infection we have no certain knowledge.

The fact that pus has formed and has escaped from the capsule is sufficient cause for grave apprehension as to the result. But what course are we to pursue for its removal? While theoretically I am in favor of early operation, yet I am not prepared to advocate what is known as early excision. I abhor retained pus, and yet I have before my mind too many cases like the following:

A. B., aged eleven, female, with long, unmistakable signs of hip disease passing through its various stages; tumor appeared on the front of the thigh; by aspirations, in each of which operations seropurulent material was evacuated, and by the employment of rest and immobilization the symptoms became quiet, and the case was cured without appearance of pus, at least on the surface, and has been walking about in perfect health for eight years.

C. D., a case in which localized swelling was so great that I was called in consultation to open an abscesss. Undoubtedly hip disease in acute stage, yet, under proper treatment, after eighteen months shows no signs of suppuration, and bids fair to recover without loss of joint motion.

Such cases cause one to hesitate when the symptoms are not very serious, and the surgeon, in all these doubtful cases, should go carefully over the whole ground, taking into consideration, in connection with the local symptoms, the surroundings of the patient, the general condition of health, and the ravages of the disease.

On the other hand, I can recall many cases which were making favorable progress, yet suppuration has suddenly appeared, and the patient has died from long-continued drain, or from lardaceous degeneration, or from tuberculosis. Others, where operation has been refused, have taken the same course. In cases where there are reasonable signs of pus formation, and yet where the existence of abscess is not positive, even though thickening and induration are markedly present, we can often afford to wait until the diagnosis is more thoroughly established, feeling confident that injury to the general health is no more likely to occur than after operation.

Incision, erasion, and drainage, as described in a later portion of this paper, sometimes offer better hope of relief than excision, on account of the thorough removal of all portions of the tuberculous material, both of hard and of soft parts; but I have not practised this plan of complete erasion for a sufficient time to speak emphatically in regard to its value, as it will require several hundred cases to yield reliable facts. In theory it is correct, and it has sometimes given me excellent results. I cannot boast of such apparently brilliant successes as have been reported by Barker (*British Medical Journal*, Dec. 15, 1888, p. 1336), yet a close examination reveals the fact that months later his cases showed evidence of continuation of the disease, even though prompt healing had taken place.

I look upon all pus confined in the body as an element of danger, and upon tuberculous material as especially fraught with risk. I do not overlook the fact that our very efforts at removal of this tuberculous material may be the means of causing bacillary infection, and that we may hasten general tuberculosis. Partial removal is dangerous. Neither do I overlook the fact that encapsulation, caseation, absorption, or organization of the tuberculous foci may occur; hence, we should always have good ground for interference before attempting operative relief. On the other hand, such foci may be a menace to the constitution for many years. The strongest argument against thorough removal and rigid extirpation of the diseased tissue is the fact that Volkmann, who followed this plan for many years, was disappointed in the results. After reëxamination of his cases he found that relapses were not uncommon. In this respect he seems to have had similar results to those secured by the rest of us.

The principal measures practised for the relief of the various stages of hip disease are:

I. Aspiration of the fluid in the joint.
II. Ignipuncture.
III. Trephining or drilling.
IV. Aspiration of abscesses more or less remote from the joint.
V. Incision of the abscess.
VI. Incision, erasion, and drainage.
VII. Excision.
VIII. Amputation.
IX. Osteotomy.

I. *Aspiration of the joint fluid.*—While thoroughly of the belief that the overwhelming majority of cases of chronic hip disease are evidences of tubercular ostitis, caused by slight injury, there are a certain number of instances of primary synovial inflammation that require treatment in order to prevent the degeneration from involving the bone structure and then becoming tuberculous. The surgeon who does not treat cases that are diagnosed as "contusion of the hip" with this possibility in view, is not only reprehensible for his carelessness but is committing an injury to his patient. The progress of a majority of these cases is hopeful. Distention of the joint by serum will necessarily produce flexion, abduction, and external rotation, and to employ traction in a straight line, without removal of the fluid, provokes muscular spasms and produces pain. If the removal of the fluid is contra-indicated or declined, traction and fixation in the line of the deformity are permissible. Should rest, or traction, or both, produce no relief within a few days, then, with a clean instrument, clean hands, and clean integument, no harm can result from aspiration. When there are evidences of increased thickening about the joint, indicating that the fluid has degenerated into pus, removal of the articular contents is advisable. The joint may be reached posteriorly or anteriorly. I prefer the former route, but am guided by the proximity of the swelling to the surface. The amount of fluid is limited unless the capsule is ruptured. Great benefit will ensue provided rest of the joint follows, and instructions are strictly followed for a long time after all apparent symptoms have passed away.

II. *Ignipuncture.*—This, as practised by Park, Bradford, and others, consists in electrical tunnelling of the bone or cautery by electricity. It is occasionally valuable and would often be of more service if we could be assured of the correct situation of the tuberculous focus. Uncertainty upon this point, however, will, for the present, at least, permit it to be only occasionally employed. The puncture is usually made over the trochanter, and the cautery is caused to enter the longitudinal axis of the neck of

the bone until the epiphyseal juncture is reached. Good drainage is thereby secured. If all bacilli could be destroyed a rapid cure would result. It will require further tests before it is recognized as an established procedure.

The actual cautery may, I suspect, in the olden time, have sometimes been buried in the bone by Pott, Brodie, and others. This method, which we now so greatly decry, secured to the patient a long period of enforced rest from which benefit was derived, and thus the agent became a large factor in the cure.

III. *Trephining and drilling.*—From this plan of operation much benefit would doubtless be obtained, if, as in the last-mentioned plan, we could locate the exact position of the tuberculous focus. Unfortunately, however, this is usually impossible. Lovett states that much relief can be obtained by the evacuation of the products of inflammation by this method. He cut a ¼ inch hole through the neck of the femur with a trephine, and curetted and drained thoroughly from the bottom of the cavity. The temperature in his case ran up to 104.5°, but he states that cure was facilitated. It seems to me that cases requiring ignipuncture and trephining would be better treated by exploratory incision followed, if necessary, by drainage or by erasion.

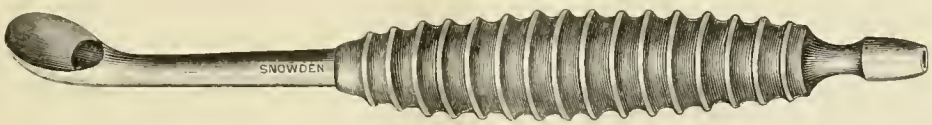
IV. *Aspiration of the abscess.*—As long as there is the slightest doubt as to the existence of pus we can well afford to delay, even though confined pus is an element of danger. Many surgeons advocate the plan of letting these abscesses absolutely alone, and statistics prove that the danger to the constitution is not thereby greatly increased.

An important element in the diagnosis is the use of the aspirator. Thorough antisepsis must be employed, and it must be certain that no element of suppuration is introduced by the operator. A needle of large size should be employed, and if the fluid secured is sero-purulent in its character, or if we have the liquefaction of caseation, I have found that it is wiser to continue this plan of operative procedure as rapidly as the abscess becomes filled. In many cases absorption or organization has occurred, and the case has gone on to excellent cure without any pus finding its way to the surface. When the instrument reveals true pus one of the following plans of treatment must be instituted, unless the let-alone policy is decided upon. If it is decided simply to evacuate the pus without any more thorough operation, I decidedly prefer the preliminary plan of drawing it off through a large aspirator and injecting into the cavity ten or fifteen grains of iodoform dissolved in glycerin and distilled water. This should be allowed to remain, the object being to excite just sufficient inflammation to strengthen and thicken the walls of the abscess, which is nature's method of protecting the system from injurious invasion.

V. *Simple incision of abscess.*—When pus is absolutely proven to be present the question of its evacuation becomes an important one. So long as the doughiness of the part indicates only caseation, the waiting policy has, in my hands, given the best results. In the stage of liquefaction of caseation aspiration or simple incision is useful, as these cases often show but little tendency to suppuration. With many surgeons the existence of caseation is regarded as the signal for incision, but I have found that many of these cases do remarkably well without serious operation. As a rule, I prefer to abstain from any interference until I am positive as to my plan of final action, or until the consent of the patient has been secured to the necessary operative procedure. Should the major operation be declined, or if there are any contra-indicating symptoms, simple incision and drainage are most desirable, under strict antiseptic precautions. I have already described how preliminary aspiration should be performed in order to diminish the risk from bacillary infection. The incision should be made at the point of the tumor which will give the greatest drainage; frequently it is desirable to make two openings so that "through-and-through" drainage may be secured. In all cases of simple incision of abscesses, it is my chief object to avoid any pressure upon the abscess wall lest fissure occur and bacillary infection follow through this route. The contents of the abscess should never be pressed out, but should be removed by a gentle current of hot sublimate solution until the major portion of its contents has been evacuated. A bulky antiseptic dressing should be applied without undue pressure, and it should be allowed to remain until signs of decomposition appear, be it days or weeks. Disturbance of an abscess is as injurious as is the opening of a fresh wound. A drainage tube should be inserted at the time of the operation. Subsequently, antiseptic washing may be practised according to the view of the operator. So long as there is no pocketing of the pus I prefer to let it escape by free drainage rather than by forcible pressure.

VI. *Exploratory incision, erasion and drainage.*—There is no special form of incision which should be followed, even when it is probable that the operation will end in excision. If the abscess has not yet opened the most dependent portion of the prominence may be selected, avoiding the large vessels and nerves, and also paying attention to the integrity of the muscular fibres as far as possible. If sinuses exist, two or more of them may be connected, or the more prominent ones may be followed to the diseased bone. The bleeding vessels should be secured by forceps and irrigation by hot sublimate solution (1-1000) instituted so as to form a protective layer of coagulated albumin upon the freshly cut surface, thus assisting in the prevention of tuber-

culous infection. Thorough exploration by the finger and probe will then disclose the origin of the pus. The joint will usually be found open; if so, no harm will arise from enlarging the wound sufficiently to admit the finger and thus determining whether the disease is limited to a small area. If the disease is localized the scoop is now brought into use and every particle of diseased tissue that can be reached either in the head or neck, or synovial membrane, or in the acetabulum, or in surrounding soft tissues, is cut away. For this purpose I prefer a hollow-handled sharp spoon, as it enables me to work more rapidly, and at the same time it supplies a constant current of antiseptic water, and thus destroys all germs before they have an opportunity to infect the incision. As shown in the cut, it is simply a sharp spoon, with a bulky handle tunnelled longitudinally with a large ($\frac{3}{16}$ inch) bore so as to allow free ingress of water from the feeding tube which is connected with a reservoir, or jar, or rubber bag. The device of Barker for shutting off the flow of water is entirely unnecessary and is cleansed with difficulty. The carpal portion of the operator's hand makes an efficient valve and is easily employed for the arrest of the current when necessary. The length of the tube and the height of the jar, or fountain syringe, must be varied according to the rapidity of the flow desired. This hollow instrument gives the operator control of the current and leaves him free from the presence of an assistant's hand.



The erasion must be carried well beyond the seat of the disease, and for this purpose a curved gouge is sometimes necessary. If the head or other portion of the bone is loose, the rough ends must be sawed or gnawed off by strong rongeurs, and all fresh foci discovered in the bone similarly treated. The knife and scissors are then brought into use and all possible fragments of the diseased tissue entirely cut away. All sinuses should be opened, if possible, and the entire walls together with that of all abscess cavities, should be removed until healthy tissues are reached. After rendering the wound thoroughly aseptic we may permit it to fill with fresh blood-clot for reorganization or dress it clean and dry. The wound can be drained with catgut or rubber tubing, according as is deemed best by the operator. In the majority of cases I regard it as far more important to effect a thorough cure than to secure primary union. Rubber drainage is, therefore, preferable, especially when there has been extensive bone disease, as it counteracts any error that is liable to occur even with the most careful antisepsis. If these tubes are withdrawn half an inch at every dressing it will accelerate the healing and will lead the pus down their track. They are usually retained too long. A large antiseptic dressing should be immediately applied, firm pressure being made over antiseptic wool.

In the discussion upon this method, which developed in the Royal Medical and Chirurgical Society (*British Medical Journal*, December 15, 1888), absolute antisepsis, subsequent attention, and absolute rest were insisted upon. The anterior incision of Hueter for erasion was recommended, although thorough removal and drainage were more difficult. Wright, who has excised 135 times in his last 800 cases, thought it impossible to remove all the diseased tissue, and as a single focus remaining might, on slight traumatism, arouse inflammation and bring on a relapse, he still believed in drainage rather than to attempt primary closure. It is certainly impossible to secure a clean, fresh wound in every portion where there has been a large amount of disease and extensive suppuration.

The temperature chart is the most valuable index of the accumulation of pus, and every rise of temperature should be followed by a careful examination of the region.

VII. *Excision.*[1]—When an exploratory incision reveals a large portion of diseased bone, and when it is impossible to remove the foci by erasion, then excision should be performed. Enough has been said, in an earlier portion of this paper, to show that excision should not become a routine practice even in bad cases of hip disease, as has been the custom with many surgeons in late years.

Excision is an operation of exceedingly great value in selected cases, but it should be performed only with the full consideration of all the surroundings of the individual case. As to early excision, reasons for its avoidance have already been given. As to the line of incision, we may be governed by the location of the sinuses, but should be controlled more by the avoidance of the muscular and nerve fibres than by any fixed line, although I prefer the curved incision passing behind the great trochanter from the posterior iliac spine. If the anterior incision is preferred, it may be commenced just below the anterior superior spinous process with the tensor vaginæ femoris and gluteus on the outside, the sar-

[1] Dr. Willard said that as the question of excision would be discussed by another member of the Association, he would not enter into details regarding it.—Ed.

torius and rectus on the inside, cutting directly downward upon the front of the capsule.

It is well to save all healthy periosteum, but this membrane when diseased should be thoroughly removed, as should any other disintegrated tissue. While excision should be thorough, it is not necessary that the trochanter, when healthy, should be sacrificed merely for the sake of drainage, as we can secure drainage by carrying a tube directly backward through the buttock, or in any convenient direction. Retention of the trochanter will add greatly to the future usefulness of the limb as well as to its length, as a short, slightly movable band of union is most useful. A narrow saw with a stout handle, similar to that of the Adams saw, with a longer cutting-blade, is usually much more convenient than a chain-saw. The soft parts can be protected from injury by retractors. For very deep work, where the ordinary chain-saw is certain to break during the operation, I have had a chain-saw made of the size and weight of an ordinary écraseur. This is much better fitted for heavy work, but is not equal to the straight saw for superficial work.

When osteomyelitis is present in the head and shaft of the femur, care should be taken not to strip the periosteum from a larger area of the bone than is necessary in removal. When the disease has extended far down the shaft of the femur the foci can be removed by erasion, especially in cases where to clear away all the disease would necessitate the removal of three or four inches. The result of entire removal in such a case would be to leave a "flail" limb, and amputation would be preferable save for appearance. It is also best in these cases to perform erasion if a secondary operation becomes necessary.

The dressing after excision which I find most convenient and comfortable, is simply light extension by adhesive strips and cord passing over a pulley, with heavy sand-bags applied to either side of the body from the axillæ to the feet. A wire cuirass is convenient and useful in cases where early transportation is required. The patient rarely suffers much pain.

In excision, as in erasion, all diseased tissues should be cut away, and the acetabulum cleaned as freely as possible, the gouge and scoop being brought into use. Drainage should be thorough and complete, but the tube should not be retained longer than is necessary to form a track for any deleterious material that may remain in the wound. Thorough antisepsis promotes rapid healing, but in excision, as in erasion, any remaining diseased foci will cause subsequent abscess.

When indications of commencing waxy changes make their appearance excision is certainly desirable in order to check the drain upon the constitution. Sometimes, even when these changes are marked, although the immediate risks from the operation are great, yet life has been prolonged by removal of the diseased foci. I have recently seen a case where excision had been performed several years since, yet where suppuration had continued and gouging had been practised three times upon the patient with a continuance of the suppuration after each operation. The kidneys, liver, and spleen showed most extensive changes, and yet the patient rapidly improved, gained flesh and strength, and was nearly freed from the discharge of pus from at least a dozen sinuses by a three months' residence at the seashore. This case evidences the effect which the bodily condition has upon the inroads of disease when the system is placed under good resistive influences, and well illustrates the fact that the tubercle bacillus can be destroyed by the individual.

By rapidity of operation, incision of moderate length, sawing the bone with a narrow saw while in position and without much disturbance of the parts, by prompt arrest of hæmorrhage by the use of hæmostatic forceps, and by extra care in all the details of the operation, the shock is greatly lessened and the seriousness of these operations has been greatly diminished in recent years. The condition of the patient has also been greatly benefited by the lessened drain upon the system through antisepsis, and he is thus made better able to cope with the tendency to relapse.

The necessity for excision, as for erasion, is greatly diminished by proper attention to rest and fixation. After the operation the weight of the body should not be put upon the bone for many months, and the diseased region should be thoroughly protected from injury by some form of apparatus for at least a year after entire recovery has taken place.

Frequently, when an exploratory incision has been made with the idea of removing the diseased portion by erasion, excision will be the final result of the operation. It is not expected that erasion can take the place of excision. It is simply to be employed where the destruction of the bone tissue has been small.

VIII. *Amputation.*—While amputation has been very serviceable in joints other than the hip, yet at this articulation, although sometimes employed, it is rarely of service, since cases necessitating so serious a loss of tissue are usually accompanied by caries of the ilium and the removal of the limb would be of only slight service save in arresting the drain. It has, however, been occasionally performed, and when osteomyelitis involving a large portion of the head of the femur is present, it would be decidedly preferable. Since Ferguson's advocacy of excision, in 1850, amputation has decidedly (and very properly) fallen into disuse, as the more conservative operation is usually of great benefit and is less

fatal. As excisions have lessened the number of amputations, so erasion will, in the future, lessen the number of excisions.

IX. *Osteotomy.*—Osteotomy is an operation to be performed only after the subsidence of all active inflammatory symptoms, and need not, therefore, be discussed in this paper.

Conclusions.—I. Mechanical measures, which enforce strict and long-continued rest of the joint, are the best preventives of operative procedures, and when they can be employed, as in private practice, operation is seldom necessary, since even if caseation or liquefaction occurs, we may often have absorption or encapsulation. Give careful attention to hygiene and general health.

II. Antiseptic aspiration of the joint is desirable if it is distended with serum, sometimes when it is filled with pus.

III. Ignipuncture and trephining give great relief, provided the focus of the disease is reached.

IV. If in doubt as to the presence of pus, wait, or test with aspirator. Repeat the aspiration if the fluid drawn is sero-purulent, since organization may occur without the opening of a sinus. If there are no signs of caseation, wait. If caseation takes place, make early exploratory incision. These latter cases are often curable by simple incision and drainage.

V. When certain that true pus has formed, aspirate and inject with iodoform in order to strengthen the walls of the abscess cavity as a preliminary to incision, provided incision alone is decided upon.

VI. If the abscess is to be only opened and no other operation performed, as soon as the sac refills after aspiration incise freely, wash out the contents with a slow current of (1-1000) hot sublimate solution, but on no account apply pressure to expel the pus, lest fissures be made in the limiting wall and infection be thus favored. Drain freely. Dress antiseptically and fix the hip. Continue to keep it at rest until closure occurs, or until further steps are necessary.

VII. When extirpation has been decided upon make an exploratory incision either along the line of a sinus or directly upon the bone, anteriorly or posteriorly, as preferred, and thoroughly examine the joint. If the destruction of tissue is small, try erasion and remove the carious bone and soft tissues with scoop, scissors, and knife. Endeavor to remove every particle of tuberculous tissue of both hard and soft parts including the abscess wall. Irrigate thoroughly with a strong antiseptic to prevent bacillary infection of the freshly cut tissue and drain freely. With antisepsis the dangers of opening the joint are only slight, and the desirability of operation is now based largely upon the question of time and the ultimate results as regards usefulness of the limb. In children it is especially desirable.

VIII. Perform a formal excision, not as a routine practice, but when the disease is found to be too extensive to be removed in any other way. In adults, especially when poor, a typical resection gives the best results. In cases of great destruction of bone, in painful caries sicca, in profusely suppurating cases, in the early stage of commencing waxy changes, the operation becomes one of special value.

Erasion differs from excision chiefly in the fact that in the former operation all diseased tissues (soft and hard) are removed and all healthy ones are spared. It is also less mutilatory. In excision a considerable portion of the good bone is sacrificed, but erasion is, of course, not as beneficial at the hip-joint as at the knee.

CLINICAL MEMORANDA.

TOXICOLOGICAL.

Hallucinations from Atropine Instillations in the Eye.—Some time since, J. B., a man of about twenty-five years, presented himself at the Presbyterian Eye and Ear Hospital, Baltimore, for treatment of a central corneal opacity of the left eye which greatly obstructed vision. An iridectomy was thought advisable, and was performed on Friday afternoon. Being the resident physician of the institution at the time, I had charge of the patient, and instilled one drop of atropine solution (4 grains to 1 ounce) in the eye three times daily. On the following Sunday, after the seventh instillation during a period of about forty-eight hours, he acted and talked strangely to the inmates of the hospital. On making my rounds that evening I found him somewhat excited. He gave foolish replies to questions, his face was flushed, pulse rapid, and the pupil of right eye was widely dilated. I discontinued the use of atropine, but did not deem an antidote necessary. About one o'clock that night, however, I was aroused by the nurse, who said she thought the man was crazy. Upon going to his room I found him dressed in overcoat, boots and hat, and crying like a child. He said that he had just seen a man split his father's head open with a broad-axe. I told him he was mistaken, and induced him to retire. After 1/6 grain of morphine, he quieted down and slept until morning. He was somewhat "flighty" during that day, but afterward was rational. Such effects are not uncommon when the atropine is instilled at intervals of an hour or two, but are extremely rare when it is used only three times during the twenty-four hours.

Washington, D. C.

GYNECOLOGICAL.

A Case of Hæmatoma of the Cervix Uteri.—Dr. J. P. Salb was recently called in consultation to see a woman, twenty-four years old, who was in labor with her second child. On examination, the doctor found a wine-colored, flattish, ragged tumor projecting five inches beyond the vulva. It was irregular, resistant, apparently torn, and bled quite freely, and resembled a placenta. The child

was presenting by the face, the chin being rotated backward. Forceps were applied, and the child delivered. After the delivery of the placenta it was found that the finger could not be passed between the tumor and the internal surface of the uterus, and that the growth was continuous with the neck of the uterus.

The following day I saw the case in consultation. The tumor was then of large size, resistant, very dark, and apparently threatened with gangrene, and causing one of the most sickening odors I ever came across. The ragged ends apparently belonged to the posterior lip of the cervix, and just above them there seemed to be a rounded opening which had the appearance of a greatly enlarged os uteri.

I concluded that the tumor was either a sarcoma or hæmatoma, probably the latter, on account of the history of the case. She was a young woman, she had been in good health up to the labor, and had had no previous discharge, pain on intercourse, or other symptom of disease. The tumor was first noticed after the labor had been in progress for several hours, and was probably caused by the faulty position of the child.

As the posterior part of the neck was evidently already amputated, we concluded to complete the operation by amputating the anterior part of the cervix. The tumor was becoming gangrenous, it bled freely, and there seemed to be no other way of checking the hæmorrhage. Accordingly the woman was placed on a table in the lithotomy position, with an oil-cloth to drain off the liquids, and, the limbs being supported by assistants, the tumor was drawn out of the vulva as far as possible. The vagina was then thoroughly irrigated with hot carbolized water, by means of a fountain syringe. A stout double ligature was drawn through the tumor just above the dark part, and each portion tied separately. Another ligature was then thrown around the growth and tied very tightly. The mass was then cut off with scissors curved on the flat. The posterior part of the cervix could now be very plainly seen. It was ragged, dark, and slightly swollen. It did not bleed, and we concluded to let it remain. The vagina was again well washed. The woman was given a dose of morphine and put to bed. We did not give her an anæsthetic, and she did not suffer much pain during the operation. Vaginal irrigations were used daily.

The patient made an uninterrupted recovery without an untoward symptom. The sloughing stump came away about a week after the operation.

The accident seems to be a rare one, judging from the literature at my command. I am convinced that the hæmatoma was caused by the faulty presentation, the head pressing for hours against an undilatable os uteri, and at last bursting through the obstruction, the greatest pressure being on the posterior part of the cervix.

JASPER, IND.

MEDICAL PROGRESS.

The Treatment of Burns.—In the *Norwiny Lekarskie*, No. 9, 1889, DR. LEON SZUMAN describes his method of treating burns as follows: as soon as possible after the injury the burned surface is covered with the following ointment:

R.—Vaseline	. . .	7½ drachms.
Pulverized salicylic acid.		15 to 30 grains.
Cocaine hydrochlorate .		2 to 4 " —M.

Over this he places a thick layer of iodoform or salicylic gauze, a thin layer of salicylic cotton, and a bandage. In burns around the mouth where the dressings become soiled they may be changed several times a day if necessary, while on the limbs or other regions they may be left undisturbed for several days. If the injured surface is contaminated with sand, mud, etc., it is washed with Carron oil before applying the ointment. The oil may also be used to soak the dressing if pain is severe. On changing the dressing if any portion of the gauze is found adherent to the surface it should be left *in situ*. Under this treatment severe and extensive burns are said to heal rapidly and without suppuration.—*Provincial Medical Journal*, March 1, 1890.

Prescription for Chapped Hands.—The following prescription for chapped hands is quoted in the *Provincial Medical Journal:*

R.—Menthol	. . .	15 grains.
Salol, Olive oil	of each . .	½ drachm.
Lanolin	. . .	1½ ounce.—M.

The pain is said to be alleviated after the first application of this ointment, the skin at the same time becoming soft and fissures healing rapidly.

Calcium Iodate as an Antiseptic.—MR. W. DINNETT SPANTON has been experimenting for some years with iodate of calcium and believes that the salt possesses powerful antiseptic properties (*Provincial Medical Journal*, March 1, 1890). A bottle of urine, to which was added a small quantity of the iodate, has been standing for seventeen years and shows no traces of putridity. Another bottle containing boiled meat is also free from odor, excepting that of iodine.

Mr. Spanton has employed it internally and in solution for washing out the bladder in several cases of cystitis with very offensive urine. It had the result of greatly diminishing the fœtor and clearing the urine, though the author considers it inferior to boric acid for this purpose.

As a dressing for wounds, either recent or suppurating, it is certainly useful as an antiseptic. In such cases its insolubility is the greatest disadvantage, as it requires 400 parts of water to dissolve. In a case of excision of the tongue a solution of the iodate made an excellent mouth wash, absolutely preventing the fœtor so common after such operations.

Given internally the author has noticed no effects other than checking the decomposition of the urine in cystitis and reducing the amount of urates. So far as his experience goes he has found the insolubility of the salt its greatest disadvantage, but its innocuous and unirritating properties and its marked effect on the urine render it useful in cystitis, nephritic abscess, and to disinfect the urine previous to operations on the kidney or bladder.

It is important that the iodide of calcium be not mistaken for the iodate. The former is poisonous, and in comparatively small doses will produce disagreeable

effects. Unfortunately, the author does not state in his paper the exact amount of the iodate used internally in any of his cases.

The Treatment of Asthma.—At the beginning of an attack of asthma, Dieulafoy directs the patient to paint the nasal cavities as high as possible, by means of a camel's-hair brush dipped in a five per cent. solution of cocaine hydrochlorate. If preferred, the solution may be sprayed into the nose and throat. If this application does not cause the attack to abort, the patient should be made to inhale from 1 to 12 drops of pyrodin, sprinkled on a handkerchief. When the attack is at its acme, inject hypodermically $\frac{1}{10}$ grain of hydrochlorate of cocaine, and repeat in a quarter of an hour, if necessary. The remedy *par excellence* for asthma is iodide of potassium, given in doses of 20 to 30 grains daily, but commencing with 5 grains only, and gradually increasing. To combat the diathesis, the author considers three principal medicaments: iodide of potassium, belladonna, and arsenic, and recommends the following course of treatment: The patient to take from 15 to 30 grains of iodide daily for fifteen days, then replace the iodide by pills containing powdered belladonna leaves and extract of belladonna, of each 4 grains, to be made into 20 pills. At the same time he is to take a teaspoonful daily of the following solution, after the principal meal:

R.—Arseniate of sodium . . . 1 grain.
Distilled water . . . . 2½ fl. ounces.

If the chest be emphysematous, the use of baths of compressed air are also useful concurrently with the foregoing treatment.—*London Medical Recorder*, February 20, 1890.

The Treatment of Prolapse of the Rectum.—Mr. Frederick Treves summarizes the various methods employed for the treatment of prolapse of the rectum, as follows:

1. Subcutaneous injections into the ischio-rectal fossa. The fluids employed consist of solutions of ergotin, nux vomica, or carbolic acid. Vidal claims three cases of cure by the use of ergotin. In one of these no less than twenty-two injections were employed. The procedure would appear to be followed by severe pain and spasms of the sphincter, and to be uncertain in its results and tedious in its employment. It can scarcely be considered to be founded upon sound scientific principles, or to be a measure devoid of reasonable risk. At least one fatal case of poisoning is reported to have followed the injection of nux vomica.

2. The application of nitric acid. This measure aims at promoting cure by producing such a cicatrix as will cause the complete contraction of the mucous membrane. It seeks also to promote adhesion between the coats of the disorganized bowel. The method may be spoken of as little less than barbarous, and as representing a survival of an evil period in the surgery of the past. The operation involves extreme pain, and is apt to produce extensive sloughing and severe inflammation of the rectum. It has been followed by fatal hæmorrhage, and by stricture of the lower part of the bowel. The after-treatment is not infrequently protracted. Mr. Harrison Cripps mentions a case in which apparent cure followed three applications of nitric acid, the period of treatment extending over four months.

3. The application of the actual cautery to the mucous membrane of the prolapse, or the removal of linear folds of the membrane by means of the clamp and cautery, are measures which are little superior to that just described. The treatment is painful, a severe degree of inflammation is excited, sloughing is inevitable, the special dangers of a burn are introduced, and more or less cicatrization is unavoidable. During the use of the clamp and cautery the weakened bowel has given way, and coils of small intestine have escaped.

Of all these methods it may be said that they are clumsy, uncouth, uncertain, and unsafe; that they are not in accord with the teachings of modern surgery; that they offer the least satisfactory mode of dealing with the affection, involve a protracted and painful period of treatment, and incur unnecessary risks. By excising the part a clean incision is substituted for a burnt and gangrenous surface, the operation area is reduced to a minimum, no damaged bowel is left in the pelvis, hæmorrhage may be rendered practically impossible, and the risk of a subsequent stricture can hardly be said to exist. The method is simple and final, it involves no protracted period of after-treatment, it induces but little pain, it leaves a simple wound which is open to inspection, and it appears to offer the best claims for being considered a method of "radical cure." Kleberg's method of removing a prolapse by means of elastic ligatures, aided by the liberal application of chloride of zinc, is a needlessly severe, complicated, and dangerous operation, which does not appear to have been adopted by any other than the inventor. It would seem that in three cases treated by this method two patients made a tardy recovery, and one died.—*Lancet*, March 1, 1890.

Prescription for Gonorrhœa.—Jullien recommends the following injection in gonorrhœa:

R.—Liquid vaseline . . . 140 parts.
Bismuth subnitrate . . . 10 "
Resorcin . . . . . 3 "
Iodol . . . . . 1 part.—M.

—*Revue de Thérapeutique*, March 15, 1890.

Cardiac Affections of the Menopause.—Professor Kisch (*Berliner klinische Wochenschrift*) has noticed that in the beginning of the climacteric, when menstruation is becoming irregular, although the heart has hitherto been normal, women often complain of attacks of palpitation with or without apparent cause, lasting some minutes, and recurring after several days. The feeling of increased heart-beat is very troublesome, and is accompanied by a sense of anxiety and of pressure in the chest, throbbing of the carotids, pulsation of the abdominal aorta, with rushing of blood to the head, occasional muscæ volitantes, noises in the ears, giddiness, and even fainting. Objectively, the cardiac action is found to be increased, with frequency of the pulse from 120 to 150, which is usually strong, well filled, and regular. The heart-sounds are normal. There is no appearance of anæmia; on the contrary, the patient looks well nourished, strong, and full-blooded. The systematic use of mild purgatives is indicated, with dietetic treatment in the shape of bland

food, while much improvement may result from active bodily movement, cold bathing, and moist applications to the abdomen. Another form of heart trouble associated with the change of life has the symptoms of cardiac weakness. It occurs usually in delicate women, who have suffered from chlorosis in youth, and from anæmia later on; or in cases where the climacteric sets in with profuse menorrhagia, or in women who have formerly suffered much from menorrhagia or have borne many children. In these cases the frequency of the pulse is not so high as in other forms, though the pulse is weak, small, easily compressible, and sometimes intermittent or irregular. Dyspnœa and attacks of cardiac asthma occur, sometimes with angina. Congestive appearances may be present, such as sudden chilling of hands and feet, often with œdema of the ankles; and sometimes there is albumin in the urine. It is very important in these cases to ascertain the condition of the pelvic organs. A third group arises from the tendency of fat to find its way into the heart as part of a general deposit throughout the body.—*Practitioner*, March, 1890.

The Treatment of Phthisis by Carbonic Acid.—It is said that lime-burners enjoy a certain degree of immunity from phthisis, not because they take in more carbonic acid, but because its diffusion when expired is impeded. Again, the course of phthisis is often seen to be arrested in pregnancy, and this has been ascribed to the increased amount of carbonic acid in the maternal blood. Chronic heart disease, by causing chronic hyperæmia of the lungs, also affords a kind of immunity against phthisis; lastly, in emphysema there is also permanent dyspnœa in more or less degree, and the blood is overcharged with carbonic acid. Acting on these ideas, DR. HUGO WEBER (*Berliner klinische Wochenschrift*) proposes to administer carbonic acid by the stomach, in the form of effervescing powders. Ten cases are reported in which decided improvement was noted after this treatment, which certainly merits further trial, especially as it can be carried out at the patients' own homes. According to Ebstein's theory of diabetes, the increased proneness to phthisis which that disease entails is due to the defective development of carbonic acid, this being not only the final product of tissue oxidation, but a body which exerts a regulatory restraining influence on the destruction of glycogen and albuminoids. Bergeon, Dujardin-Beaumetz, and others have used in phthisis gaseous injections *per rectum* of hydrofluoric acid, copiously diluted with carbonic acid, and the good results they met with are claimed by Dr. Weber as due to the diluent. —*British Medical Journal*, March 8, 1890.

Medical Examinations for Life Insurance.—In the *Dublin Journal of Medical Science*, March, 1890, DR. A. W. FOOT contributes an article of great interest to examiners for insurance companies. Referring to the influence of apoplexy upon risks, the author writes that the apoplectic habit, in so far as it is characterized by broad chest and shoulders and a reddish face, is found absent in a majority of those who suffer from cerebral hæmorrhage, and he apparently thinks that these signs should not be taken into consideration; but it is important to bear in mind that apoplexy, or at least the tendency to arterial degeneration, is often inherited.

There is seldom any attention paid to the existence of a discharge from the external ear, yet such a symptom betokens incalculable dangers to life, and it is suggested that the applicant should invariably be questioned upon this point.

Erysipelas is also frequently neglected, yet it is well known that the disease is often associated with diminished vitality, with depraved digestion, and with defective assimilation, and that one attack predisposes to others.

Another matter which should not be overlooked, is the occurrence of fæcal obstruction, especially if originating near the right iliac fossa. The applicant, deeming it simple constipation, may not consider it worth mentioning; but such cases are liable to a recurrence of obstruction which may prove fatal.

With reference to phthisis the author insists on the importance of not overlooking the fact that, when many brothers or sisters of the applicant have died in infancy from diseases of the brain or of the abdominal organs, tuberculosis is probable, and the risk thereby increased. Further, it is a sound principle of action to reject a life when so many as two immediate relatives are admitted to have died of consumption. Applicants often try to cover up the existence of the disease by terming it "asthma," or "bronchitis," when careful inquiry will elicit the fact that the disease was undoubtedly phthisis. The examiner must also be on the watch for inherited tendencies to insanity, which in the family history are described as "nervous debility," "congestion of the brain," etc.

Many cases have occurred in which insurance companies have lost money, after a short period of insurance, by the examiner neglecting to investigate the rectum. Cancer of this organ in the early stages may be considered hæmorrhoids by the applicant.

The author then reviews the question of the influence of albuminuria on the risk, and concludes that, however small the quantity, unless clearly extra-renal, albumin in the urine should positively exclude an applicant from insurance.

While examining the urine, it should in all cases be tested for sugar regardless of the specific gravity. It is only by routine examination that the early stage of diabetes can be discovered, for at that time the amount of sugar is insufficient to raise the specific gravity to a marked degree.

Iodoform in Cerebro-spinal Meningitis.—DR. G. LEVITSKY in the *Vratch* has recently called attention to the excellent effects obtained in cerebro-spinal meningitis by the internal administration of iodoform, in doses of two grains three times daily. He reports the case of a woman suffering with an exceedingly severe form of the disease, in whom, after other means had failed, the administration of iodoform was immediately followed by steady improvement. On the third and fifth days of the treatment contractures disappeared from the right and left arm. By the end of the fourth week the patient was practically well, and the drug was discontinued. A relapse then occurred which yielded at once to iodoform, a complete and permanent recovery taking place. In all, one ounce of iodoform had been taken in the course of two months; no untoward effects of any kind being noticed.—*Journal of Nervous and Mental Diseases*, March, 1890.

THE PREVENTION OF OPHTHALMIA NEONATORUM.

THE statistics of Professor Magnus, of Breslau, carefully compiled for Europe, and Germany in particular, have demonstrated that 71.99 per cent. of all who become blind during the first year of life are rendered sightless by purulent ophthalmia; in other words, he has shown that of every 10,000 children under five years of age. 428 are blinded by this type of conjunctivitis. The proportion of blind from this cause in the asylums of Switzerland is 26 per cent.; in Austria, Hungary, and Italy, 20 per cent.; in Spain and Belgium, about 12 per cent.; and in the United Kingdom, 30 per cent. of the inmates of institutions, and 7000 persons have lost their sight from the same disease. These facts are recorded in the Report of the Royal Commission of the Blind, and are in accord with the abstract published in the *Lancet* of last year. The subject cannot be presented more forcibly than has been done by Rivière of Bordeaux, who says that purulent ophthalmia alone is responsible for nearly one-third of the cases of blindness, and has placed in the care of Europe well-nigh 100,000 victims. In our own country, according to the statistics of Howe, in spite of the improved methods of modern medicine, blindness is on the increase. Perhaps one of the most potent factors of this increase is ignorance on the part of the emigrant population, and the suggestion of the Royal Commission that at the time of the registration of the birth of a child a paper containing an account of the dangers of the disease and the best simple means of treatment be handed to the parents, deserves consideration. The plain duty of physicians demands the practice of that means of prevention which careful experience has taught to be effective.

To Crédé belongs the credit of having secured, by the use of nitrate of silver, a rational method of preventative treatment, although before his time Bischoff employed in his service at Basle vaginal injections, and bathed the eyes of the newborn with lotions of salicylic acid; and in 1876 Schies used instillations of carbolic acid. In 1881 Olshausen proposed to substitute for nitrate of silver a carbolic acid solution of the strength of 1 per cent. A year later de Wecker recommended bathing the eyes of the newly born with a lotion of boric acid, 4 to 100, or carbolic acid, 2 to 100. In the Obstetrical Clinic in Berlin, in 1883, nitrate of silver was replaced by instillations of corrosive sublimate, 1 to 1000, and the same practice was employed in the Maternity Hospital of Breslau. At the Congress of German Doctors held at Munich in 1886, Kaltenbach advocated vaginal douches of corrosive sublimate, and washing the eyes with distilled water; with this procedure he was able to conduct 200 labors without a single case of ophthalmia. Cohn and Hegar-Kohrn, by the employment of simple measures and scrupulous cleanliness, obtained good results in the Maternity Hospital in Dresden, namely, among 1000 children 7 cases of purulent ophthalmia, and 15 of slight conjunctivitis (*Archiv für Gynäkologie*, 1888). Puech (*Archiv de Tocologie des Maladies des Femmes et des Enfants Nouveau-nés*, Février, 1890) records the methods to which he has had recourse in the Obstetrical Clinic of Montpellier His paper is of considerable interest because it affords an opportunity of comparing the value of the method of Crédé with that described and advocated by Hegar-Kohrn. Both of these methods were employed in the service to which allusion has just been made, and comparisons instituted. The method of Crédé, as is well known, consists in the instillation of two drops of a 2 per cent. solution of nitrate of silver in the eyes of the newly born child, which, as soon as it is expelled from the maternal passages, and before the cord is cut, is placed upon its back in the bed, the eyelids parted, and the drug introduced. This, in some

instances, has been repeated on the second day, in the meantime small compresses soaked in a solution of salicylic acid having been laid upon the closed lids.

The method of Hegar-Kohrn is conducted in the following manner: A convenient vessel contains small pledgets of antiseptic, absorbent cotton, moistened with Van Swieten's solution (corrosive sublimate 1 part, alcohol 100 parts, water 900 parts). This receptacle is placed within reach of the accoucheur, who supports the perineum with one hand, the other remaining free to take up the moistened pledgets. As soon as the head of the child is born, the closed eyelids are carefully dried with two or three portions of the prepared cotton. When the child is entirely expelled it is placed upon its back, and before the cord is tied the eyelids and all of the tissue surrounding them, especially the angles of the eye, the root of the nose, and the eyebrows, are carefully cleansed with the same solution until an absolutely aseptic surface is obtained. During this whole procedure care is taken that the child does not put its hand to its eyes before they have been cleansed in the bath which is prepared for the infant. This manœuvre, as Puech declares, requires a longer time for description than it does for its performance, and is always ended before the time has arrived to cut the cord.

Three series of observations constitute the basis for his communication. In the first, among fifty children treated alternately by the method of Crédé and by that of Hegar-Kohrn, two cases of ophthalmia appeared. The cause of the two cases, however, is explained away and the blame should not be attached to any imperfection in the preventive treatment. In the second, among twenty-six children treated by the method of Hegar-Kohrn, not a single case of ophthalmia arose; and in the third, nine children subjected to the method of Crédé escaped ophthalmia.

The efficacy of the method of Crédé admits of no controversy, and even those, like Kaltenbach, who have suggested other forms of prevention, admit without reserve that nitrate of silver properly applied meets with invariable success. Not infrequently it has been urged against the employment of this drug that its action is irritating, and that occasionally it is followed by a sharp conjunctivitis requiring the use of cold compresses, and one or two cases of really serious inflammation are on record, notably the remarkable instance recorded by Pomeroy some years ago, in which a well-nigh fatal hæmorrhage followed the instillation of a few drops of a 2 per cent. solution of nitrate of silver. The occasional accidents following the use of Crédé's method are so insignificant as compared with its favorable action, by which its author was able to reduce a percentage of 10.07 cases of ophthalmia to 0.1, a result which has been equalled and even exceeded by a number of careful obstetricians including the names of Koenigstein, Braun, Leopold, Garrigues, and Rivière, that they scarcely merit objection. At the same time if another method equally efficacious is presented for consideration, and one unobjectionable as far as any irritating properties of the application are concerned, it is certainly worthy of trial. Hegar-Kohrn has devised a method of this character, and Puech, by comparing it with the Crédé application, has come to the conclusion of its undoubted efficacy.

Purulent ophthalmia is caused by a contagium contained in the utero-vaginal secretions of the mother, and the very frequency of these secretions, whose absence, indeed, in the pregnant woman is the exception, demands on the part of the doctor invariable recourse to a preventive treatment of ophthalmia neonatorum. He knows that with Crédé's method he is safe, provided its application is properly and conscientiously performed. If desirous of avoiding any chance of irritation from the nitrate of silver application, or of adopting some other method, like that of Hegar-Kohrn, the final conclusion of Puech's paper, based, as it is, on a conscientious study of the literature, as well as practical experience in the maternity wards, offers a safe guide: "We believe the method of Crédé is still the chosen method, but the incontestable value of that of Hegar-Kohrn seems to us to be proven. We do not doubt that it will render real service. While the method of Crédé is applicable to maternity hospitals, or in the course of grave epidemics of ophthalmia, the method of Hegar-Kohrn will be that to which we can turn in private practice, where the chances of contagion are less imminent."

THE LOUISVILLE CATASTROPHE.

IN another column under the head of Special Telegraphic Correspondence, we publish a despatch from our correspondent in Louisville, detailing the medical aspects of the city after the storm. As will be seen from this account, the health of Louisville is at present fairly good, but it is worthy of note that the danger from epidemic and acute ill-

nesses exists rather in the future than in the present. This was the case at Johnstown, where, for many days after the flood, the health of the survivors and workmen was unusually good, the real evidences of illness only asserting themselves after order was somewhat restored. The most serious cause for alarm at Louisville is the destruction of the water works and the consequent water famine.

REVIEWS.

The Student's Surgery. A Multum in Parvo. By Frederick James Gant, F.R.C.S. 12mo., pp. 817. Philadelphia: Lea Brothers & Co., 1890.

In these days of compends and condensed medical literature it is refreshing to open a volume written for students, yet readable, and not divested of everything but the bald facts required to pass a successful examination.

The *Student's Surgery*, though condensed from Mr. Gant's well-known and elaborate *Science and Practice of Surgery*, is, excluding the various specialties, a fairly complete and excellent text-book on surgical practice. It is essentially practical; pathology and theories being briefly reviewed, diagnosis and treatment being fully discussed.

The author has omitted, and wisely we think, all consideration of the surgery of the eye, ear, teeth, skin, and female genital organs, and also orthopædic surgery; subjects which could only have been introduced in outline, and with the sacrifice of more important matter. It is doubtful if, at the present day, these departments should have a place in any text-book on surgery.

The faults of the book are chiefly those of omission. For instance, in the pathology of erysipelas, carbuncle, and tetanus, no mention is made of microörganisms as possible causative agents: a serious oversight in the present state of our knowledge.

The absence of an index is also to be regretted, though the table of contents is so thorough that an index is not an absolute necessity.

The illustrations, though not numerous, are good, and the appearance of the book is all that could be desired.

Massage and the Original Swedish Movements. By Kurre W. Ostrom. Illustrated, 12mo., pp. 97. Philadelphia: P. Blakiston, Son & Co., 1890.

It cannot be denied that massage occupies an important position in the therapeutics of many diseases; the Swedish movements, though less frequently used by physicians, are also a valuable method of treatment. Either, if ignorantly and improperly used, is capable of doing much harm to the patient, and it is the object of the book before us to describe the proper methods of performing the manipulations, and to indicate the cases to which they should be applied. The first object at least is well attained. The desciptions are clear, and so well supplemented by the illustrations, that any one with this book and a subject on which to practise, could undoubtedly become proficient in the art of massage. An excellent feature is the simple classification of the manipulations adopted by the author, which makes the whole subject much easier to grasp.

Turning to the section which deals with the diseases to which massage is applicable, we find traces of the specialist's enthusiasm. We doubt if "movements will yield good results in the majority of cases of chorea," nor do we believe that "most neuralgias yield readily to massage," though we know that, in both these diseases, massage is a useful adjunct to other measures. We naturally wonder if the author means *acute* rheumatism when he says that "active movements as well as hacking and beating of the affected parts are of great benefit in cases of rheumatism. In severe attacks the treatment should be applied twice daily (!). Ten to thirty treatments are generally sufficient to effect a cure." However, the work is intended chiefly to teach methods, and for this reason should be in the hands of all nurses and physicians who wish to use massage intelligently and with benefit to their patients.

Spinal Concussion. By S. V. Clevenger, M.D. With thirty wood engravings. Philadelphia and London: F. A. Davis, 1889.

Dr. Clevenger has placed before the profession a book of some three hundred odd pages followed by a glossary, containing words which are frequently used in the consideration of nervous diseases, and by plates which illustrate the motor points of the extremities, both upper and lower, as well as of the head and neck. While the book is one which consists in an accumulation of the writings of different individuals under one heading, the reader cannot fail to notice that the author has, to a certain extent, put his own stamp upon the work, and the handsome plates which are scattered between the pages show in a very useful way the points at which the different nerves leave the spinal column. Colored plates illustrate the anatomy of the spinal cord and of the tracts which it contains. The most interesting portion of the work consists in the chapter on differential diagnosis and that on "Recent Discussions of Spinal Concussion." That upon "The Treatment of Concussions" has of necessity to be quite short. To the medico-legal investigator the illustrative cases of spinal disease, which are made up of instances derived from personal observation and the observation of others, will be of value in that in this way the general symptoms shown by groups of cases are readily noted and understood. Altogether the book may be considered as one which in a comparatively small space has brought together a large amount of literature of a reliable character, and it is to be recommended to those who are apt to be called upon the witness stand to testify in regard to the results of injury in railroad and other accidents.

The publisher's work is very well done and the plates are excellent.

The Neuroses of the Genito-urinary System in the Male, with Sterility and Impotence. By Dr. R. Ultzmann. Translated by G. W. Allen, M.D. Philadelphia and London: F. A. Davis, 1889.

This book is to be highly recommended, owing to its clearness and brevity. It is illustrated wherever illustrations are necessary, and is divided into two portions, as indicated in its title, of which the portion on "Sterility

and Impotence" contains much matter which is of interest. Altogether, we do not know of any book of the same size which contains so much useful information in such a short space.

A TREATISE ON FRACTURES. By ARMAND DESPRIS. TRANSLATED BY E. P. HURD, M.D. Detroit, Mich.: George S. Davis, 1890.

THIS is one of the recent numbers of Mr. Davis's series, and embodies in a very small space the opinions and methods of its French author.

We confess to the belief that we have treatises upon fractures in plenty by Americans; but the publisher's wisdom is greater than that of the medical editor, and Mr. Davis evidently thinks such books profitable, so we have only to thank him for his business tact and foresight.

BY TELEGRAPH.

LOUISVILLE.

(*Special to* THE MEDICAL NEWS.)

To the Editor of THE MEDICAL NEWS,

SIR: The total number of persons killed by the tornado is ninety-six, wounded about two hundred. The injuries resulting fatally are, in the order of frequency, fractures of the skull, thoracic injuries from pressure, asphyxiation from gases, burns, and shock. But few of the wounded will die. As a comparatively small number of the poorer classes were among the injured the hospitals are not crowded, the City Hospital having but five cases, Sts. Mary and Elizabeth and Norton Infirmary having about fifty.

The water-works are so seriously damaged that repair is impossible for many days, and a water famine with its serious results is certain.

The hygienic condition of the city is now more influenced by the snow and rain than by the direct effects of the cyclone.

There are rather more zymotic diseases and pneumonia present than usual, but otherwise there is little of medical interest. No outside help is required.

CORRESPONDENCE.

MUNICH.

(*From our Special Correspondent.*)

To the Editor of THE MEDICAL NEWS,

SIR: The treatment of massage, first established by Thure Brandt, and afterward advocated successively by Profanter, Schultze, Resch, and v. Preuschen, is claiming here such a conspicuous place in the therapy of pelvic and uterine disorders that it may not be amiss to describe briefly the method and mention a few of the features which recommend it.

For example, in retro-positions, without adhesions, the so-called "lifting movement" is employed. The patient lies upon a couch with her knees drawn up and her feet together. The operator stands over her with one knee on the couch and places a hand, on either side, flat against the abdomen, the palms directed slightly toward each other. He presses his hands with gradually increasing force, first upward and together, then downward until he grasps the uterus and ligaments on either side. He slowly draws the uterus upward and forward, at the same time making an oscillating movement with his hands from side to side, gradually allowing the ligaments to slip from his grasp as they become stretched. This movement is repeated three times at one sitting. In addition, the patient is made to undergo a movement by means of which the muscles of the pelvic floor are strengthened. She lies in a half-recumbent position, with her thighs and legs extended and her knees separated; then, while she elevates her pelvis, she brings her knees slowly together. In retroflexions the "lifting movement" is modified as follows: The round ligaments and the peritoneum extending from the bladder to the uterus, forming the vesico-uterine ligament and containing abundant muscular fibres, are stretched by the operator forcing the fingers of the right hand inward over the symphysis, directly against the internal os, while, with the first and second fingers of the left hand introduced into the posterior fornix, he makes counter-pressure.

Brandt offers the following propositions as grounds for his treatment: 1st. The ligaments in positional disorders are relaxed and their muscular fibres are devoid of function. 2d. The support furnished by the floor of the pelvis is in proportion to the tone of the muscles. 3d. By stretching, the muscular fibres of the ligaments are excited to contraction and the uterus held in a normal degree of fixation. 4th. By massage, the pelvic circulation is augmented and function thereby restored.

Such a plan of treatment is difficult to pursue in an institution like the Frauenklinik, where so many cases are handled and where operative treatment for obvious reasons remains the most practicable. It has, however, been used with success, and Professor Winckel includes it in the discussion of the therapy of every case in which it is available.

Influenza attacking pregnant women at the Frauenklinik, presented, as a rule, no unfavorable complications in the course of pregnancy and labor. One case occurred, however, which is of interest on account of the unique combination of symptoms. The patient, suffering from influenza, was first presented in the klinik on January 7th, in the second stage of labor. On the 11th she was again brought before the class, when a history of gonorrhœa, for which she had been treated in the general hospital, was elicited, and the relation of condylomata acuminata, which appeared in profusion over the anterior vaginal wall, to gonorrhœa, was discussed. Two days later a papulo-erythematous eruption appeared over the abdomen and inside of the thighs, without an additional rise in temperature. It was diagnosed urticaria. The cough from which she had suffered now increased, and the temperature rose. Catarrhal pneumonia was diagnosed. Three days before her death, which occurred twelve days after labor, she complained of pain in the abdomen after coughing, but there was so little tympany, and the abdomen was so relaxed and free from tenderness, that the diagnosis of peritonitis was disregarded.

The section, performed nine hours after death by Professor Bollinger, revealed acute, diffuse peritonitis, pleuritis, catarrhal pneumonia with bronchiectasis and multiple abscesses. The uterus was soft and as large as the fist; the lymph spaces in the muscular tissue, here

and there, were dilated and filled with pus. The ligaments, tubes, and ovaries were covered with plaques of fibrin, their neighborhood evidently being the most active seat of inflammation. The tubes were filled with pus, in which, later, gonococci were found; the fimbriated extremities were permeable. During the autopsy the question arose whether the case was one of puerperal septicæmia with peritonitis, pleuritis by direct extension through the diaphragm and pyæmic abscesses in the lungs, or whether the peritonitis and catarrhal pneumonia were processes due to separate causes. The former view was held by Professor Bollinger; but, later, Winckel, in reviewing the case, established the diagnosis of peritonitis due to gonorrhœal salpingitis; the pneumonia being a continuation of the bronchitis, with bronchiectasis in the course of influenza. The appearance of the Fallopian tubes and their surroundings marked them as the starting-point of the pelvic peritonitis, which evidently had found its origin in the escape of pus from within the tubes by pressure during coughing—an *überfluss Peritonitis*.

An extremely interesting point is the occurrence of the eruption. After a thorough examination no evidences or history of syphilis were discovered, and the eruption was classed among the rarer symptoms of influenza; the report of similar cases from St. Petersburg, and elsewhere, gave a reasonable support to this hypothesis.

If space permitted, I should like to add a fuller description of a case of extra-uterine pregnancy in which Professor Winckel extracted piecemeal, through the dilated urethra, a fœtal skeleton which measured in length twenty-one centimetres. The fœtal sac had perforated into the bladder through the posterior wall near the vertex. The right femur projected into the bladder and was covered with incrustations. The perforation had been gradual and was not accompanied with any discharge of pus in the urine. In such cases Winckel tries, within the first three months, to interrupt the pregnancy by the injection into the sac through the abdominal wall, at intervals of from six to eight days, of 0.03 gm. of sulphate of morphine, two or three injections usually sufficing.

PARIS.

A New Disease of the Heart. Erysipelatous Pneumonia. Colotomy. Treatment of Club-foot.

To the Editor of THE MEDICAL NEWS,

SIR: At one of the last meetings of the Académie de Médecine, Professor Renaut, of Lyon, made an interesting communication on a new organic disease of the heart denominated chronic essential segmentary myocarditis. According to the author this affection presents a train of symptoms which easily differentiate it, at the bedside, from other cardiac diseases. From an anatomical point of view the disease is characterized by what might be called a segmentary dissociation of the muscular tissue of the heart.

This lesion consists in the softening of the cement substance uniting the cardiac muscular cells end to end. When this cement disappears, it is easy to understand that the fibres of the myocardium will no longer contract synchronously, or with sufficient force, and that cardiac asthenia must result.

This softening of the uniting cement is the only lesion found at the autopsy. The myocardium is in a flaccid condition, its color is gray, and the ventricle can be easily torn.

Histological examination reveals everywhere numerous patches of segmentary dissociation, either isolated or united together. Even where the dissociation is very limited, it is constantly and profusely present in the papillary muscle of the mitral valve.

The disease is most frequently observed in old people, and the first symptom is an irregularity of the heart's action not preceded by hypertrophy. This irregularity takes place without modifying the general characters of the normal pulse-tracing. In segmentary myocarditis, whatever may be the degree of the irregularity, the pulse never takes the form of the asystolic pulse of valvular diseases, nor becomes small, unequal, intermittent, or irregular.

Another important sign is the disappearance of the localized præcordial beat. The beat is diffused or totally absent, or impossible to localize.

The third physical sign is an area of flatness limited by four straight borders. The external border ascends from the fifth interspace vertically to the third interspace, always inside of the mammary line; the internal border goes from the sixth or seventh chondro-sternal articulation to the third interspace. Two transverse lines, one above, along the third interspace, the other below in the fifth, complete this typical rectangular flatness.

On auscultation, one finds a weakening of the normal sounds, and a greater or less irregularity of the cardiac rhythm. In a certain number of cases these signs exist alone, but sooner or later another sign makes its appearance, viz., the medio-cardiac systolic sound. It is a soft, very light sound, situated half way between the apex of the heart and the aortic valves, its maximum being about the middle of the heart; it is not transmitted down the sternum, nor toward the axilla. Another very important character of this murmur is its instability. It will disappear for very long periods, then return again.

The disease may terminate: 1st, by sudden death from syncope in about one-quarter of the cases; 2d, by asystole, which is the most frequent termination. Patients suffering from this disease die easily; a common cold or a traumatism may bring on, in an aged person, rapid death by asystole. The most important pathogenic condition for the development of this variety of myocarditis is senility; almost every old person having the disease to a greater or less degree. In persons of middle age, as possible determining causes, we find alcoholism, the eruptive fevers, and especially typhoid.

As regards treatment, increasing doses of the infusion of digitalis are given when arhythmia exists, or digitaline and champagne, and the patient is protected against bronchitis. In old people, if bronchitis is persistent, as this is probably due to fragmentary myocarditis, the heart tonics and regulators of the arterial circulation are to be prescribed. To digitalis the author adds ergot as a tonic for the vessels.

At one of the last meetings of the Académie de Médecine, Dr. Mosny presented a clear case of erysipelatous pneumonia, which occurred in a girl, who, while nursing a patient with facial erysipelas, was taken with pneumonia and died in two days. At the autopsy, a very limited

area of lung tissue presented the lesions of broncho-pneumonia, which was demonstrated by histological examination. On the other hand, bacteriological cultures showed characteristic colonies of the streptococcus of erysipelas without the presence of any other micro-organism.

Professor Laboullene, at the next meeting of the Académie, mentioned the fact of having observed erysipelas followed by a special form of pneumonia. Six persons were successively taken with pneumonia; this disease being at first localized, then extending to the whole lung of one side, finally extending to the opposite lung, and invariably ending in death. One of the patients, who had a well-established pneumonia, developed a facial erysipelas. There is no question that the contagious agent was the microörganism of erysipelas in every one of these cases.

At the Société de Chirurgie Dr. Kirmisson defended Dr. Phelps's (of New York) treatment of club-foot by section of the retracted muscles. Last year, Dr. Kirmisson performed this operation seven times in four children. The first case was a child four years old, who, by Phelps's tenotomy, has now a useful, though, perhaps, not a very well-formed foot. The second case had already been operated upon, the tendo-Achillis had been cut, and the patient had worn many different apparatuses; the result by the above method was perfect. The other two had been previously operated upon—excision of the astragalus had been performed in both cases with bad result; Phelps's method gave these patients good use of their feet. Volkmann has also used this method in twenty-one cases, with the best results.

On the other hand, Dr. Lucas Championnière, who is the antiseptic surgeon, *par excellence*, of Paris, advocates the removal of as much bony tissue as necessary to correct the deformity; he himself claims to have excised in one case the astragalus, scaphoid, part of the cuneiform, the cuboid, and calcaneum. Dr. Championnière adds that a large excision assists very much the union of the soft parts, and this rapid union plays an important *rôle* in the final success of the operation. Treated in such a manner, a patient is able to walk at the end of six weeks, at first wearing a boot with lateral splints, to prevent a sprain or lateral movements.

Professor Verneuil spoke before the Société de Chirurgie on iliac colotomy, and rapidly passed in review the different methods of operations recommended.

Dr. Verneuil usually operates as follows: 1st. The intestine is drawn out, so as to expose through the abdominal wound about two-thirds of the intestinal circumference. 2d. This exposed portion is temporarily transfixed. 3d. From ten to twelve sutures are inserted in the form of an oval crown. 4th. Excision with the thermo-cautery, of all the portions of intestine comprised within the sutures. Verneuil has practised this method more than twenty times, and has had no bad results; the important point being to excise a large portion of intestine—about two-thirds of the circumference.

Maydl's process is a different one: the sigmoid flexure of the colon is drawn out of the abdominal wound until its mesocolon becomes visible; the mesocolon is then perforated near its intestinal insertion with a blunt instrument; in this opening is introduced a rigid rod, such as a piece of a catheter surrounded by iodoform gauze; this rod is then laid flat upon the abdominal wall. From the fourth to the fifth day a button-hole incision, through about one-third of the circumference of the intestine, is made. On the fourteenth day all the protruding part is excised.

Professor Guyon presented at the last meeting of the Académie des Sciences a very interesting work on the pathological anatomy and physiology of retention of urine, as a result of his clinical observations. Dr. Guyon finds that whatever may be the causes, forms, or duration of retention of urine, fever will never be present if the retention is not of septic origin, or if the patient has not been subjected to infection. Retention of urine, and especially incomplete retention, is always accompanied by polyuria. Moreover, retention of urine always brings on congestion of the urinary organs, which explains why, in prolonged retention, the urine is brown or red. Even a true hæmaturia may occur after a complete and rapid evacuation of the bladder. Experimentally one finds, in the bladder and kidneys, small interstitial hæmorrhages; or even, in prolonged retention, more apparent lesions which are characterized by a flattening and granular state of the renal epithelium.

If the retention lasts a long time, the secretion becomes very much reduced; the bladder loses its contractile power, next the ureters; and then complete stasis of the urine is established. If the retention is only of twenty-four hours' duration, the urethral contraction can be regained by simply evacuating part of the contents of the bladder, or by electrization. If, however, retention has been of long duration, nothing will establish the contractile power—for this phenomenon is under the immediate influence of the intra-vesical tension.

As regards polyuria and congestion, the anatomical lesion and physiological disturbance are in direct relation to the intensity and degree of the tension. Every fact corroborates this, whether in acute states brought on by experimentation, or in chronic states observed in the clinic.

As regards the final results or consequences, they will depend entirely upon the early or late intervention of the surgeon, and whether the bladder alone is involved, or whether all the renal apparatus is out of order.

At the last meeting of the Société Médicale des Hôpitaux, Professor Hayem made an interesting communication on the contractile power of red blood-corpuscles and pseudo-parasites of the blood in extreme anæmia. If normal blood is examined under the microscope, the red blood-corpuscles are found to be immovable; if, however, the blood of an anæmic in whom the number of blood corpuscles is reduced below one million be examined, one finds movement in one part or in the whole mass of the corpuscle. Four different types are described by the author:

In the first, the red globules contract in a mass, and the globule is seen to fold itself up, even appears to undergo segmentation; this is due to an amœboid contraction.

In the second type, one finds red corpuscles of medium or small size presenting prolongations in the form of a glove or flagellæ. These corpuscles are sometimes immovable; at other times their prolongations are seen to move about.

In the third type, one finds corpuscles oscillating around an axis passing through the long diameter.

In a fourth, we have the very small elements of the

blood, which easily displace themselves, and resemble true parasites; they also oscillate around their vertical axes, and are capable of folding movements.

These four types of blood elements can exist in one single drop of blood, excepting the first, which the author has only found in one patient.

THE MILWAUKEE CLINICAL SOCIETY.

To the Editor of The Medical News,

Sir: Your journal of March 1st published a communication from Milwaukee, giving its present standing in the medical world. Mention was made of some medical societies, and amongst them "The Clinical Club." This club was founded January 1, 1886, and up to the present year was known as "The Bartlett Clinical Club"—named after one of our pioneers in medicine, and a man well known as an active worker in the American Medical Association. Considering that this name was not broad enough to demonstrate the club's work, it has been changed to "The Milwaukee Clinical Society."

The organization and principles upon which it is founded being rather different from medical societies in general, I have thought it might be of interest to the profession to learn of its existence and the groundwork upon which it rests. It is a chartered corporation, without stock, and governed in a measure by a board of directors. The directors not only look after the finances, but all business, usually known as "miscellaneous," is first discussed and voted upon by them, before being presented to the Society for ratification, thus saving the Society's time and giving more chance for clinical work. Members are elected by ballot, and the election must be unanimous. The candidate must be balloted for by every member of the Society, either in person or by sealed ballot to the secretary.

The motto of the Society is *Fraternitas et Scientia*, and in order that the "brotherhood" may be the firmer, the number of members is at present limited to twenty-five, and members are not taken in any faster than they can be thoroughly assimilated. The meetings are monthly. A dinner is served in the rooms at 6 P. M. This social feature of the Society renders that brotherhood so much the firmer. At 8 P. M. the scientific work commences. Two papers more particularly relating to clinical work are read and discussed; then follow clinical reports by members in rotation, and no member is allowed under any condition whatsoever to say during this part of the session, "Nothing to offer." He *must* say something, be it ever so trivial; and it has often been found that some of the simplest and most common clinical work elicits the most discussion, and is of immense advantage in practice. The chair is occupied by a different member of the Society, in alphabetical rotation, at each meeting; thus each member feels that he has a governing voice in the work. The time for adjournment by the constitution is 10 P. M., no matter what may be in process of discussion.

It is an unwritten law that every member must be present at the meetings, and an absence from three consecutive meetings, without good excuse, is sufficient cause for expulsion.

Last year, with nineteen resident members, the average attendance was fifteen. May and December found every member present. Each member has the privilege of inviting a guest to its meetings, thus serving as a convenient means for new-comers to become acquainted with members of the profession, and also giving a good opportunity of entertaining professional visitors from abroad.

The Society owns a library of 1500 volumes, and subscribes for twenty-two German and English journals, and has also commenced a pathological museum.

These methods have been found to be most satisfactory, and a society with more harmony of feeling, personal and professional, cannot be found in the country. It will be seen that the motto, *Fraternitas et Scientia*, is freely carried out in its organization.

BACTERIOLOGICAL EXAMINATIONS AT AUTOPSIES. BACTERIOLOGICAL EXAMINATION OF DRINKING-WATER.

To the Editor of The Medical News,

Sir: I am only a general practitioner, residing in a small place in what the people of Philadelphia would denominate "the far West." I have not the privilege of weekly attendance at an academy of medicine or other learned body of medical men. For these reasons I must depend almost exclusively upon reading, in my endeavor to keep within sight of the advancing hosts of medical science. In my reading I meet with a few things which amuse me very much, and with many things which afford me a great deal of instruction. I desire, with your kind permission, to make an occasional comment on what I read.

Among the things which have amused me are two with the titles as given above. The first is a leading editorial in what claims to be, and really should be, one of the best American medical journals. The learned editor attempts to give a synopsis of the instructions of Babes for making bacteriological examinations at autopsies. I will make a quotation from this editorial, italicizing the amusing points so that all may recognize them.

"The first section of the skin, from the chin to the pubes, should include the subcutaneous cellular tissue and the muscles, and is made with one sterilized knife. Another sterilized knife is then used to open the peritoneal and thoracic cavities. *The liquids contained in the peritoneal, pleural, and pericardial cavities are then sterilized by plunging a platinum wire into them, and they are then collected in culture-tubes or on plates previously prepared.* When these liquids are used for inoculating animals, a sterilized syringe should be used. For the bacteriological examination of organs, the surface of the organ is burned with a hot glass-rod over an extent of about 2 cm. The tissue underlying the burn is then torn out. *'From this fragment is taken, by means of a red-hot platinum wire, a piece to be used for inoculation. The liquids contained in the intestines, bronchi, bladder, ureter, etc., are collected on gelatin plates.'*

Did anyone ever write anything more mirth-provoking than the above? We may stop laughing at the homoeo-

path who talks about the great dynamical potency of his high dilutions. Our editor sterilizes the "liquids contained in the cavities of the body by *plunging* a platinum wire into them." What a deadly instrument a bit of platinum wire must be! But the wonder does not stop here; these very liquids which have been so expeditiously sterilized are used for the preparation of cultures. By what magic power the poor germs in these liquids are endowed with new life when transferred to the tubes and plates we are not told. In the examination of organs, the bit which is used for inoculation purposes is taken up on a red-hot platinum wire. Here the platinum wire, while red-hot, seems to have lost all its powerful germicidal properties. The able editor has not informed us as to the size of the gelatin plates on which he collects the liquids contained in the intestines, bronchi, bladder, ureter, etc., but as he is a Chicago man we could not expect him to be satisfied with drops of these fluids. I wonder if Babes has seen this learned exposition of his instructions? If so, he has probably a very high opinion of the learning of the profession in America.

The second thing which has afforded me much amusement comes from Germany in the shape of a book written by two distinguished professors. Of course, it is the height of absurdity for a village doctor in America to criticise anything from a German professor, but there is no law against being amused, even when the cause is imported at 50 per cent. duty. I have paid the German publisher, and I have helped to swell the surplus in the treasury of the United States, and I want to tell my benighted brethren about the funny things for which I have paid. The volume before me is one of more than 700 pages on the subject of the analysis of drinking-water. The first part is devoted to the chemical analysis of drinking-water, from the pen of Professor Tiemann, of Berlin, and is worth having on account of its great merit; the second part discusses the bacteriological examination of water, is written by Professor Gärtner, of Jena, and contains many facts of value, but its chief merit lies in the conclusions which the learned professor has reached, and which I will lay before your readers. They are as follows:

(1) "A water which contains pathogenic germs should not be used."

These are wise words, but the author goes on to tell us that it is well-nigh impossible to detect pathogenic germs in water, and that we cannot expect to be able to succeed much better in the future.

(2) "A water which may possibly contain pathogenic germs should not be used."

The question now arises, how are we to decide whether or not a given water might possibly contain pathogenic germs or not. The author tells us to decide this matter by an inspection of the surroundings of the source of water-supply. Why, then, we may ask, is there any need of the bacteriological examination?

(3) "A large number of germs in the water of a well whose surroundings are unsanitary, and whose construction is improper, should condemn the use of the water."

(4) "However, if the surroundings are sanitary and the construction proper, the water may be used, notwithstanding the fact that it contains a large number of germs."

Comments upon these conclusions are unnecessary. We have been promised so much from the bacteriological examination of water, and now we are told in sum and substance that if the water contains human excretions and dead animals it is not altogether safe to drink it, but we cannot find out whether these undesirable additions to nature's beverage are present or not, save when we are fortunate enough to see the sewer or other sources of contamination pouring its contents into the water.

NEWS ITEMS.

Lectureship on Orthopædic Surgery in the Woman's Medical College.—H. Augustus Wilson, M.D., Professor of General and Orthopædic Surgery in the Philadelphia Polyclinic and College for Graduates in Medicine, has been elected Lecturer on Orthopædic Surgery by the corporators of the Woman's Medical College, and commenced his course on Thursday, March 20th. The corporators established this new course at the request of the Faculty, who also nominated Dr. Wilson.

A Vacancy.—At present there is a vacancy in the Chair of Pathology and Practice of Medicine in the Medical College of the State of South Carolina, and the Trustees and Faculty are anxious that all persons desiring such a position should apply to them. As is probably known to most of the readers of THE MEDICAL NEWS, this college has now adopted a three-year course, to take effect with the matriculates of 1890.

New York Eye and Ear Infirmary.—The corner-stone of the new building of the New York Eye and Ear Infirmary was laid, with appropriate ceremonies, by the President, Benjamin H. Field, Esq., on March 15th. Addresses were delivered by Mr. J. Harsen Rhoads, the Hon. George William Curtis, and the President. The Hon. Chauncey M. Depew presided over the exercises.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MARCH 25 TO MARCH 31, 1890.

By direction of the Secretary of War, HENRY P. BIRMINGHAM, *Captain and Assistant Surgeon*, is relieved from the station at Fort Klamath, Oregon, and from temporary duty at Vancouver Barracks, Washington, and will report in person to the commanding officer Boise Barracks, Idaho Territory, for duty at that post. —Par. 6, *S. O. 72, A. G. O., Washington, D. C.*, March 27, 1890.

TAYLOR, M. E., *Captain and Assistant Surgeon.*—Is granted leave of absence for one month, on surgeon's certificate of disability, with permission to apply for an extension of one month. —Par. 3, *S. O. 26, Department of the Columbia*, March 18, 1890.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FROM MARCH 3 TO MARCH 24, 1890.

LONG, W. H., *Surgeon.*—Leave of absence extended five days, March 11, 1890.

DEVAN, S. C., *Passed Assistant Surgeon.*—To proceed to Erie, Pa., as Inspector, March 12, 1890.

HEATH, F. C., *Assistant Surgeon.*—To proceed to Cleveland, Ohio, for temporary duty, March 18, 1890.

STIMPSON, W. G., *Assistant Surgeon.*—Commissioned Assistant Surgeon March 11, 1890. Assigned to temporary duty at New York, March 13, 1890.

ORIGINAL LECTURES.

REMOVAL OF THE HAND-CENTRE FROM THE CORTEX CEREBRI IN A CASE OF FOCAL EPILEPSY.

A Clinical Lecture,
delivered at the Jefferson Medical College Hospital.

BY W. W. KEEN, M.D.,

PROFESSOR OF SURGERY IN THE JEFFERSON MEDICAL COLLEGE.

GENTLEMEN: Before beginning the case of to-day, I want to pass around some specimens which will interest you.

The first is a scar, which was removed from the scalp in September, 1888, in a case of epilepsy, the result of a fall, without fracture of the skull. A year later, September, 1889, no benefit having accrued from the removal of the scar, the boy was trephined and a considerable mass of damaged brain tissue removed. Since that time there has been no recurrence of his fits.

The second specimen is a very large tumor which I removed from the brain two years ago. A large part of the dura, as you will observe, is adherent. The patient has suffered with a few epileptic attacks since the operation, but his attacks have been very much less frequent and less severe than before. His eyesight, which was almost gone, has slightly improved, though his general condition is but little better.

The third specimen is another one of damaged brain tissue with a portion of the dura, in which you will plainly see a scar. The injury to the dura and brain resulted from a depressed simple fracture and was followed by epilepsy. The patient has had no attacks since the operation, now nearly two years ago. He was out on the street on the eighth day after the operation.

These cases will show you how fearlessly and successfully we can now operate on the brain, and will encourage you as to the probable result in the present case.

Let me now narrate the history of the case upon which I shall operate to-day. The little boy, Willie P., aged six years, comes from Delancy, N. Y. When fourteen months old he fell from a haymow a distance of ten or twelve feet, upon a plank flooring. He was brought into the house unconscious and remained so for some time. He was examined from head to foot, but no evidences of injury could be found. It is not positively known that he struck upon his head at all, although it was thought so from the unconsciousness which followed the fall. His disposition soon after this changed materially for the worse. He became irritable, obstinate, and ill-tempered, and has remained so up to the present time, and to such a degree that when he was referred to Dr. Hansell for examination of the eye-ground, a few days ago, he bit and scratched so violently that, in order to have a satisfactory examination, etherization was necessary. At two and a half years of age he had dysentery, and on the second or third day of this sickness, January 6, 1886, his first epileptic fit occurred. He has, therefore, been an epileptic for four years. His attacks usually occur from three to six times *per diem*, with intervals of comparative freedom from them. His father, an intelligent clergyman, estimates that in the four years he has had over 5000 fits. Of these about 80 per cent. began in the right hand, while the other 20 per cent. began in other parts of the body. A year ago, for a time, they began in the face. He has suffered also from a number of attacks of *petit mal*.

When he came here I immediately placed him in the hospital under the charge of a competent nurse, who had been familiarized with such cases in the Philadelphia Hospital. My object in placing him under her care was to obtain exact observations of the character of his fits. I regard this point as of great importance. Never rely too much on the statements of parents or other relatives. Invariably, and very properly, the impulse with them is not to observe but to succor the patient. The nurse, whose sympathies were not specially involved, was strictly enjoined to make the most cold-blooded scientific observations of his attacks, being careful, of course, however, to see that the boy did not injure himself in any serious manner. "Do not touch him," I said to the nurse: "simply look at him; see everything; make a note of it the moment each attack is over, no matter whether they appear precisely alike or not; then give me the result." This result I have now obtained in some twenty attacks.

First, the child fell; his eyes were fixed, the pupils being immobile to light, as was ascertained by the nurse with a match. The eyes usually turned to the left, but the head turned to the right. The right hand began to tremble violently and then became flexed. The whole arm was then raised in front of and across the chest. The convulsive movements then became universal. Sometimes the boy will not fall, but will run to and fro within a very limited area. A rather unusual observation of his father's is, that a large dose of bromide was almost always followed by paralysis of the right hand. When the attacks began the child had a vocabulary of about forty words, but gradually he has lost this vocabulary, word by word, until it has come down to three words and a little jargon. He says "papa" and "mamma" and "no," but never "yes."

Dr. Hansell has tested his eye-ground and found nothing abnormal. His sense of vision he believes to be good, but the patient's age and disposition prevent absolute judgment as to this point. Word-blindness cannot be tested, of course; word-deafness does not exist, for he recognizes a command, and if in a good humor will obey it.

These are the facts in the case. Medically every-

thing has been exhausted. What are the principles by which we may determine whether surgery can come to his aid?

Cases of epilepsy can be divided into the traumatic and non-traumatic varieties; and again, in the traumatic variety the injury may have been either in the motor zone or in the so-called latent zones. This diagram of the brain centres as ascertained by experiment upon animals shows the motor zone with the centres for the head, and, from above downward, those for the leg, the arm, and the face; and in the arm centre, from above downward, the centres for the shoulder, the elbow, the wrist, and the hand. Notice that in this boy the centre for the right hand is, presumably, the focus from which originates the spasm, and near it is the centre for the right face, and yet lower down, but near by, the motor centre for speech. Now, as I stated to you, his face was involved for a time, and his speech has become limited and there is also a certain aphasic character to it.

If there be an old depressed fracture over the motor area corresponding to the muscles first involved in the epileptic attacks, it would be proper to trephine at once and treat the brain as the facts discovered by the trephining would indicate—probably by excision of the centre for such initial spasms.

But suppose, now, as in the first specimen which I showed you, there is a scar over the motor zone but no depression of the skull and no positive evidence of injury to the brain. It would not be wise for you to trephine at once. First, the scar should be excised, as was done in that case. If the attacks return and still begin in the muscles supplied by the cerebral centre lying directly under the scar, then it would be justifiable for you to trephine and to remove the portion of the brain in which the spasm begins. It would be right, I say, in the present state of our knowledge, for trephining is not at the present day a dangerous operation. The mortality from trephining, *per se*, is only about 1.6 per cent.

Note the expression that I have just used, "in the present state of our knowledge." Cerebral surgery has but just begun, and we are making its history at present. While it is true that many cases have not been cured, not a few of them have been improved, and it is impossible for us as yet to say what surgery can do for them. It is only by trying, in the cases which afford a reasonable prospect of benefit, that we can tell. Were the operation dangerous to life, it would not, in my opinion, be justifiable; but, as I have stated, the danger is but slight, and if, as is probable, further experience will show us methods more satisfactory and efficacious than the present, an immense gain will have been made.

Secondly, you may have a case of traumatism situated in one of the latent zones—that is, the area of brain tissue the functions of which have not been as yet ascertained. In these cases the propriety of trephining is still very doubtful unless evidence of injury is very decided, and especially unless there be a distinct depression.

There are certain centres, as that for sight, to which the same reasoning will apply as is applied to the motor zone. If evidence of injury is clear; if there is hemianopsia from injury to one cuneus, for example, it would be proper to trephine; but where the evidence of injury and the symptoms are doubtful it would be wiser at present to wait.

Thirdly, in the clearly non-traumatic cases, as a rule, it is best not to trephine, for we are in great doubt as to what part of the brain is the seat of the lesion. Especially is this the case in those long-standing epileptics in whom the "epileptic habit," as it has well been termed, is so established that the fits will continue in spite of any operation.

One exception may be made, the so-called "focal" epilepsies, in which the spasms begin always, or nearly always, in one part of the body. Removal of the centre supplying these muscles may in time be proved to be the proper course. At present we are gathering the evidence, but it is not yet all in, and until we have a much larger experience than at present it would be unwise to be too dogmatic.

Now, let me apply these principles to the case in hand. It is uncertain whether this is traumatic, and, naturally, you will ask me if I have shaved the patient's head in order to determine whether any scars exist. I have not done so, because his wilfulness is such that he could only have been shaved during anæsthesia, and that will be the first step in the operation. His hair, however, has been cut sufficiently short for me to ascertain almost positively that there is no visible scar either over the centre for the right hand or at any other point. Shaving of the head is, in my opinion, an indispensable prerequisite to a careful diagnosis. Unknown scars I have constantly found, and in the boy from whom the first specimen came the scar that was thought to be the result of the fall was not over the injured portion of the brain, but it lay under another one not far away, and of this scar no history could be obtained.

I have determined in the present case, in spite of the fact that no scar exists, to examine the centre for the right hand on account of the immense preponderance of attacks in which this is the initial part of the body involved. It is not at all improbable that the boy may have been injured over this area by the fall, which, though not producing any scalp lesion, yet may have ruptured or otherwise injured the brain tissue underneath. Whether this is so or not can only be ascertained by an exploratory operation. Having shaved the boy's scalp, the next thing is to map out his brain. Here are two instruments, Horsley's and Wilson's cyrtometers. I shall use Wilson's in this case, as it gives the location of the fissure of Rolando proportionally, instead of in inches, and I prefer it especially for this case because the patient is a child, and to apply the same measures in inches to his head as to that of an adult might lead me into error. The fissure of Rolando extends from near the middle line at a point posterior to the glabella of 55.7 per cent. of the distance between the glabella and inion and runs downward and forward at an angle of 67 degrees. I mark it now with an aniline pencil by means of Wilson's cyrtometer. In an adult the length is three and a quarter inches; I shall assume it to be three inches in this child. Having fixed the fissure of Rolando, I can readily locate the position of the hand-centre by means of this diagram of the cerebral centres, and it is over this centre that I shall trephine. The child's head, after the hair was cut, was very carefully scrubbed yesterday with soap and water, then with ether, then with bichloride solution (1 : 1000), after which a dressing of bichloride of the strength of 1 : 2000 was applied, and, as you saw, was still remaining upon his

head when he was brought into the room. While in other parts of the body a dressing of the strength of 1 : 1000 will do, I have found that to the recently shaven scalp a dressing of 1 : 1000 is irritating and often pustulates; therefore, it is always well to use a dressing no stronger than 1 : 2000. The disinfection was repeated to-day with special care, in consequence of not having been able to shave his head yesterday.

Next, I will mark the line of the fissure of Rolando on the skull itself, by making two little cuts in the scalp at the upper and lower ends of the line of fissure, and then with a small gouge through these cuts I make two little nicks in the bone. You can readily understand that when I have raised the flap, and with it the mark of the aniline pencil over the fissure of Rolando, there would be nothing on the skull itself to guide me. These little nicks, then, will show me the two ends of the fissure of Rolando, and, therefore, where the fissure itself lies.

Next, I make a large horseshoe-shaped incision with the convexity upward and reaching well toward the middle line. Each vessel that spurts on the scalp I seize at once with hæmostatic forceps until the field of operation is almost dry. You need not fear to grasp the entire thickness of the skin, or even of the scalp, in the bite of the forceps. Even though the skin is severely compressed by them for an hour or more it never sloughs.

With this trephine I remove a disk of bone an inch and a half in diameter. The dura being exposed, I carefully lift it by a tenaculum one-eighth of an inch from the margin, and make a little nick in it sufficiently large to admit the point of a blunt pair of scissors. This nick is made at the upper part of the trephine opening. I then divide the dura circularly throughout three-fourths of its circumference, leaving the remaining quarter as a means of sustenance and nourishment. This base of attachment is best left below, because the vessels come from below upward. In cutting the dura you will notice that I have lifted it very carefully with my forceps. I am very careful that the scissors shall not injure any of the large veins beneath. The brain is now exposed, and, to the eye, nothing seems abnormal. Next, I examine it by touch, and herein comes the value of experience. I have now had my finger on the living brain substance fifteen times, and I am able to determine far better than two years ago, at my first operation, what is normal hardness or softness, and what abnormal. In this case I find nothing abnormal. In the exposed brain precisely under the line where I marked the fissure of Rolando you can see a fissure which is evidently the one we are seeking. I shall next locate the hand centre by means of the battery. From the moment that the brain was exposed no antiseptic solution has been applied to it; my reason for this being, that, as Horsley has shown, all antiseptics diminish the susceptibility of the cortex, and we are apt to get no response from the faradic current. Touching the lower part of the convolution, in front of and behind the Rolandic fissure, I get no response, as you see. Touching it a little further up the thumb moves, and a little higher still the wrist. But as I am now so near the edge of the opening in the bone, and may have trouble from these large dilated veins, in order to have more room it is necessary for me to enlarge the opening with a pair of rongeur forceps until I get an area sufficiently large for my manipulations, and space sufficient to cope with what I expect will be rather free hæmorrhage from the veins. Again applying the battery you see the movements of the thumb, and now of the wrist, and, further toward the middle line, of the elbow. Having fixed by this means the position of the hand centre, I now excise it. The hæmorrhage, as you see, is very abundant; much more than any that I have previously seen. It is chiefly from one of the large veins near the superior longitudinal sinus. Hæmostatic forceps hold some of the cerebral vessels well, but these veins are so fragile that they tear with the weight of the forceps. Next, by water as hot as I can comfortably bear in my manipulations, probably about 120°, I try to arrest the hæmorrhage, but the vessel is too large, and I shall, therefore, ask Professor Forbes to place his finger on it while I pass a strand of catgut immediately under it. Tying this with great care, gently, and with exactly equal tension on both ends, you see that the hæmorrhage is arrested. I will now test the cortex surrounding the excised part with the battery to see whether I have removed all the centre for the wrist and hand, and you notice that the test shows that I have done so. Seeing that the hæmorrhage is entirely arrested, I shall now introduce a drainage tube, sew up the dura, and put the bone back with a few strands of horsehair under the scalp and suture the latter. The piece of bone, you will observe, was placed in a sublimate solution (1 : 2000) in a cup, and this cup has been placed in a basin filled with hot water constantly renewed by an assistant whose sole business is the care of the bone, and who sees that the thermometer in the outer basin constantly marks from 100° to 105°. Over the wound, which I have now closed, I place an abundant sublimate dressing and a bandage. The little patient, although suffering somewhat from shock, is not in a precarious condition, but I shall apply some external heat and get him to bed as quickly as possible. The operation is always a long one, and has lasted to-day over an hour and a half.

Note.—Speedy recovery took place, and the child was taken home three weeks later. Up to February, 1890, he was steadily improving. He had had a few attacks of *petit mal*, but no severe convulsions. His vocabulary has gradually increased so that he is using twenty-three words—a gain of twenty—and combines them occasionally into sentences of two or three words. His disposition is greatly improved, so that he is much more docile and plays peaceably with other children. Dr. Coplin, in his report of the microscopic examination, states that there are distinct evidences of alterations of structure, both in the vessels and the brain tissue. This will be more fully reported elsewhere.

EXCESSIVE DYSMENORRHŒA. CHRONIC OVARITIS.

A Clinical Lecture
delivered at the Hospital of the University of Pennsylvania.

By WILLIAM GOODELL, M.D.,
PROFESSOR OF GYNECOLOGY.

Gentlemen: The first case I show you this morning is one of excessive dysmenorrhœa. The woman is unmarried, and twenty-four years old. Her puberty began

about the age of fourteen with painful menstruation, and it has been going on from bad to worse until now her sufferings have become so great that her life seems a burden to her. Cases like this are not confined to the experience of the specialist. Each one of you who engages in general practice will meet with them. Therefore you should know how to treat them.

I have not yet examined her, but let me tell you what I expect to find. I am nearly certain that there will be found an anteflexion of the uterus, with a stenosis of the cervical canal. This anteflexion of the organ is the natural condition of the virgin uterus, but its exaggeration makes the flexion pathological. The cervical canal being bent, does not allow the fluid in the uterus to come away as rapidly as it exudes from the mucous membrane, so that it accumulates both in the womb itself and in a portion of the cervical canal above the flexure, producing greater and greater pain, until by dilating the parts it straightens the obstructive bend, and thus gains an avenue of escape.

For this affection the remedies that I use are either medicinal or mechanical. Among the former I put antipyrine foremost. This drug is of especial value, because in these cases much of the pain is not traumatic, but sympathetic. My plan is to give ten grains at once and then five grains every hour or half hour until twenty to thirty grains have been taken. If this affords relief, I know that I am on the right track, and continue this method of treatment *pro re natâ*. But if this plan fails to give relief, I adopt some other method of treatment. Instead of giving this remedy by the mouth, it is often best to administer it by enemata, in twenty-grain doses, until sixty or ninety grains have been given. This will as fully test its efficacy as the twenty-grain doses by the mouth. If this fails, I resort to other remedies, hoping to find one that is of avail. A tentative empiricism, founded upon sterling common sense, is not quackery. The second medicine that I generally give is the hydrobromate of hyoscine. One-fourth of a grain is dissolved in four ounces of water and one teaspoonful of the solution, viz., one one-hundred and twenty-eighth ($\frac{1}{128}$) of a grain, is taken every hour until either relief is secured or its physiological effects, which are extremely like those of atropine, become manifest.

But I think this is a case of mechanical dysmenorrhœa, and now let me see whether my off-hand diagnosis is correct. Upon making this physical examination, I find that I was nearly right, but not quite. She has a comparatively rare uterine displacement, which may, at first, sound to your ears like a paradox, viz., she has retroversion of an anteflexed womb. That is to say, the anteflexed womb as a whole has fallen backward. This mechanical obstruction—the anteflexion—by not allowing a perfectly free exit for the uterine secretions, causes primarily their accumulation, and secondarily their decomposition before they exude from the body, so that women often have foul-smelling discharges during painful menstruation.

The treatment here is rapid dilatation of the cervical canal, which should be performed as follows:

First, I cleanse the vagina by syringing it out with a 1 : 2000 bichloride solution. I now introduce my speculum, which reveals a cervix exceedingly small, and an os imperfect or undeveloped in character. Again is the vagina swabbed and syringed out.

During this time my instruments have been lying in a 1 : 2000 bichloride solution. From this solution I take my slender dilator, which, with its curvature in the posterior direction, I shall pass up into the cervix until it meets with resistance. Then I shall turn the chord of the curve toward the opposite direction, in hopes thereby to pass the obstruction at the internal os. I fail to get the dilator to pass the angle of flexure, so I stretch open the canal with it and try again. Twice I fail in the attempt, but at the third time I succeed in passing the dilator into the uterus by carefully feeling my way.

Before going any farther, let me stop for a moment to do what I should have done before beginning the operation, and that is, to introduce into the rectum a suppository of one grain of the aqueous extract of opium. This is done because after she recovers from the effects of the ether she will suffer a good deal of pain, and she may indeed need another suppository in addition to this one.

Having now passed the instrument well into the womb, I am ready to dilate slowly and carefully up to its full extent. This little instrument having done its work, the time has come to introduce a larger and stronger dilator with furrowed beaks so as to prevent slipping. I find I have a good deal of difficulty in getting this larger instrument into the womb. When it passes the internal canal its blades are slowly dilated, generally up to one inch and a quarter. But since this cervix is smaller than usual, I shall rest contented with one inch.

Having accomplished this and with rather less trouble than I had expected, I now complete the antiseptic process by thoroughly syringing out the whole vagina and cervical canal with bichloride solution. The cervical canal being now dilated, there is not so much danger of the bichloride remaining in the womb and thus causing uterine colic, as there would be with a very small canal, which might retain the mercurial solution.

This is the three hundred and forty-second case of rapid dilatation that I have made, and the results have been most satisfactory. I happen to have these numbers at my tongue's end, because I am just now writing an article on the subject for our *University Medical Magazine*.

The *rationale* of rapid dilatation is as follows:

Just as a piece of India rubber will, when overstretched, contract again, but never to its original length, so this cervical canal will contract, but never to its original small calibre. Hence I can assert with great confidence, that the woman will be greatly benefited, if not cured. I say if not cured, because there are in the world to-day thousands of women who have never consulted a physician, and yet who suffer more or less acutely at their menstrual periods. Absolutely painless menstruation is indeed the exception.

The last thing I do is to put into the vagina a ten-grain suppository of iodoform. This is done after thoroughly cleansing all the parts once more with the sublimate solution. I have in this case torn the cervix a trifle, but it will add to the success of the dilatation, and it is of no consequence considering the antiseptic precautions used at the operation. I once made a tear as long as a third of an inch, but it was followed by no bad consequences. Indeed, until comparatively recently, the knife was constantly resorted to for the purpose of enlarging the cervical canal throughout its entire length.

The medicine that she will take will be ten grains of the bromide of ammonium and five grains of the chloride of ammonium in one teaspoonful each of the compound tincture of gentian and water before meals. If much pain follows the operation, another opium suppository will be administered.

Beginning to-morrow morning, she will have twice a day a douche of 1 : 4000 solution of the bichloride of mercury. When vaginal injections are used, some of the fluid will be retained on account of the curve in that canal and mercurialization may ensue. Therefore I shall direct the nurse, when she gives this douche, to press upon the upper edge of the perineum and carefully thereby expel all the fluid remaining in the vagina, the curve of which is straightened by this manœuvre.

For nervous dysmenorrhœa I give the following mixture :

R.—Chloral . . . . 2 drachms.
Potassium bromide . . 4 "
Camphor water . . . 6 ounces.—M.

One tablespoonful three times a day. If the pain is great, I add to this mixture three grains of the sulphate of morphine, and in some severe cases it may be necessary for a patient to take this remedy even more frequently ; but I make it a rule to use the morphine as little as possible, as it deranges the stomach and digestive apparatus.

Let me here give you the benefit of a useful observation. There are many women and men who will tell you that they cannot take opium, in any form, because it disagrees with them. They will, it is true, suffer greatly from the after-effects of opium, provided it is given for any nervous condition or for any nerve pain. But let them have traumatic pain—due to an accident or to an operation—and opium will perfectly agree with them. I have verified this fact so many times, that I never hesitate to give opium after a surgical operation in defiance of the patient's protest or of that of her physician.

The causes in general of dysmenorrhœa are as follows: 1. Anteflexion, which I have just discussed. 2. Retroflexion, especially when it is congenital. Both these causes are often cured by pregnancy. 3. Stenosis, for which mechanical dilatation is the great remedy. 4. False membranes blocking up the cervical canal. For this I used to apply nitric acid, but now I prefer dilatation followed by curetting and intrauterine applications. 5. Polypi, which act like ball valves and demand removal. 6. Those cases of neurasthenia that are characterized by an irregular distribution of nerve force, causing spasm of the circular muscles of the cervix. Such undue discharge of nerve force may occur in other groups of muscles, especially of the circular muscles or sphincters. Thus we may have asthma from spasm of the bronchioles; aphonia from spasm of the vocal muscles; constipation from spasm of the sphincter ani; or irritable bladder from spasm of the vesical and urethral fibres. The treatment of nervous dysmenorrhœa is rest in bed, massage, electricity, and tonics of iron and arsenic.

CHRONIC OVARITIS.

This woman has been brought to me for a diagnosis of her disease. She is thirty years old, has been married six years and some years ago had one child. After this labor she had a serious leucorrhœa, which I fear was specific in character. She is now suffering from dysmenorrhœa, retroflexion, and backache, and has an irregular body behind the uterus, which feels a good deal like an ovary. Some months ago she was treated at our dispensary for a time, and improved while under treatment; but she afterward relapsed into her former condition, and has now come to be examined with reference to the advisability of having her ovaries removed. She will be etherized, as the examination would cause her considerable pain, and I shall, while she is being etherized, take the opportunity to tell you that the woman upon whom I performed a double ovariotomy two weeks ago, on account of adherent appendages, suffered for awhile with the same character of pain as if the organs were still present. This was a form of neurasthenia, and it lasted only a short time. It has disappeared and she now feels much better than for a long time.

Our patient being now unconscious, I find upon examining her, *per vaginam*, that there is an immovable body in the left broad ligament, which I believe to be the left ovary, that is adherent high up behind the uterus. The right ovary, too, is enlarged and plainly adherent, so that they are both giving her more or less pain and destroying her health.

I shall feel justified in removing her ovaries under these circumstances, if she desires to have the operation done after I have explained to her the results. I tell women in these cases that they will probably gradually lose in a measure their sexual feeling, although it will not cause in them so much difference as castration does in the opposite sex. The popular idea, that if a woman has her ovaries removed her voice will change and hair will appear on her face, is a mistake. Such changes do not take place when the ovaries are extirpated after puberty.

It has been stated that in fifteen per cent. of the cases of oöphorectomy there is a loss of all sexual desire. It is difficult, however, to arrive at the true statistics, because women do not like to be approached on this subject. It is often the case that many women, after having their ovaries removed, will have for awhile greater sexual desire than they had felt for a long time. This is because the ill health, resulting from the long ovarian suffering, has been cured by the operation. But in a few years' time there will be a lessening of sexual feeling, and in some a complete loss. In the opposite sex after castration the sexual desire may remain for some time, also the power of erection and of ejaculating a prostatic fluid, which, of course, contains no semen. Analogous sexual capacity is observed in oxen, in geldings, and in other altered animals long after castration.

ORIGINAL ARTICLES.

CARBOLIC ACID GANGRENE.[1]

By RIDGELY B. WARFIELD, M.D.,
of Baltimore;
Chief of Clinic to the Professor of Surgery, University of Maryland; Surgeon to the Baltimore General Dispensary.

While the escharotic action of strong carbolic acid is well known and molecular death of soft tis-

[1] Read before the Medical Journal Club, March 22, 1890.

sues may undoubtedly be brought about by this agent when employed in too strong solution or for too long a time, death in mass produced in the same manner seems to have been observed very rarely. I am fortunately able to add another to the few cases already recorded.

The literature of this subject dates only from the end of December, 1888, at which time Dr. Max Kortüm,[1] of Schwerin, published a short article detailing two cases of gangrene produced by the action of dilute carbolic acid continuously applied on compresses for some hours, to fingers which had received inconsiderable injuries. The first case was that of a young woman who, thinking she had a beginning felon, applied through the night a compress wet with an eight per cent. solution of the acid, which by morning had produced a blackening of the surface corresponding to the area covered by the drug and which developed into a sharply circumscribed gangrene. The slough separated slowly and, after some months, the patient recovered with a disfigured but useful finger. The second case described by this author, while less typical than the first, illustrates the same points, and the article constitutes the first record of this singular lesion. On May 8, 1889, M. Monod[2] presented to the Surgical Society of Paris a case of digital gangrene in a woman whose finger had been for some time in contact with a very strong solution of the acid. The gangrenous part was intensely black. At the same meeting M. Quénu reported two cases of a similar lesion, one complete, the other partial, both following strong applications of the acid on compresses. There were mentioned also, without detail, several analogous cases by Messeurs Kirwisson, Terrier, Nicaise, Legroux, and Le Dentu. The last observer, who reported three cases, speaks of the sharply circular appearance of the gangrenous part and the tendency toward retraction on healing. Billroth[3] in a letter written in August, 1889, also mentions that he has seen on four occasions gangrene of the fingers following the local use of carbolic acid, but gives no description of his cases. Dr. Emile Müller,[4] of Strasburg, reports two cases of gangrene of the index finger, following the use of dilute solutions applied for a considerable time. His first case was a boy of twelve years. For a slight punctured wound under the nail, the child's mother had wrapped the part in lint soaked with a two per cent. solution of the acid. Some burning pain was experienced on the second day and the finger was found to be much discolored, but the cause not being recognized the treatment was continued until the third day when Dr. Müller was consulted. The gangrenous area corresponded exactly to the extent of the applied lint. The last phalangeal point was exposed, opened, and required subsequent amputation. The second case in a boy eleven years old followed an application of a three per cent. solution of the acid for twenty-four hours to a finger which was the seat of a small punctured wound. At the end of this time the part of the finger covered by the compress was seen to be blistered and blackened and was finally destroyed by the gangrenous process. Dr. Müller expresses the belief that on plain surfaces such results are less apt to be seen, and condemns the use of carbolic acid of whatever strength when applied on compresses encircling the whole circumference of a part. My own case is as follows:

Henry B., an Irish laborer, aged fifty years, intemperate, robust, and without syphilitic or other taint, came to me at the Baltimore General Dispensary about October 1, 1889, with the following history. Four days before consulting me he had caught the end of his right index finger under some heavy body, with the result of producing a slight contused wound about the nail. By the advice of a friend, "to take out the soreness," he had applied to the finger, first wrapping it in lint, some strong carbolic acid solution, entirely saturating the dressing. At first he had felt considerable pain but afterward the finger became quite comfortable and the bandage was allowed to remain undisturbed over night. The following day the pain becoming acute and constant, the dressing was removed and the whole surface seen to be blackened and inflamed. Vaseline was then freely applied to the injured finger and used constantly until the patient came to me. On examination I found the following condition. The right index finger from its extremity to midway between the metacarpo-phalangeal and first phalangeal articulations on the dorsal, and to the first phalangeal articulation on the palmar surface, was the seat of general gangrene. The affected area was intensely black, embraced the whole contour of the finger, and was sharply separated by a beginning line of ulceration from the healthy tissue beyond. There were no signs of systemic infection, no apparent lymphatic involvement, and beyond a little œdema of the dorsum of the hand the surrounding parts were normal. An occasional poultice was ordered to encourage the separation of the necrotic mass, and every second day the part was irrigated with a mild solution of bichloride of mercury and dressed with iodoform ointment. Under this treatment the case progressed satisfactorily but slowly, the patient being under observation until the end of December, at which time he was discharged with a stiff and rather deformed finger, which was without a nail and covered with cicatricial tissue.

[4] Gazette Médicale de Strasbourg, November 1, 1889.

Including my own I have been able to collect from all sources some account of twenty cases of carbolic acid gangrene. Most of these cases have been only mentioned, not described. Of but six have any detailed accounts been given, the best reports being those of Drs. Kortüm and Müller. It is noteworthy that in the cases described by these observers the gangrene was produced by solutions not stronger than eight per cent. and in one case only two per cent. The carbolic acid employed in Monod's case is mentioned as having been very strong and in my own was, I suspect, not weaker than fifty per cent. Of the remaining cases we have no record on this point. All the reported cases forcibly illustrate the possible bad results which may follow the careless or ignorant use of this so-called antiseptic agent.

A reason for the production of this interesting lesion has yet to be found. Kortüm citing the observations of Neill[1], of Edinburgh, upon the action of carbolic acid on the peripheral nerves, and referring to the well-known local anæsthesia produced by the agent, concludes that in association with this action trophic changes may be brought about in the nerves underlying the applied drug and, as a consequence, the local death follows. The fact that the gangrene has been seen only in the fingers where peripheral nerves are abundant may favor this view. Of even more interest is the fact that a complete envelopment of the circumference of the finger seems essential for the production of the gangrene. In explanation of this peculiar feature I have no theory to advance. In conclusion we may say: 1. That carbolic acid applied to a skin surface may bring about rapid death of the part. 2. That the gangrene thus produced is always sharply circumscribed and corresponds to the skin area in relation with the drug. 3. That this gangrene is apt to be produced only when the entire circumference of the part is in contact with the destructive agent. 4. That the strength of the solution employed seems to be of less importance than the length of time of its application. 5. That the employment of a strong solution of carbolic acid to the whole circumference of an extremity should be condemned as should also that of even a very dilute solution when continued for a considerable time.

THE TREATMENT OF CARDIAC ARHYTHMIA DUE TO DISEASE OF THE KIDNEYS AND VASCULAR SYSTEM.[2]

By JOSEPH M. PATTON, M.D.,
of Chicago, Ill.

The title of this paper is not entirely satisfactory to me, inasmuch as the therapeutical methods adopted are such as do not affect the heart directly, and while cardiac arhythmia is at times the most prominent symptom, it is symptomatic of trouble elsewhere, and does not depend alone on organic changes in the heart, even though such be present. Still, as these measures relieve the irregularity of the heart the title employed may be excused.

Cardiac arhythmia is a wide subject, and I wish to speak only of that form which is caused by chronic disease of the kidneys, and is generally associated with more or less arterio-sclerosis, principally affecting the medium-sized and smaller arteries.

The kidney and vascular changes are extremely interesting, but a thorough consideration of them is not the object of this paper. Three conditions of the kidneys and vessels have been described by Delafield, viz., *chronic congestion*, *chronic inflammation*, and *chronic degeneration*. The arterial changes consist in more or less irregular thickening of the middle coat of the vessels.

These changes are found in persons of middle life or over, are usually associated with chronic rheumatism or with a rheumatic diathesis, and may or may not be associated with valvular lesions and their sequences. Arhythmia from the latter cause presents various forms, is not so spasmodic in character, and not so severe, unless it be in an advanced hyposystolic condition of the heart.

The patients are subject to spasmodic attacks of arterial contraction, which greatly increases the work of the heart, and it is at such times that the cardiac arhythmia presents itself. The attacks are characterized by partial suppression of urine, irregularity of the heart, dyspnœa, passive congestion or œdema of the lungs, and all the signs of cardiac failure.

The urine may not vary much from the normal, the specific gravity being between 1010 and 1030, usually about 1020; albumin or casts may or may not be found, depending on the character and extent of the kidney lesion. At the time of the attack the urine will be scanty and high colored, albumin will generally be found, also casts, if the kidney lesion is far advanced. In many instances our first acquaintance with the patient will be occasioned by the onset of one of these attacks; he may have been under medical care for other ailments and the ordinary lesion escape attention until an attack of arhythmia and dyspnœa leads to investigation.

We find the patient with a more or less irregular heart; in mild attacks the rate may not be much increased; in severe attacks, especially when degeneration and dilatation of the heart have been produced, the rate may be very much accelerated, and the heart gradually passes to a condition of asystole. In those unpromising cases where, from the duration and progression of the heart and kidney lesions combined, recovery is impossible, the arhythmia be-

[1] Edinburgh Medical Journal, June, 1886.

[2] Read before the Chicago Medical Society, March 17, 1890.

comes more pronounced until conditions of *delirium cardis*, and finally *tremor cardis*, are developed precedent to a fatal termination.

As all manner of disease of the heart may be associated with chronic disease of the kidney, it is important to determine how much of the ataxia of the heart is due to a hyposystolic condition of that organ, and how much to an increased demand for work. In those cases where the heart has undergone change as a result of chronic endocarditis, it is not always easy to place the responsibility for the arhythmia; here failure of compensation which has arisen from cardiac disease and its accompanying arhythmia will be associated with ataxia of the heart from nephritis and arterial contraction, and to define clearly the relation of each form to the individual case requires considerable skill and discrimination; yet the success we will have with these cases depends upon our ability to make this distinction.

Leyden, of Berlin, says that the condition of the heart muscle is determined essentially by the tension and frequency of the pulse, the character of the renal secretion, and the degree of dyspnœa.

This is true in conditions which apply to the heart directly, but in the form of arhythmia under consideration this would lead us to wrong conclusions and misapplied therapeutics. We must depend on physical examination of the heart for our information in regard to the condition of the heart-muscle, and on such information will depend the measures directed toward the heart. If actual failure of the heart-muscle is not concerned in the ataxia, the heart tonics are not indicated and may be harmful. The most difficult point, as has been said, is to determine the exact indications for their use. The dyspnœa may be from cardiac asthma, or from diminution of breathing space through congestion and œdema. Generally from a combination of these two causes it is labored in character and is at times extremely distressing. Œdema of the extremities may be present, but is not constant, even in those cases which show some passive congestion of the lungs.

Gastric disturbances usually accompany the attacks of arhythmia and are apt to be caused or aggravated by constipation. For arhythmia due to disease of the kidneys and vessels, the necessity is not to force the heart to work harder, but to give it less work to do. This end is gained by increasing the function of the kidneys and by lessening the tension of the arteries by dilating them. The dilatation of the vessels attains two objects: by furnishing a larger channel for the blood it diminishes the work of the heart, and thus it allows the *vis a tergo* of the heart to reach the kidney circulation and diuresis is increased, with the elimination of materials, which, by their retention in the circulation, may either directly irritate the vessels, or may influence them indirectly through the nervous system. In whatever manner the vascular influence may be produced, a diminished tension cannot be sustained unless the function of the kidneys is carried on.

Of the various medicines used to produce vascular dilatation opium has been most serviceable to me. Nitrite of amyl, trinitrin, chloral hydrate, and the various other drugs used as vaso-dilators, are too transient in their effect. They may be useful temporarily in urgent cases, but not much permanent benefit can be obtained from their use. The bowels should be kept free, the diet light and easily digested, and attention should be given to the condition of the stomach. I have found Husband's magnesia useful in antagonizing the constipating tendency of opium when the latter is used. Such special diuretics as are best adapted to the individual case should be employed. I have usually employed nitrate of potassium and buchu, as this combination has proved satisfactory.

The following cases may be of interest in connection with the foregoing:

Case I.—Mr. T., aged forty, rheumatic history, had been under my care about a year for organic disease of the heart—mitral stenosis, slight mitral regurgitation, dilatation of left auricle, moderate hypertrophy of right ventricle. Heart constantly irregular from character of heart lesion. Could not bear digitalis, but improved on strophanthus, iron, and anti-rheumatics. He had always been able to come to my office. I was called to see him one evening; found him sitting in a chair unable to lie down; great dyspnœa; heart so irregular that rhythm or pulse-rate could not be determined: urine scanty, dark, and contained albumin; some congestion and œdema of posterior inferior portions of lungs, particularly the left side. Gave him citrate of potassium and caffeine, which is particularly recommended by Dujardin-Beaumetz in such conditions of the heart, without relief. I then gave him 5 drops of tincture of opium with nitrate of potassium and buchu, every four hours; also 12 drops of tincture of strophanthus three times daily. This was followed by immediate improvement. This treatment was continued as the indications required and in a few weeks afterward he walked a distance of two miles to my office.

In this case there was arhythmia, due to the spasmodic attacks of arterial contraction added to that usually present, and due to the organic changes in the heart,

Case II.—In the fall of 1889 I was called at midnight, in consultation, to see Mrs. T., aged fifty-five. She was suffering from severe dyspnœa. The heart was irregular, hypertrophied, degenerated, and slightly dilated; its action was weak. The lungs were slightly œdematous, and there was a small amount of fluid in the pleural cavities, a few ounces

of which had been removed in an attempt to relieve the dyspnœa. The urine was scanty; had not been recently examined for albumin, as her physician had not apprehended serious trouble from the kidneys. She was given morphine and diuretics. The urine showed quantities of albumin. She improved sufficiently in a week or ten days to be about the house, the dyspnœa being immediately relieved. The kidneys, however, were so seriously diseased as to be unable to perform their function, and she gradually developed uræmic coma and died in three or four weeks.

Case III.—In February of this year I was called to the country in consultation to see Mrs. P., aged sixty, a sufferer from chronic rheumatism, having but partial use of her lower extremities. I found her suffering from dyspnœa, unable to be out of bed and obliged to assume a sitting posture most of the night in order to breathe. She had just recovered from an attack of *la grippe* characterized by a severe bronchitis. The heart was very irregular and hypertrophied, but the muscle was in fair condition; the urine was scanty, dark, and contained albumin. She was given nitrate of potassium, buchu, and 5 drops of tincture of opium four times daily. A week later her physician wrote me that she was up and about the house.

Case IV.—About four weeks since I was called to see Mrs. O., aged seventy. She had been suffering for a week from severe dyspnœa, and had been treated for asthma without relief. She was unable to lie down or to walk across the room, very somnolent, stomach irritable, heart very irregular and slightly enlarged, but otherwise in good condition. Lungs œdematous, legs also quite œdematous, one having been moderately so for years because of varicose veins; urine scanty and containing a small amount of albumin, but no casts. She was given diuretics with 5 drops of tincture of opium four times daily. Stomach improved, bowels kept open. She was fed on milk and beef-peptonoids. In two days the albumin had disappeared from the urine, dyspnœa was relieved, pulse considerably improved. In four days she could sleep quietly all night, œdema of feet and lungs had disappeared and pulse was perfectly regular and of good volume. Could go down stairs for her meals. She returned home at the end of a week, and now, at the end of a month, writes me that her health continues in a very satisfactory condition.

INTESTINAL SURGERY.[1]

By BENJAMIN T. SHIMWELL, M.D.,
of Philadelphia.

Intestinal surgery was dormant for years, until Senn, of Milwaukee, by his brilliant experiments gave it an impetus. What was the aim of his work? Not to increase the complexity of an operation already difficult, but to lessen the time required, and to make the result more certain. In his footsteps follow others, each adding his mite, until in time we will see a perfect operation.

The object of this paper is to give the results of some experiments on a large number of dogs: results that are good and bad, as shown by repeated trials. These operations or experiments were made on dogs irrespective of age, size, or condition. No preparatory measures were taken to increase the chances of the operation, and they were fed up to the time of being placed on the table. As the manner of operating is now generally understood by the profession, I do not propose to describe the technique, but to discuss certain conditions that seem to me of paramount importance in the successful performance of this work. Starting on the premise that the operation is known, I will take up each point separately.

Senn's plates are objectionable on account of the difficulties in making them. The sawing of the bone to the proper size; the decalcifying, which takes at least seven days; the drying under pressure; the filing and trimming; the boring of the ligature-holes and the opening to allow of the passage of fæces, and the arrangement of the ligatures, consume considerable time and labor. There is no question that they give a larger approximation surface, but this is not an important factor. They are not easily handled, and, as but two ligatures are passed through the bowel, there is not the same facility in tying the end ligatures that there is in tying those of the sides.

Abbe's catgut rings, while theoretically good, are practically imperfect. They require time in the preparation of the catgut and in the making of the ring. They are then put under pressure in alcohol until used. The advantage claimed for them is that they are absorbed or disintegrated, and are easily separated and removed. This is not so, for I have found the catgut practically unchanged and passed from the anus entire, or remaining in the proximal portion covered with fæcal matter, and acting as a foreign body. Like Senn's plates, they cannot be made in an emergency. They are also objectionable on the ground that when removed from the alcohol and the pressure of the glass plates, and placed in carbolic solution, they twist and become difficult to manipulate. Then the fact of having six ligatures in each ring makes the tying of the proximal ligatures a difficult matter.

After faithful trials, I found that the simplest and most perfect ring is that of Brokaw, which can be rapidly made and used immediately. It is made by taking a piece of rubber tubing two and one-half or three inches in length and threading it with catgut, which is tied at the end, converting the tubing into a ring. The ring is fenestrated to allow of the attachment of four ligatures to the catgut. This takes but a few moments, and the rings are easy of manipulation. They are compressed into a straight

[1] Read before the Philadelphia County Medical Society, March 12, 1890.

line, introduced into the bowel through the incision, and then turned on the flat. The four sutures are passed through the bowel wall, and easily tied. Firm approximation is secured, with sufficient surface to furnish strong union. The catgut used in threading the tube should be unprepared and as fine as can be obtained, in order that it may be disintegrated readily. Non-disintegration with retention has occurred in two cases. The silk ligature is the safest and most easily handled. Catgut is unreliable; the knot has a tendency to slip, even when the utmost care is taken, making the approximation unsafe. The objection raised that catgut is absorbed too soon, is not well founded. If the catgut is well prepared in oil of juniper for twenty-four hours and kept in alcohol, sufficient resistance is given it to keep the rings in place until union is firm. The finer the silk, consistent with strength, the better the approximation, as too heavy silk prevents coaptation. The knot can be tucked under, which allows the bowel surfaces to lie together outside the knot. After the ligature is passed through the bowel, and before tying, it should be washed with bichloride solution. The passage of the invagination sutures is an important matter, as there is a tendency on the part of the invaginated portion to be everted by the contraction of the mesentery and bowel walls. It is a matter of vital moment to prevent the occurrence of this accident. I do not know that any one would pass the sutures directly through the walls of the invaginated portion, still the temptation exists. To see what would be the outcome of this, I tried the experiment on twelve dogs, passing the continuous sutures directly through the walls and over the end, by which the part was firmly secured. In every case ulceration took place in the suture tract, and the dogs died in twenty-four hours, apparently from shock. The proper method is to pass the suture through the serous and muscular coats and over the end to the other side, and repeat. The mesenteric side should be sutured first, and a moderately firm knot tied. The invaginated end will be nicely rounded and the sutures completely covered by plasma in a few hours; I do not know the exact time, but dogs killed as early as the eighth hour have shown this condition.

Reliable works on surgery, and some of the experimenters in this work, suggest the division of the mesentery from the bowel at the point of invagination. Treves and Greig Smith lay stress on the non-division of the mesentery at this point. This separation has been suggested to prevent retraction of the mesenteric side of the invagination. I tried this on twenty-four dogs, dividing the mesentery from the intestine at the point of invagination, and finishing the operation as usual. In every case gangrene of the intestine occurred, showing that the vitality of the bowel is entirely dependent on its mesenteric blood supply at the point of attachment. The contraction and retraction of the bowel after division would be sufficient to cut off the blood that could come from a distant point. This was so positive that I then inverted the mesentery into the lumen of the gut along with the walls. I then passed the first invagination suture through the mesenteric portion. The securing of this is absolutely necessary, for the mesentery contracts to a considerable extent, as is very noticeable in operations where a free invaginated portion is left. In such cases there is a marked concavity toward the mesentery, and if the specimen is seen some time after the operation, it will be found that the free end has been drawn down to some adjoining portion of gut, lying in close apposition, but not attached, except by the contracted mesentery.

When we consider special operations, the value of this method is readily appreciated. Take, for illustration, a gastro-duodenostomy. I have done this by two methods. First by simply incising bowel and stomach, passing the rings, scarifying the surface and then approximating the parts and tying the sutures.

In some cases, I have passed additional interrupted sutures; perfect union resulting from both methods.

The other form of operation was done after the method of Dr. Weir, of New York. The duodenum and stomach were brought together at the site chosen. They were then pinched up and a continuous catgut suture passed through their serous and muscular coats. This formed the posterior attachment of the union. After doing this, the duodenum was incised, the ring inserted and sutures passed. The stomach was then treated in the same manner, the surfaces were scarified and approximated, and the sutures tied. The catgut from the posterior wall was then carried around the sides and the anterior attachment. This is an excellent method; the parts are not only supported and injury by dragging prevented, but extravasation is not likely to occur. When the posterior suture is passed, it is important that it is placed well toward the mesenteric surface of the bowel, so that when contraction takes place, enough approximation surface is left to give good union, besides preventing narrowing of the new opening and union of its divided wall. In the human subject, I would be inclined to give the preference to Senn's bone plates, as they by their rigidity would prevent union of the divided walls. By the contraction of the stomach and duodenum the rubber rings are compressed, the divided surfaces meet, and stenosis may result. The difference in time of these two operations is marked; the first is completed and

dressed in thirteen minutes; the second takes twenty-five minutes. Though time is a factor, I think it will pay for the spending. The prognosis is exceedingly good. I performed six gastro-duodenostomies, with five recoveries. In the case that died the post-mortem did not show the cause of death, and as the union of the duodenum to the stomach was perfect, I think it would be fair to class it with the recoveries.

The next operation to which I wish to call attention is ileo-colostomy. This is performed by two methods, viz.: Approximation and implantation. Brokaw has modified the implantation; his operation being an implantation with approximation. In approximation two rings are used, one in the colon, the other in the proximal portion of the ileum. This is a rapid method but not the safest, as extravasation is apt to occur. This can be prevented to a certain extent by additional interrupted sutures, but with Senn I am forced to believe that it is not a safe method. Implantation has given me the best results; every case operated upon terminating favorably. The risks of extravasation are either prevented or reduced to a minimum, though I think it is a safer plan to place a few extra sutures between the original sutures. This operation I have always done with catgut.

Brokaw's modification possesses no advantage over Senn's method, either in security or time, and has one disadvantage—the possibility of obstruction. Brokaw uses two rings, one in the colon, the other in the ileum. The ring used in the ileum must be of such a size that it will not impinge too firmly on the mucous membrane. For this reason it must be exceedingly small when the ileum is of small calibre. Thus the lumen of the ring is so narrow that fæcal matter cannot readily pass through, and as the catgut does not always disintegrate, the ring acts as a foreign body, for it cannot pass unless unfolded. I performed only one operation by this method. The dog was small, consequently the ileum was small and the ring in proportion. The dog did well, was placed on the floor on the third day and took care of himself. But the bowels refused to move, and on the eighth day he sickened and on the eleventh died from obstruction. The post-mortem showed perfect union, the ring *in situ* and the catgut still firm. The bowel above was entirely filled with fæcal matter. If the catgut had disintegrated the ring would have passed and the dog's life would have been saved. This to me seems the great objection to the method. In an adult, where the ileum is larger, a better result might be possible.

Through circumstances, I came into possession of a bad lot of silk, but, as good may come from evil, I have been able to prove a fact that is of the utmost importance. In performing these operations, the ligatures broke in eight cases, with seven deaths. In each case everything was tried to remedy the accident but without success. Catgut ligatures were passed through ring and bowel and tied to the remaining ligature. Interrupted and continuous sutures were tried with no satisfactory results. It is too late to replace the ring after one, two, or three of the ligatures have been tied. What occurs when the ligature breaks? After division, the bowel contracts to one-third or one-half of its diameter. The rings are introduced, the ligatures are being tied, putting the bowel on the stretch, a ligature breaks, the bowel is slightly ruptured, retraction takes place and the opposing surfaces are drawn out of relation. To illustrate: if it is the last ligature that breaks, as the other three are tied, the ring is firmly applied to the bowel walls at their points of union. The part remaining ununited by the broken ligature leaves that portion of the bowel unsupported; then, when contraction of the bowel or peristalsis occurs, the position of the ring changes with the bowel, and fæcal matter can be forced through the intervening surface of the non-supported part. The peculiarity of the colon in being subject to tenesmus when interfered with, keeps up the strain on the point of approximation. I am inclined to believe that it is the tenesmic action of the colon that makes ileo-colostomy by approximation unsafe. All these cases of broken ligature, excepting the eighth, were operations for ileo-colostomy. The eighth occurred while doing a jejunostomy. The bowel was secured by interrupted sutures carried well beyond the ring approximation, and retaining the ruptured suture tract inside. This case recovered. The only theory that explains recovery is based on the mobility of the small intestine. If peristalsis or retraction occurs, there is sufficient mobility of both parts to prevent severe strain. In ileo-colostomy the colon is fixed by its mesentery and the ileum is free to the length of its mesenteric attachment; then the movement is not uniform, and the strain must be on the approximation. What is the remedy? The only thing that can be done is to remove the portion of the ileum operated upon and to insert a new ring into the colon, being careful to pass the sutures well beyond the former sites. So confident am I of the result of this accident, that if I were to operate on a human being, I should have two sets of rings and if a ligature broke I should do as I suggest.

It has been advised to unite the small intestine in its natural direction. To me, there is an objection to this mode. When division of the bowel has been performed, and the ends invaginated, the convex surfaces are to be united. As the axes of the two portions are the same, to approximate these

surfaces it must be done at the expense of the mesentery. The two ends of the bowel must be moved side by side in opposite directions in the line of the axis, to the point of approximation; this is a loss of mesentery to the extent of four or six inches by overlapping. Then to bring these together, the two portions of bowel must be rotated on their long axes to bring the convex surfaces together. This shortens the mesentery. As the mesentery always contracts in these operations, a further shortening of its length occurs, thereby lessening the freedom of action. This is not of much importance when the mesentery is long; but, if it is short, it may give rise to annoyance. In my operations I have always folded the two ends on themselves like the leaves of a book, and attached the convex surfaces side by side. The mesentery is not interfered with, and its length is preserved; the ends of the bowel beyond the point of union rounding off and contracting until only a knuckle is left.

Senn advises scarification of the surface before approximation; by this rapid union is obtained by exudation from the irritated surfaces. Dr. Davis, of Birmingham, Alabama, suggests denudation of the peritoneal surface, and reports a number of cases to show its advantage over scarification. While not decrying his method, complete scarification will give quick union. A specimen of gastro-duodenostomy, which was removed fifty hours after operation, shows that union had taken place at a much earlier period than Davis says is possible. I have removed specimens in twenty-four hours that showed good union which would prevent fæcal extravasation. My results lead me to suppose that the strength of the union depends entirely on the thoroughness of the scarification. I used two needles fastened in a cork; these irritated the surfaces sufficiently without producing bleeding.

Contrary to the experience of other operators, there was persistent vomiting in every case (excepting the gastro-duodenostomy), which lasted from twenty-four to seventy-two hours, and during this time no food would be voluntarily taken. Milk and lime-water, for at least seventy-two hours, was all the nourishment they received, and this was always given by force. Meat they would not swallow. I thought this was due to the confinement in the apparatus; but when, after thirty-hours, they were placed on the floor everything but water was still refused. The location of the operation did not seem to influence the vomiting. The cases of gastro-duodenostomy retained all food given, and caused less trouble than any of the other operations.

The only thing noticed in reference to the urine was in the operations upon the colon, and in these strangury was always present—as many as thirty-six hours passing without voiding urine. Strangury may be present in any abnormal condition in the colon, and shows itself in operations on the part.

The bowels were not moved in any case before the fourth day. The rings were passed at that time if the operation was low, or later, according to location. The cessation of defecation is evidently due to the local paralysis produced by the interference, as the lumen of the bowel is perfect at the point of anastomosis. The dogs received no preparatory treatment, and in no case was any medication resorted to after the operation.

In conclusion, I wish to give some reasons for special treatment of the omentum after laparotomy. In every operation that requires abdominal section, the omentum receives more or less handling, at times with considerable roughness for such a delicate tissue. In making the post-mortems I always found one of two conditions existing. The omentum was either attached to the intestine at the point of operation, or contracted and more or less adherent to the upper portion of the abdomen. Therefore, by these conditions the functions and anatomical relations of the omentum were lost. In my later operations I passed the first one or two abdominal sutures through the omentum and brought them up to the line of incision when the abdomen was closed. By this I not only retained its relation, but I attached it to the cicatrix. Hernia after laparotomy is one of the sequelæ, and possibly it could be prevented by this method; for, in making the post-mortems, I have found it more or less difficult to tear the omentum loose even as early as the eighth hour after operation. When made later it not only showed the attachment to the cicatrix in good condition, but also that to the adjoining parietal peritoneum. By this the abdominal cavity is shut off from outside influences in a few hours.

Summarizing the points of this paper, they show:

1. The advantage and disadvantage of special rings.

2. The value and security of silk over catgut as a ligature.

3. The manner of passing invagination sutures, and the necessity of securing the invaginated portion to prevent retraction.

4. The danger of division of the mesentery, and the manner in which it should be treated to make the operation successful.

5. The two methods of performing gastro-duodenostomy, and the advantage of Weir's operation over simple approximation.

6. In ileo-colostomy the values of approximation and implantation, and the possible disadvantage of Brokaw's modification.

7. The danger from breaking of ligatures while performing approximation, and, in such cases, the necessity of repeating the operation.

8. The manner of uniting the small intestine, and its influence on the mesentery.

9. The use of scarification or denudation of the peritoneal surface to secure prompt union.

10. The persistent vomiting in all cases except gastro-duodenostomy.

11. The strangury in low operations.

12. The time between the operation and defecation, and the passage of the rings.

13. The treatment of the omentum, and its possible importance in laparotomy.

CLINICAL MEMORANDA.

SURGICAL.

Sloughing of the Gastrocnemius following Amputation in a Diabetic Patient.—The patient, a man aged sixty-two years, had suffered for twelve years from diabetes, the amount of sugar varying greatly and being absent when the proper dietetic rules were followed. On September 5, 1889, the day after a long tramp in the mountains, he noticed four blisters forming on the toes of the right foot. Two were on the outer side of the little toe, and one each on the outer side of the two adjoining ones. The accompanying pain was great, and was increased by a depending posture. On the following day the same conditions existed, but were aggravated. The blisters were opened, allowing a bloody serum to escape, and leaving ulcers with black bases, but with no distinct line separating them from the healthy tissue. At this time sugar was present in his urine. In the course of four days it was possible to make a positive diagnosis of dry (or perhaps better here, diabetic) gangrene.

On October 22d a well-marked line of demarcation existed, showing the diseased area to be the outer two-thirds of the foot extending from the articulation of the os calcis and cuboid downward over the metatarsal bones, but not including the great toe. At this date an amputation was done at the junction of the lower and middle thirds of the leg, with lateral flaps, the usual antiseptic precautions being taken.

It was noticed during the operation that the anterior surface of the gastrocnemius was of a dark blue color, as though bruised, while the soleus was of a normal color. From the immediate effects of the operation the patient rallied well, but in five days the flaps had sloughed, excepting the central portion over the tibia. Later a portion of this also sloughed, exposing an area of the tibia about one inch in diameter. This all granulated with the exception of a small portion on the outer side, from which were daily taken shreds of necrosed material, probably part of the aponeurosis.

About January 10th he had an attack of influenza, which left him much exhausted, and following it all the inner part of the stump became red, swollen, and very painful nearly to the knee, and in another week this condition extended above the knee on the inner and posterior aspect. Over the lower portion of the swelling a vesicle formed, with a black base and distinctly marked edges. Beneath this, pus was detected. It was freely opened. Large pieces of necrosed material would plug the opening, and were removed, only to be followed by others. Two fragments the size of the thumb came away, besides many smaller ones. Above the knee over the inner head of the gastrocnemius a free opening was made ten days later, and from this also many shreds were removed. The two openings communicated. The superficial structures were not involved in the sloughing process and apparently the outer head of the gastrocnemius was not affected. The stump is now very thin and pointed, showing plainly the absence of the muscle.

Before the attack of influenza his urine contained no sugar, but when the sloughing began sugar appeared to the extent of nine-tenths of one per cent. At present sugar is absent.

Large quantities of morphine were used during the course of the case, which may have accounted for the disappearance of the sugar.

HOSPITAL NOTES.

INDURATING ŒDEMA. PAPULAR AND ULCERATING SYPHILIDES. LUPUS ERYTHEMATOSUS. TINEA TONSURANS.

Abstract of a Clinical Lecture delivered at the New York Post-Graduate Medical School.

By ROBERT W. TAYLOR, M.D.,
PROFESSOR OF DERMATOLOGY.

Case 1.—The first case to which Dr. Taylor directed attention was a man, forty-nine years of age, who having had an erosion on the foreskin for some weeks, had connection with a woman about seven months ago. Five weeks after this intercourse a hard nodule appeared upon the erosion, and a second nodule about one month later. Eight weeks ago the penis and scrotum began to swell, and at the end of two weeks they had become so enormously swollen that he entered Bellevue Hospital, where an attempt was made to relieve the phimosis by a dorsal incision of the prepuce. Subsequently the swelling was reduced slightly by the application of leeches to the penis. The true condition of the patient had not been recognized when he first came under Dr. Taylor's observation at Charity Hospital about six weeks ago. At this time the swelling had existed for several weeks, and the patient was very anæmic. He was put to bed and given mercurials and tonics. The swollen scrotum was about as large as a cocoanut, and the penis correspondingly large. There was no succulence of the tissues, but the prepuce was of a purplish color, and as hard as cartilage, and the phimotic condition was still present. Although the penis was involved in the swelling, the excessively hard œdema was in the prepuce. Circumcision was performed only one week ago and the hardness is markedly less, but there is now no evidence, nor has there been, of inflammatory engorgement or of œdematous infiltration, and the patient has improved rapidly since the removal of the mass.

The erosion on the penis was a good port of entry for the syphilitic virus. He denies having had headaches, sore throat, alopecia, or any rash; but he has undoubtedly had a roseola, a few spots of which still remain; and there is enlargement of the ganglia. The condition presented by this patient is known as "indu-

rating œdema," and usually begins about the genitals, although sometimes about the face, making its appearance commonly during the first years of syphilis, and upon some primary or secondary localized syphilitic lesion. It is not an accompaniment of any other disease. As this subacute inflammatory quasi-œdema usually affects some primary or secondary lesion of syphilis, the successful treatment of the special condition is necessarily dependent upon the healing of the lesion in question.

This condition of indurating œdema is sometimes complicated by a seemingly erysipelatous condition, in which the parts, although not hot, have a brick-red color which may extend for some distance upon the neighboring parts.

This man's scrotum, when pinched between the fingers, is found to be still fully one inch thick.

Treatment.—In male patients the hard œdematous prepuce should be excised, but if this is impossible, the penis must be constantly covered with mercurial ointment. Inunctions of mercurial ointment should be made to the scrotum with the greatest caution, for they are very liable to cause inflammation and even gangrene. It is better, therefore, to follow such inunctions by the application of an evaporating or lead lotion.

Case II.—The next patient was a woman, twenty-two years old, with indurating œdema of the right labium majus. She gave a history of having had a sore on the inside of the vulva, a slight eruption, abundant alopecia, nocturnal headache, and other symptoms of syphilis. About sixteen weeks ago, the right labium began to swell, and ultimately reached the size of the fist. In the course of a few weeks, sores appeared on these parts but disappeared after a short time. The present sores began as pustules about the size of a pin's head, and by infection with micrococci which entered through the hair follicles, the warty looking ulceration now present was produced. This, however, can only be regarded as a complication developed upon a much hypertrophied labium majus.

Treatment.—As the mass cannot be removed in this case, it is important to observe the strictest cleanliness of the affected and neighboring parts, to avoid all sources of irritation, and to envelop the whole mass in a twenty-five per cent. mercurial ointment applied on lint, both inside and outside of the vulva. By the use of sitz baths at 101° F. containing some sal soda for its cleansing action, the circulation of the parts is accelerated, and the tissues softened and rendered more amenable to the action of the mercurial.

Case III.—The next patient, a man forty years old, was admitted to the hospital twelve days previously, but did not develop the present eruption until six days later. He stated that twenty-seven days after connection, a sore appeared on the end of the penis and extended into the urethra. The period of incubation of syphilis is subject to considerable variation, the shortest time being about ten or twelve days, and the longest from sixty to seventy days. The longest period of incubation observed by Dr. Taylor was sixty days in two trustworthy cases, but Fournier says that he observed one of seventy days' duration.

This patient shows general enlargement of the glands, and presents an eruption which is general in its distribution, and consists of small, flat, smooth papules, which are by no means florid in color, but of a decidedly pinkish tint. This is the first week of the eruption, and therefore it is not copper colored, or of the tint of lean ham. The congestion must be of longer duration, and the pigment changes more advanced before the characteristic appearance will be present. Later on, the eruption will also be scaly. The patient complains of great itching, and the cause of this is to be found in such subjects usually in the general condition of the system, or in the presence of pediculi in the clothes; for, as a rule, syphilitic eruptions do not itch.

Treatment.—Whenever one has to treat these localized infiltrations of syphilitic material called papules, tubercles, etc., it is better to bring the medicine in contact with them by means of inunctions, rather than by the roundabout method of administering mercurials by the mouth. By the employment of inunctions, gastric irritation is avoided, and an opportunity offered for the administration by the mouth of suitable tonics. In carrying out the treatment by inunction, take different regions of the body on successive nights, giving about one inunction in each week to lesions of the head and neck.

Case IV.—This woman, thirty-eight years of age, has been syphilitic for six years, and consequently presents lesions of a more advanced stage of the disease. Her first eruption, she says, began with small papules about the face, and since then, the eruption has returned almost every year. About the shoulders and clavicles, under the right breast, and in several other places about the head and neck, and behind the ears, are to be seen infiltrated nodular patches, which are in places ulcerated. These lesions present an admirable illustration of what is known as the "ulcerating tubercular syphilides." Two forms of syphilitic tubercles are found—the ulcerative and the non-ulcerative form; and this patient presents illustrations of both, chiefly the former, however. She is pale and anæmic, and the lesions from which she suffers show a strong tendency to degeneration. The cause of these degenerations of tubercular syphilides is two-fold: (1) The inherent tendency in a tissue of low grade, like syphilitic material, to degenerate; and (2) the opportunity presented by the low grade of vitality of these tissues for the entrance of pyogenic bacteria or micrococci. In other words, these degenerative changes are brought about either by a general systemic infection through the syphilis, or a local infection by micrococci of the products of this general infection.

Then again we must remember that the syphilitic neoplasm is a young and rapidly growing granulation material, but one possessing little vitality, and that the small cells accumulate around the bloodvessels from which they are effused, and when their number is so great as to compress the bloodvessels, strangulation and ulceration follow.

The pyogenic bacteria lodging upon a skin infiltrated by syphilis, and having its nutrition seriously impaired thereby, gain entrance perhaps through the hair, sudoriparous, or sebaceous follicles, and finding a favorable soil for their development, form little pustules, which, increasing in size and number, fuse together, producing ulcers. Many, if not all, of the ulcerative lesions of syphilis are instances of this mode of infection. It is

further evident that the vulnerability of the tissues will be increased in proportion to the general debility of the patient. These facts explain why tubercular syphilides do not always become ulcerated.

Treatment.—In considering the question of treatment, it is important to remember that the mercury only assists by removing the new growth, and, accordingly, the ulcerative condition may remain after the new growth has been absorbed. Hence, the local treatment is essentially an antiseptic method, and consists in the removal of all crusts, and washing the parts with a two or three per cent. solution of carbolic acid. If it were practicable to cover all such ulcers with the usual antiseptic dressings, the process of healing would be very rapid. Having removed all the crusts and purulent secretions, and secured a fairly healthy condition of the parts, apply an ointment consisting of two drachms each of carbolic acid and mercurial ointment to the ounce of vaseline. Internally, the patient is taking the following prescription:

R.—Biniodide of mercury	.	2 grains.
Iodide of potassium	.	3 drachms.
Syrup of iodide of iron	.	320 drops.
Simple syrup	.	2 ounces.
Water, sufficient to make	.	4 " —M.

One teaspoonful in water, three times daily.

Case V.—The next patient, a woman of thirty-three years, presents a different form of cutaneous disease from the preceding cases. She is suffering from lupus erythematosus, a disease which is rather more frequent in women than in men, and which usually begins as a little spot the size of a pin's head, situated around a follicle, which is often seen in the centre, and which is plugged with sebaceous matter. From this origin, single or multiple discoid plaques are developed by peripheral extension, usually beginning about the nose, spreading from there to the cheeks, and very often eventuating in an outline reminding one of the shape of a butterfly. It does not, however, necessarily follow this particular mode of distribution. In the present case, the greater portion of the forehead, all of the right cheek as far as the angle of the jaw, and part of the mouth, are involved, with several other patches indicating the multiple origin of the disease. She says that the eruption itches severely. The skin is thickened, reddened, and scaling, and, what is often insisted upon, *i. e.*, thickened, scaling patches, with plugged-up follicles, are not seen, for they have been removed by treatment.

Treatment.—The treatment is largely one of stimulation, and it is evident from the appearance of this patient that this method has been judiciously and successfully followed. The parts may be painted with pure carbolic acid or with tincture of iodine. Dr. Taylor prefers to paint with either carbolic acid or iodine, and then to apply over this a coat of collodion, re-applying it as often as it falls off. Some cases are markedly benefited by the vigorous application of the vinegar of cantharides; but care must be exercised not to allow the irritation produced to proceed too far. For this purpose, soothing remedies like the lead and opium lotion, or zinc ointment containing one drachm of calomel to the ounce of ointment, may be used. The patient must also be protected against changes of temperature, and from disorders of the gastro-intestinal tract, which may cause flushings of the face.

Case VI.—Dr. Taylor next brought before the class a boy, ten years of age, who had a typical incipient ringworm on the scalp; the case being rendered more interesting by the fact that his reddish hair made it very easy to overlook the patch of disease. On passing the finger over this patch it felt like sandpaper, owing to the inflammatory hyperplasia in the hair follicles. It is sharply marginated, and, in the upper portion, hairs are scattered which are yet uninvaded by the disease. A little lump just above this patch gives evidence of an extension of the disease, in the fact that the hairs are broken off and lustreless.

Treatment.—In considering the treatment, the question of prophylaxis must first claim attention. The patient must be prevented from playing or sleeping with other children, and others must be warned against wearing his hat or his clothes. The diseased patch should be kept painted with flexible collodion containing thirty grains of chrysophanic acid to the ounce. This application is an energetic parasiticide, and has the advantage of preventing the scales from flying off and so carrying contagion. It is particularly to be commended in small and limited patches of ringworm.

MEDICAL PROGRESS.

Hydrastinin in Uterine Hæmorrhage.—Dr. Edmund Falk (*Archiv für Gynaekologie*, Bd. xxxvii., 2d part) has administered the muriate of hydrastinin to twenty-eight cases of uterine hæmorrhage from various causes.

In three cases of congestive dysmenorrhœa, with excessive flow, the results were most excellent. In one case, five days before menstruation was due, a daily hypodermic injection of about ¾ grain (.05 gm.) was given, and at the beginning of the discharge the dose was increased to 1½ grains. The period lasted but three and one-half days and was absolutely painless, whereas previously they had always been very painful and continued from six to eight days.

In another patient, who for more than twelve years had menstruated twice each month, the flow continuing with great pain from eight to twelve days, menstruation was postponed for three weeks, after beginning the injections of hydrastinin.

In nine cases of hæmorrhage from metritis and endometritis, the treatment was successful without exception.

Four cases in which bleeding was caused by disease of the adnexa, parametritis, pyosalpinx, etc., were also promptly relieved by the treatment.

Nine cases of hæmorrhage from uterine myomata were also subjected to the treatment, with success in each case.

Falk concludes from his studies that hydrastinin is a sure remedy against uterine hæmorrhage; that it is of especial value in cases of congestive dysmenorrhœa, and in menorrhagia in virgins; that in myomata, hydrastinin will control the hæmorrhage; and that the result is less sure in bleeding from chronic metritis, and is very uncertain in cases of neurotic origin.

The author employs a ten per cent. solution of the salt in water, and usually injects half a syringeful (.05 gm.)

twice weekly. In 500 injections, abscess following the operation was not seen, and rarely any irritation. It is important that hydrastinin and not hydrastin be used, as, according to Falk, the latter is a powerful cardiac depressant.

Unna's Medicated Gelatins.—Unna's gelatins are indicated in superficial inflammatory affections when the skin is swollen, moist, and itchy. Very high temperatures and profuse sweating forbid their use. For a general basis the following formula is given—the figures within parentheses being taken when a hard zinc gelatin is wanted:

R.—Zinc oxid.	15	(10) parts.
Gelatin	15	(30) "
Glycerin	25	(30) "
Water	45	(30) "

In adding other drugs the following directions may be useful:

(1) White lead, lead iodide, white precipitate, sulphur, iodoform, chrysarobin in fine powder may be mixed in any proportion required. A proportion of five to ten per cent. added to soft zinc gelatin is recommended.

(2) Carbolic and salicylic acid, resorcin, naphthol, creasote, and potassium sulphide may be added to the hard gelatin basis in any proportion up to ten per cent.

(3) Fats, balsams, tars, and ichthyol all make the basis softer. The proportion added is usually from ten to twenty per cent.

(4) If we wish to combine drugs in rules 2 and 3, then the sum of the proportions must be used. For example, if resorcin and salicylic acid were both ordered, we should not prescribe more than five per cent. of each if we wish the gelatin to form a good covering.

(5) Powders may be combined in any proportion.

(6) Tannin, pyrogallol, and oxide of mercury cannot be added to the basis.

(7) Corrosive sublimate up to three per cent., camphor, chloral, and camphor chloral, all to two per cent., extract of cannabis Indica from two to five per cent. may be used with soft zinc gelatin.

The pharmacist is to dispense the different glues in pots, which are to be put in boiling water when the preparation is to be used. It is to be painted on the skin with a long-haired brush.

The diseases of the skin for which Unna's glues are recommended are:

Pruritus.—Zinc glue with extract of cannabis Indica, chloral, carbolic acid, creasote, salicylic acid, camphor, camphor chloral, etc.

Eczema Intertrigo.—Hard zinc glue with ten per cent. of ichthyol or five per cent. of resorcin.

Eczema, with Great Itching.—Two per cent. of ichthyol or five per cent. of extract of cannabis Indica.

Desquamation after Acute Eczema.—Two per cent. of ichthyol or resorcin, five per cent. of sulphur, or one per cent. of salicylic acid.

Wounds and Ulcers.—Iodoform zinc glue.

Acne Pustulosa.—After opening the pustules paint with twenty per cent. sulphur, five to ten per cent. resorcin, or one per cent. bichloride of mercury with or without two per cent. of salicylic acid added to the zinc glue.

The soft zinc glue will form a useful protection to the sound skin near diseased areas to which strongly irritating applications have to be made.—*Medical Chronicle*, March, 1890.

Treatment of Local Syphilitic Manifestations.—Dr. G. Frank Lydston gives the following advice upon the treatment of local syphilitic phenomena (*Western Medical Reporter*, March, 1890). In treating the chancre avoid caustics and grease as a rule, and keep the part dry and perfectly clean. The only exceptions with reference to caustics are mixed sores with a minimum of induration, and sores which become sluggish and refuse to heal after induration has nearly or quite disappeared. In such conditions pure carbolic, followed by fuming nitric acid may be applied, but the galvano-cautery preceded by cocaine is better. Iodoform ointment may be used in sluggish or painful sores. The following formula will be found excellent, the odor of iodoform being completely disguised by thymol:

R.—Menthol	5 grains.
Iodoform	4 drachms.
Spermaceti	2 "
Cerate, sufficient to make	1 ounce.—M.

To be applied on lint. Where there is much pain cocaine and extract of belladonna may be added.

Black and yellow wash are not objectionable for cleansing purposes, provided the part be well dried thereafter and packed with absorbent powder. However a 1 to 500 solution of sublimate is preferable. The effects of the latter may be obtained by washing the part with a weak solution of common salt, and sprinkling with a small quantity of calomel, the two combining to form corrosive sublimate. The best absorbent is the powdered zinc oleate (P. D. & Co.) combined as follows:

R.—Bismuth subnitrate	2 drachms.
Salicylic acid	5 grains.
Zinc oleate, sufficient to make	1 ounce.—M.

Zinc oxide and lycopodium, equal parts, are also useful.

Cumbersome dressings must be avoided, especially such as require for their retention constriction of the penis.

Pronounced indurations often persist for months without ulceration, or after it has healed. Bathing in hot water, with frictions of oleate of mercury, five per cent., will dissipate them after a time. The easiest and best method is excision. The author recommends excision of all clearly-cut chancres upon the prepuce or integument. Care should be taken, however, never to excise them until they have become stationary, else recurrence is almost certain.

The roseola seldom requires attention; should, however, pigmentation be marked and lasting, hot baths, with frictions of twenty per cent. oleate of mercury will be serviceable.

Papules, tubercles, squamæ, and other dry lesions can be controlled and rapidly resolved by applications of the following formulæ. Care should be taken in selecting the proper strength—blistering may result, which, although beneficial sometimes, causes the patient to lose confidence; there is great variation in integumentary susceptibility. The collodion preparation is the most likely to blister.

℞.—Corrosive sublimate . . 5 to 20 grains.
Collodion . . . . 1 ounce.—M.

or,

℞.—Corrosive sublimate . . . 5 grains.
Comp. tincture of benzoin . 1 ounce.—M.

Apply with a hair pencil.

Tincture of tolu is also an excellent vehicle.

The results obtained by these preparations are often remarkable. They are of especial value in removing facial blemishes, hastening the removal of pigmentation very markedly.

Crusts and squamæ, if thick, are benefited by applications of ointment of nitrate of mercury. The ammoniated mercury ointment is useful in some instances, but is not often sufficiently strong.

Ulcers require some care. Ointments of iodoform, oleate of mercury, mercurial ointment, citrine and white precipitate ointment, are all of service in different cases. Occasional stimulation with nitrate of silver, or even the acid nitrate of mercury, may be required. Should ulcerations become phagedænic, Ricord's paste or the actual cautery may be used, but pure bromine is preferable. Applications of the potassio-tartrate of iron are useful in some cases—twenty grains to the ounce.

Nodes and diffuse osteo-periosteal swellings may be benefited by frictions of mercurial ointment, oleate of mercury and compound iodine ointment. Good results may be obtained from hypodermics of a solution of bichloride immediately contiguous to the swelling. A blister, followed by mercurial ointment, is often efficacious in disposing of obstinate nodes.

The obstinate headaches of both late and early syphilis, whether associated with cranial bone lesions or not, are benefited by friction of the scalp with oleate of mercury ten per cent. In obstinate cases a blister to the nuchia, followed by mercurial plaster, is quite effective.

Syphilitic iritis is greatly improved by frictions of the brow and temples with the oleate. Care is necessary lest the ointment get into the eyes, as it is extremely irritating. Occasional bathing of the eye in a solution of the bichloride, 1 : 20,000 is of service. In case it becomes necessary to blister the temples, mercurial ointment should be applied to the raw surface.

Mucous patches and fissures of the mouth, if very painful, should not be cauterized until their irritability has been in a measure allayed; they then require cauterization. The best application is the acid nitrate of mercury; in some cases, however, the nitrate of silver is better. Obstinate tubercular lesions and post-ulcerative thickenings should be destroyed by the galvano-cautery, as transformation into cancer is possible.

In irritable oral, lingual, and pharyngeal lesions, the following is the best application:

℞.—Carbolic acid . . . . 10 grains.
Resublimed iodine . . . 5 "
Menthol . . . . . 10 "
Oil of eucalyptus } of each 2 drachms.
Glycerite of tannin }
Boro-glyceride sufficient to make 1 ounce.—M.

Apply with a brush.

Condylomata and mucous tubercles disappear under the collodion or benzoin and bichloride mixture already mentioned. Condylomata and mucous tubercles mean local irritation and filth, both of which are in great measure avoidable. Calomel and oleate of zinc are the best dusting powders for these lesions.

The Treatment of Hemiplegia.—In discussing the treatment of hemiplegia, Dr. Bastian (*Lancet*, March 8, 1890) writes that while in the apoplectic condition, the patient should be put in a recumbent position in a cool room, the head and shoulders being well raised; and if there is much heat and throbbing about the head, cold applications or an ice-bag should be applied and the legs and feet wrapped with flannel and hot bottles applied. If the face be much flushed, some sedative, such as twenty grains of potassium bromide and four or five minims of the tincture of aconite, should be given to calm the circulation and thus help to check further bleeding. Cases of apoplexy often admit of very little being done in the early stages in the way of direct treatment, because of the great difficulty in diagnosing between cerebral hæmorrhage and incipient softening due to thrombosis. Some physicians are apt to think—and the less experienced they are the more they are apt to think—that hæmorrhage and incipient softening are diagnosed very readily; that there is not, in fact, much difficulty in distinguishing the one from the other.

In cases of thrombosis nothing should be done to lower the tension within the vascular system, which, indeed, should be increased so as to assist in opening up the anastomosing channels and thus help to diminish the area cut off from its blood-supply. The patient requires stimulants in moderate amount, digitalis with ether or aromatic spirit of ammonia, to strengthen the cardiac action. But if the conditions are due to hæmorrhage, this treatment would be harmful to the patient. For in that case the action of the heart should be depressed and the tension within the vessels diminished. The indications are diametrically opposite during the comatose conditions due to hæmorrhage and to thrombosis respectively. In certain cases it may be clear that we are dealing with embolism, as in the case of a child with valvular disease of the heart and paralysis coming on abruptly. But in a large number of cases it is not safe to act in any very decisive way, and therefore the treatment should not be active.

The Prevention of Urethral Fever.—Mr. G. Buckston Browne (*British Medical Journal*, March 15, 1890), in a paper upon the treatment of retention of urine, expresses his views upon the etiology and treatment of urethral fever. The theory of the causation which he adopts is that catheter fever is a nervous fever entirely due to urethral shock, communicated through the nervous connections to the excretory apparatus of the kidneys and producing all degrees of suppression of urine from the most transient to the most complete. He is satisfied that it is not due to the absorption of urine through a urethral wound, for the passage of a fine bougie through the stricture is often followed by high fever, while a free division of the stricture with a knife is followed by little or no elevation of temperature. He does not consider it septicæmic because it may come on directly after the passage of an instrument, and, moreover, patients may live for years with their bladders full of fœtid urine and without signs of septic poisoning. If his is the true theory, the author considers it evident that gentleness of manipulation is exceedingly important.

Of drugs which have a prophylactic influence, he believes opium, morphine, and codeine to be the most valuable. He has often found that when the passage of a catheter is followed by high fever, in the same individual and with the same instrument no fever follows the procedure if a small dose of morphine has been previously administered. If the preparations and derivatives of opium are not well borne, small doses of chloral may be employed.

Prescription for Incontinence of Urine.—GRISOLLE recommends the following pills in cases of incontinence of urine:

R.—Extract of nux vomica . . . 3 grains
Black oxide of iron } of each . 45 "
Pulverized quassia }
Syrup, sufficient quantity. —M.

Divide into twenty pills, of which from one to three may be given daily.—*L'Union Médicale.*

Prescription for Pigmentation of Pregnancy.—The following ointment recommended by MONIER is quoted in the *Internationale klinische Rundschau:*

R.—Cacao butter } of each . . 2¼ ounces.
Castor oil }
Zinc oxide . . . . . 45 grains.
Ammoniated mercury. . . 2 "
Oil of rose, sufficient quantity. —M.

To be applied morning and evening.

Vaccination of Newborn Children.—DR. WOLFF has recently performed a series of vaccinations upon newborn children with human as well as animal virus, and concludes that infants are susceptible to vaccinia from the first day after birth.

Vaccination of the mother, even when successful, while the child was *in utero*, gave negative results as far as a protective influence on the infant was concerned—that is to say, after birth the latter could still be inoculated with the usual effects. The inoculations on the mother were made at various periods of time between the seventieth and sixth day before labor.

In the author's experience very young infants bear vaccination well, the course of the disease being always free from fever. A particular advantage of such early vaccination is the fact that by it the child is protected from smallpox from the first day of birth, the incubation period of the latter disease being longer than that of vaccinia.

Such being the case, Wolff believes that early vaccination should be compulsory.—*Centralblatt für klinische Medicin*, March 8, 1890.

Small Doses of Antimony in Inflammations.—SURGEON-MAJOR E. LAWRIE, of India (*Indian Medical Gazette*, January, 1890), advocates the employment of antimony in various inflammatory diseases. He believes that the physiological action of the drug is not yet understood and that further studies should be made.

In all inflammatory diseases which are not of a specific nature, antimony is always used at the Afzalgunj Hospital, and, according to the author, it may be given without fear of causing nausea, diarrhœa, or depression, even in diseases where its use would seem contra-indicated. For example, during the past year it has been given with unfailing success in mucous enteritis, which is of all diseases the most fatal to children on the plains of India. In these cases it arrests the diarrhœa and fever when nothing else will do so. Dr. Lawrie has also used it lately in the treatment of typhoid fever, and makes the startling statement that it cuts the disease short with such certainty that it almost appears doubtful whether the lesions of typhoid are not rather incidental than specific. In typhoid fever, no less than in mucous enteritis, the diarrhœa depends upon an inflammation of the intestine, and though it might be thought that antimony would increase the diarrhœa, it in reality stops it, for the simple reason that it arrests the inflammation.

It has no depressing effect upon the heart unless given in doses that ordinarily produce nausea and diarrhœa.

Dr. Lawrie does not state clearly the dose usually given, but in one case, a girl of eleven years, suffering from typhoid fever, he administered 15 minims of antimonial wine every hour until twelve doses had been taken.

Cocaine Anæsthesia in Surgical Operations.—DR. ALBERS (*Centralblatt für die Gesammte Therapie*), after considerable experience with cocaine in major surgery, concludes that a five per cent. solution is the proper strength with which to secure local anæsthesia, even in operations lasting as long as three-quarters of an hour, as in the enucleation of large tumors. Stronger solutions are not necessary, and in the future he will not use them. With adults, a five per cent. solution, properly applied, is preferable to chloroform as an anæsthetic, being safer and more prompt in its action.

In the same journal is described the method of DR. ZWAARDEMAKER for anæsthetizing the nasal cavities previous to operations, or to the passage of a Eustachian catheter. This author uses pulverized starch containing from five to ten per cent. of cocaine. To the anterior nares the powder is applied by means of a feather; to the naso-pharynx, by insufflation through a curved glass tube.

Preparation of Aseptic Catgut.—BRUNNER has recently studied the methods of disinfecting catgut for surgical purposes (*Schmidt's Jahrbücher*, Number 3, 1890) and believes that *raw* catgut is easily rendered aseptic. His method of preparing it is as follows: The catgut is first scrubbed with a potash soap, then placed for twelve hours in ether, and then for a time in a 1 : 1000 watery solution of sublimate. It is preserved in a solution composed of sublimate 1 part, glycerin 100 parts, absolute alcohol 900 parts. Before using, the gut must be placed in 1 : 1000 watery sublimate solution.

The author's experience with gut prepared in this manner shows that it is absolutely safe and unirritating to the tissues.

Referring to the use of silk and linen sutures and ligatures, Brunner says that though they may be thoroughly disinfected by boiling, experience has shown that even then, if placed deeply in the tissue, they will occasionally excite suppuration.

SATURDAY, APRIL 12, 1890.

THE EFFECT OF HEAT ON THE RED BLOOD-CORPUSCLES.

No fluid of the body is more open to inspection than the blood, and the simplest apparatus suffices for its study. With nothing more than a microscope and a glass slide the tyro may observe the protean transformations which the expert cannot interpret. This fatal facility has betrayed many an unwary observer into the commission of curious mistakes, and, as a result, much hæmatological work has been spent in the unfruitful field of controversy.

As an example of the obstacles in the path of the hæmatologist, it need only be mentioned that one authority regards the so-called hæmatoblasts as of vital importance, while another degrades them to the rank of products of decomposition and claims, with great show of reason, to be able, by variations in his *technique*, to cause or to prevent their appearance.

It is no wonder then that announcements of discoveries in this field of research, even when made by those whose work has already been stamped with approval, are received with a certain amount of scepticism, for experience has abundantly shown that this attitude is, at least provisionally, the only proper one to assume.

The dictum of Galen with reference to the spleen —that it was an organ *mysterii plenum*—is certainly at the present day more applicable to the blood, for many problems concerning the origin and destruction of its component parts still await solution.

The border-lines between disease and health are probably more faintly traced in the blood than in any other tissue or fluid of the body. This fact is manifestly of the utmost importance in the interpretation of what are supposed to be morbid appearances, and it is owing to its oversight that many fatal blunders have been made. The mere preparation of a blood specimen may give rise to alterations in the corpuscles, which simulate most closely those universally recognized as morbid.

A remarkable simulation of morbid appearances is produced by the application of heat to the red corpuscles, the changes thus brought about closely resembling those so often described in the journals as characteristic of malarial poisoning: 1. If a fresh preparation of blood be held for a few seconds over the flame of an alcohol lamp, many of the red corpuscles may be seen to contain one or more *hyaline bodies*. 2. A certain number of these bodies escape from the corpuscles and may unite with others in pairs, so as to simulate diplococci; or in chains like streptococci. 3. Many of the corpuscles are deformed in various ways, some resembling a tadpole, others a leech, a cocked hat, etc.

The most interesting change, however, consists in the formation of flagella, some of which are attached to red corpuscles, others to the free hyaline bodies above mentioned, while still others are entirely free. These flagella are possessed of a decided undulatory movement.

These effects of the application of heat to the red corpuscles are well described and figured by Talamon in a recent article (*La Médecine Moderne*, March 6, 1890).

The significance of these alterations of the blood is twofold. In the first place, they are singularly like the changes produced in the blood by the hæmatozoon malariæ, and, secondly, heat, the agent producing them, is constantly employed in microscopical *technique*.

Talamon has plainly shown that, in the microscopic preparation of blood, heat is to be used with great caution or dispensed with altogether if serious errors are to be avoided.

NURSES AND THEIR TRAINING SCHOOLS.

In another column we print an interesting letter from one whose name always insures a hearing. Mrs. Turner's services to the public, in very many

ways, are so widely recognized and appreciated, that we are always pleased to answer any such questions as are referred to in her letter.

Nursing has become so important a part of the practical applications of medicine to the relief of suffering, that anything which will help to elucidate the problems which have come up in the new régime is of great importance to the sick, as well as to our own profession. The days of the untrained nurse are numbered. The large number of intelligent, educated, and refined women who are entering into nursing as a profession is a most healthful sign of the times. The establishment in this and other cities of directories for nurses, which correlate nurse, patient, and doctor, is one of the greatest advances in making nursing practically useful, and nurses quickly available. During the last year the Directory for Nurses in Philadelphia sent out 1326 nurses, many of them to distant parts of the country, and has supplied a want, strange to say, but little appreciated, though long in existence and recognized.

Turning to our correspondent's letter, it would certainly be desirable that nurses trained in special hospitals only, should not be sent for private nursing to other cases than those allied to the class in which the nurse has received her training. Lectures without clinical and practical instruction cannot insure general competency. Of course, there is a certain substratum of nursing common to all cases of disease, and a certain general qualification of the nurse which would warrant the over-stepping of this rule in special cases.

In reply to the second question, we can only state that at the Directory for Nurses the course of instruction of each training school for nurses and the other facilities for training are inquired into, and if found satisfactory, the diploma of such a school is considered, and we think rightly, a sufficient guarantee of the nurse's competency. A reasonable criterion of education and refinement should be required of each applicant before entering a training school, and we take it for granted that this would always weigh largely with a judicious superintendent of any training school. The personal manners of the nurse should always be taken into account, especially at present, when happily not a few ladies by birth and breeding are taking up nursing as a calling.

Cooking is an essential part of the nurse's education, and no one should obtain a diploma without having received instruction in this branch.

Our correspondent well asks, "What is the philosophy of making so large a part of a nurse's life in the hospital consist of common drudgery?" We confess that there is no philosophy in it, and would urge training schools, so far as possible, to eliminate such drudgery from a nurse's life. We can readily understand that there is, however, in such schools a preponderating reason which may necessitate such a departure from philosophy, and that is, the question of economy. They must live within their means; and this may require the nurses to do the common housework until the friends of the schools provide larger means.

The remaining three questions can, perhaps, be answered together. That nurses are overworked by having too many patients, by too long hours of service and too little rest, is unquestionably the case—at least at times—and in a hospital they are very apt to be so overworked, occasionally it may be for many days consecutively. Precisely the number of patients a nurse can attend to, with justice to them and herself, will vary not a little; but certainly, of ordinary cases, from eight to twelve would be all that a nurse ought to attend, and the smaller number rather than the larger. A colt should not be overtrained at the beginning of its career on the turf, and still less a woman at the beginning of her career as a nurse. The Indian mode of eliminating the weak alluded to by our correspondent will often tax and test the vitality of the strong to a dangerous extent, and may readily lead to later disease.

We must remember, however, that on the other hand something must be said for the training schools. The weak and the lazy form a large proportion of mankind, and nurses are not exempt from the ordinary frailties of human nature. The exigencies of hospital service are very many, and are not a bad preparation for the exigencies of private nursing, which not uncommonly test a nurse's powers of endurance even more than the nursing in a hospital. Good judgment and reasonable requirements are all that either side should demand.

While alluding to this question, we cannot refrain from adding one more word, namely: that it is a great pity that thus far the training of nurses has been exclusively for women. One of the best signs of the times is the recent establishment in New York of a similar school for men. We would commend this to the charitable in this city, as well as elsewhere. While, of course, there will never be the same demand for male nurses as for female, yet

those that are needed should be as well trained as women.

TYPHOID FEVER AT CUMBERLAND.

In another column we publish an account, obtained by sending a special correspondent to the spot, of the outbreak of typhoid fever which for four months has ravaged the town of Cumberland, Maryland. As will be seen by this article, the entire outbreak is dependent upon absolute disregard of the common laws of nature and health, and of the entrance into the water of a specific germ before the sickness which was prevalent became typical of enteric fever. Another interesting addition is made to our knowledge of the spread of diseases and their dependence upon an individual cause in many instances for their existence, and the world at large is treated to the sight of a fairly intelligent body of citizens establishing a vicious circle between their mouths and the drainage of their houses and pig-styes.

REVIEWS.

The Year-book of Treatment for 1890. A Critical Review for Practitioners of Medicine and Surgery. 12mo., pp. 324. Philadelphia: Lea Brothers & Co.

The *Year-book* for 1890 possesses all the excellent features which in past years have won a recognized and important position for the publication. The general plan of the book is the same, and the only change noted in the list of contributors is the absence of the name of Dr. Sidney Coupland, who contributed an excellent section upon anæmia to the issue of 1889.

To those who are unfamiliar with the work it may be said, that it is a careful and complete review of the advances made in the treatment of all diseases—medical, surgical, and special; and that the description of each new method of treatment is commented upon by the editor of the section. In the present progressive state of medical science some such work is a necessity, and none can be found that is more satisfactory than the one under consideration.

Vaccination: its History and Pathology. Vols. I. and II. By Edgar M. Crookshank, M.D. 8vo., pp. 466 and 610. Philadelphia: P. Blakiston, Son & Co., 1889.

It is seldom that an opportunity is offered in which the reviewer can give so much praise, leavened by so little blame, as in this instance. The book which Dr. Crookshank has written bears upon each page evidences of the most laborious research and thorough understanding of the subject with which it deals. Not content with the collection of facts from outside sources, he has in every instance obtained his information either from the manuscript of the author whom he quotes, or, at least, from the authorized version of the writer's publications. Unlike most books of its character, which are too frequently gotten up in such a way as to command popularity among the profession or laity, this work has been written with absolute disregard of everything else except exactitude and correctness of assertion.

The interest which attaches to its pages is very materially increased by the reproduction of autographic letters of the illustrious Jenner, and other eminent men of his time, in regard to vaccination; while the front page is embellished by a handsome picture of Jesty. In order that the description of the cow-pox may be understood, handsome colored plates are scattered here and there, illustrative of the text; and while it is only in rare cases that colored plates convey to the reader a clear idea of a disease-process itself, we think that in this instance the artist has been peculiarly fortunate.

Braithwaite's Retrospect of Medicine. Vol. C., July to December, 1889. London: Simpkin & Co.

The medical profession, both in the United States and Great Britain, are so thoroughly familiar with Braithwaite's *Retrospect*, which for fifty years has semi-annually brought to them the substance of medical progress, that anything which we can say of it is superfluous, the only object in mentioning its appearance being to announce formally its having come once more to this office.

An Essay on Pneumatology. By J. N. Demarquay. Translated, with Notes, Additions, and Omissions, by Samuel S. Wallian. 8vo., pp. 300. Philadelphia: F. A. Davis, 1889.

The constantly increasing frequency with which oxygen and other gases are now employed, either in solution or in the form of gas, for the treatment of diseased conditions, renders the appearance of this book of interest, although it was written a number of years ago, and though an entire part of the original work has been omitted by the American translator. We are glad that the profession in this country may obtain, at a moderate price, full directions as to the employment of gases as medicinal agents. The subject is considered with the thoroughness which is only seen in the Continental writings; and after the consideration of the physiological action of oxygen, the remaining gases are taken up, such as nitrogen and hydrogen, and their employment in both medicine and surgery is given in considerable detail. It seems to us that, while these gases are of great value in certain instances, their best friends are, in reality, their worst enemies, since by their universal recommendations in all diseases, failure in some instances is bound to occur. Perhaps this fault may exist to some extent in the book before us, but it is not such a prominent feature as it generally is in such works. Altogether, the book is a valuable one, which will be found of service to the busy practitioner who wishes to keep abreast of the improvements in therapeutics.

The Long Island College Hospital.—At the graduation exercises of this college, held March 13th, fifty-five candidates were granted diplomas, among whom was a native of China.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Section on Theory and Practice of Medicine.

Stated Meeting, March 18, 1890.

FRANCIS DELAFIELD, M.D., CHAIRMAN.

PULMONARY CONSUMPTION IN THE LIGHT OF MODERN RESEARCH.

In a paper with the above title, DR. S. S. BURT reviewed the recent studies upon this subject, dwelling more particularly on the important questions of infection and prophylaxis. He said that while his experience had led him to believe that pulmonary consumption was not contagious in the ordinary acceptation of the term, there was abundant evidence to show that those who were long and intimately associated with phthisical patients were liable to contract the disease; and he instanced in support of this assertion the high mortality existing in certain cloisters, where as many as fifty per cent. of the inmates died from the disease. Absolute safety could only be secured by segregation. He had great hopes for the future from Koch's discovery.

The paper was followed by a lantern exhibition by DR. DR. J. H. LINSLEY, who illustrated the appearance of tubercular tissues and bacilli by an unusually fine series of photo-micrographs.

In the discussion which followed, most of the speakers felt called upon to consider the question, "What is the use of Koch's great discovery?" Their answers embraced the two extremes of enthusiasm and despondency.

DR. A. JACOBI, who opened the discussion, spoke particularly of the question of the direct transmission of the disease by inheritance. There was an inherited predisposition, as shown by congenital deficiencies in the lungs, the circulatory apparatus, and the conformation of the chest. He cited the views of a number of eminent pathologists, showing that the general opinion among them was against direct transmission. Nevertheless, in five out of eight cases, one investigator had found tubercle bacilli in the spermatic canal and in the prostate of phthisical individuals, although there was no tubercular process in this particular locality.

DR. W. H. DRAPER thought that Koch's discovery had contributed but little toward mitigating the great scourge of tuberculosis and that it had even complicated the subject. The *role* played by the bacillus in this disease had not yet been definitely determined; for, in certain localities, and under certain conditions, it seemed to be comparatively harmless. Thus it was that the bacilli were present in the glands, and in lupus for long periods, without giving rise to any serious symptoms. Even in the lungs, where they usually gave rise to grave disorder, one occasionally found only a circumscribed process which eventually terminated in complete recovery. It had been suggested that phthisis was a mixed infection, and that the bacillus itself must come in contact with some other organism before it could cause general infection. The bacilli were far too widely disseminated for us to hope to exterminate them; and although we had reason to believe that dried sputum was a very common medium for the spread of the disease, he doubted very much whether it would be possible to control the American habit of expectoration. The discovery of the tubercle bacillus had helped us, chiefly by giving more definite and cogent reasons for urging our patients to avail themselves of the advantages of a change of locality.

DR. A. H. SMITH was also disposed to take a gloomy view of the situation. While the search for specifics should not be entirely discarded, it had the disadvantage of leading us away from useful and well-tried methods of treatment. He had had opportunities of watching the progress of tuberculosis in families in rural districts, and he had been led by these observations to conclude that the great mortality in such families was referable not so much to hereditary tendency, as to environment. These people lived in poorly ventilated apartments, whose furnishings often remained unchanged for generations, and so harbored the elements of contagion. If we were to accomplish anything by prophylaxis, we should begin with the little children, and our efforts in this direction were very commonly frustrated. No mention had been made in the paper about the relation between bronchial catarrh and tuberculosis. The former was often the starting-point of consumption; and the explanation might be found in the fact that it affords a favorable soil for the bacilli, or that the protection afforded by the epithelium against the entrance of these organisms is lost. In regard to treatment, he had been much impressed by the value of supplementing the ordinary methods by a resort to rectal alimentation. He had seen very remarkable results from this method.

DR. R. C. M. PAGE touched another point in prophylaxis by calling attention to the evils following the marriage of tuberculous people. He thought such unions should be prohibited, or at least restricted.

DR. J. W. ROOSEVELT, while not an enthusiast, believed that the use of Koch's discovery was already more apparent than that of many previous discoveries. If it only enabled us to save a few lives, it was still well worth knowing. It had certainly led to much foolishness; but it had given a point upon which in the future we might build up a method of treatment, both prophylactic and curative. It had certainly taught us that it was our duty to destroy the bacilli as far as possible; and, although we might be unable to control the national habit of expectoration, it was none the less our duty to win over as many as possible to the new order of things, and make them spit into the fire, or into receptacles which could be afterward burned. Among the most foolish methods of treatment which have claimed the attention of the profession in recent times, were the use of gaseous enemata and hot air. The latter method was particularly absurd, and was advocated in defiance of well-known principles of physiology and physics. The cooling power of the lungs, from the presence of so much air, and of the constantly circulating blood, was so great, that it was easy to see that it would be a difficult matter to raise the temperature of this air to any great degree. Moreover, the specific heat of water is high, and the latent heat is 54° C.; hence, if the air reached the temperature claimed by the advocates of this method, the albumin of the blood would be coagulated. In accidents from the bursting of steam-pipes, the steam must be below 212° F., or else it would not appear as a visible vapor; and yet such patients were severely scalded, and

often suffered from a complicating pneumonia. It had not as yet been made clear why pulmonary phthisis should attack by preference the upper lobes of the lungs; and there seemed to be no mechanical, or other reason, why the bacilli should lodge there more abundantly. It had been said that these portions of the lungs had a more limited movement; but if so, they would receive less air, and, therefore, fewer bacteria. Others had claimed that the upper lobes were deficient in expiratory power; but this theory was still more perplexing; for, if such were the case, the air would necessarily accumulate, and ultimately cause a rupture of this portion of the lung. It had been recently shown that fresh blood-serum contained something which was capable for a short time of destroying bacteria. It was not impossible, therefore, that we might be able to find some such substance, which, when supplied to the blood-serum, would result in the destruction of the bacilli.

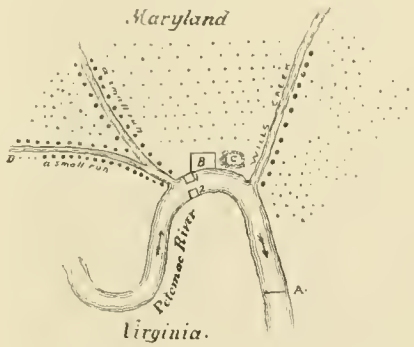
Dr. E. F. Brush related an interesting experiment which he had made while endeavoring to raise tubercular chickens. Six laying hens were set apart and fed exclusively with the lungs from a cow that had died of acute miliary tuberculosis. At the end of seven days, one hen was killed, and tubercular deposits and bacilli were found. The twenty-six eggs which had been laid by these fowls were removed to another part of the farm, and set under other hens. Twenty-five of the eggs developed chicks, but not one was hatched alive. If he had anticipated such a result, he would have made use of control experiments at the same time. There were certain cows which were always "in heat," and no matter how often served with the bull, they never became pregnant. He had removed the ovaries from three such, and had found them tubercular. He had lost no opportunities of examining fœtal calves from tuberculous cows, but he had never seen in them the gross appearances of tuberculosis.

SPECIAL CORRESPONDENCE.

THE TYPHOID FEVER EPIDEMIC AT CUMBERLAND.

Since the early part of December, 1889, the town of Cumberland, Maryland, has been subjected to an epidemic of enteric fever closely resembling in its cause and course that which occurred at Plymouth, Pennsylvania, some five or six years ago. While the mortality has been by no means so high, the causes of the disease are strikingly similar in both cases. Cumberland is a town of several thousand people, situated upon the Potomac River in a valley, with steep and rather precipitous mountains surrounding it. The town depends for its existence chiefly on the railroads which centre there, the largest of which is the Baltimore and Ohio. The population is a "railroad population," and is made up largely of persons in the middle walks of life. The drainage of the streets is surface drainage, and even this is exceedingly bad, while the rainfall is somewhat excessive and the entire town damp.

It will be seen, therefore, that in this instance a peculiarly favorable soil for such an epidemic was present, and the townspeople have, with a disregard of the plainest rules of sanitation, simply brought the disease upon themselves, as the following diagram and description will show.



Dots represent houses in Cumberland.
Heavy dots represent privies.
A. Dam.
B. Water-works.
C. Garbage lot, with pigs feeding.
D. House where first case appeared.
1. Supply pipe, supposably closed.
2. Supply pipe, supposably open.

It will be seen that a line of privies, a mile long, empty directly over the bank into Will's Creek, this part of the town being made up of the poorest classes, and that two other lines empty themselves into the two small "runs" to the left of the diagram, while the entire drainage of the remaining houses eventually reaches the same streams, though not so directly. The position of the pumping station *B* is about two hundred feet below the mouth of the two runs and on the same side of the stream, on the periphery of the bend. From the point where Will's Creek empties into the pool, formed by the dam, to the pumping station is about one hundred yards, and this space is covered on the shore by several acres of garbage over which pigs roam freely. If engineers had wished to plan a means of pumping sewerage into a town instead of away from it they would not have succeeded more completely. But the stupidity permitting such an arrangement in the first place outdid itself some months later when a "Philadelphia expert" arranged to have the pipe from the pumping station carried to the opposite shore to get the water before it was contaminated. As the stream is only about one hundred to two hundred feet wide this is, on the face of it, absurd since the pool formed by the dam consists in quiet water and not water rapidly flowing. Again, the mouth of the pipe being now on the short side of the bend soon became occluded by the mud deposited there, while the water of the stream naturally followed the outer part of the course and kept the channel free. After

the epidemic was established the city engineer found the pipe on the Virginia shore bent out of place and buried under six feet of mud, and that all the water supplied to the town was obtained from the old pipe on the sewage side of the stream.

Having given an account of the water-supply, let us turn to another interesting portion of this outbreak. Typhoid was not present until the discharges from a case of typhoid fever, living on one of the little runs at *D*, found their way into the city supply, although it is to be noted that a large amount of diarrhœa of a dysenteric type had been epidemic, and is now prevalent. In other words, the drainage of a large number of privies caused diarrhœa and dysentery, but it required a case of the specific disease named to cause an outbreak of that affection.

The mortality of the outbreak has been, so far as could be learned, about ten per cent., and the character of the cases has usually been pretty severe. In many instances the rash was present in extraordinary degree, though in others it was almost absent. Epistaxis has been an unusually common symptom, and the chief complications have consisted in intestinal hæmorrhage and hyperpyrexia. The hæmorrhages have usually been severe.

Dr. W. W. Wiley told your correspondent of an interesting case showing that the town water is at fault. A young woman, belonging to a family who used well-water exclusively, insisted upon drinking the river water, and was taken with typhoid fever, from which she suffered seven weeks, while the rest of the family escaped. Dr. Wiley also said that he had seen no case in which the disease occurred where well-water was used, and this was found to be the experience of many others. The epidemic is now less severe, but, for some unknown cause, no means are being actively taken to remedy the trouble.

CORRESPONDENCE.

BOSTON.

To the Editor of The Medical News,

Sir: During the last few days two medical meetings have been held in this city, which were practically devoted to the subject of hypnotism.

At the first meeting, that of the clinical section of the Suffolk District Medical Society, Dr. Prince read a paper treating the subject from the psychological and philosophical sides rather than as a question of practical therapeutics. This paper was followed by the exhibition of two cases, both rather sensitive and showing the phenomena of post-hypnotic suggestion, illusions, and the like. Both of the cases were diseased, one perhaps having locomotor ataxia, the other having hemianopsia, hemianæsthesia, and optic neuritis of long standing—in short, the lesions pointing to organic trouble at Charcot's sensory crossway. The point of chief interest was, perhaps, that the second case, when in the hypnotic state, apparently had perfect sensation on the anæsthetic side. Dr. Prince, while not committing himself to any theory, was clearly inclined to entertain the idea of a second consciousness, brought out by hypnotism, which recognizes, but is not recognized by the normal state, and he gave several experiments in illustration. These were certainly suggestive of such a state, but seemed to the writer, as well as some others, to be more of an index of Dr. Prince's skill in imbuing the subject with his ideas.

At the second meeting, that of the Boston Society for Medical Improvement, Dr. Osgood read a long paper on the history and therapeutic value of hypnotism followed, of course, by illustrations. Dr. Osgood being a pupil and strong advocate of the Nancy school, made no extraneous suggestions, and simply showed various states of hypnotic sleep. As to treatment, Dr. Osgood disclaimed all effect on organic disease, but reported thirty-four cases, including paralysis, hysterical bronchitis, indigestion, constipation, and the like, as much improved or cured with but few exceptions.

A discussion then arose, which, but for the late hour, would have been both earnest and long. Dr. Knapp opened the debate for the opposition by doubting the legitimacy of hypnotizing patients for ordinary ailments—placing it more among the measures of last resort. Dr. Knapp also objected to the Nancy doctrine of the close connection between, or identity of the hypnotic state and sleep, in so far supporting the tenets of the Salpêtrière, and held that suggestion is not the sole cause since animals are susceptible to hypnotism. Dr. Knapp was supported by Drs. Stedman and Folsom, the former holding that there was a distinct tendency to induce a permanent semi-hypnotic state, the latter that as in the mind and faith cure, the time would soon come when patients would return to be cured of the cure.

The question was also raised as to how suggestion cured all varieties of indigestion; one, due to too much acid, another to too little, a third to organic fermentation, and so on; did the patient make an analysis, correct the chemical failure, and eject the offending germ, or must the results of modern studies of stomach troubles be discarded?

In closing, Dr. Prince strongly supported Dr. Osgood, and with him denied all bad effects.

THE TRAINING OF NURSES.

To the Editor of The Medical News,

Sir: At a recent meeting of the New Century Guild of Working Women of Philadelphia, a number of whose members are trained nurses, we endeavored to consider the following questions, and, finding them too difficult for us, we should like to submit them to some higher authority. Any enlightenment on these subjects would be gratefully received by our Society.

1. Would it be right for nurses who have received their training in a hospital devoted wholly or chiefly to special cases, to be sent to general cases in private families? As, for instance, one from a surgical hospital to a nervous case—one from a hospital for nervous diseases to a maternity case, etc. This question does not refer alone to the danger of carrying disease, but to the probable competency of the specially trained

nurse to manage cases outside her specialty. Would the fact of her having listened to a course of lectures on general nursing, without clinical or other practical instruction, insure her general competency?

2. Is the possession of a diploma from some medical institution considered a sufficient guarantee of the competency of a nurse, or must she have the written endorsement of some physician, under whose eye she has worked in her hospital or training school?

3. Is there any criterion of education or refinement for the admission of applicants to instruction in nursing? Would it be proper to admit a woman, however honest, sober, and healthy, whose ignorance, uncouthness, loudness, and general unfamiliarity with the niceties of household life would make her objectionable in a sick room? May not the personal manners of a nurse be sometimes a matter of vital importance to the patient?

4. Is delicate cooking an essential part of a nurse's education? Is she expected to be able to prepare, or oversee the preparing, of whatever special food is ordered for her patient? Is this made so essential that she cannot get her diploma without it?

5. What is the philosophy of making so large a part of a nurse's life in the hospital consist of common drudgery? After she has once learned, as she certainly ought, to make a fire, wash dishes, wash and scrub a floor, etc., would it not be better to relieve her of such work, and thus allow her more time than she can now command for the higher parts of her profession—notably dainty cooking?

6. To how many patients, excluding cases exceptionally hard or easy, can the average nurse do justice, without injustice to herself? And would not the practice, in any institution, of exceeding the adjudged number, result in breaking down the very conscientious, and making habitual shirkers and slovens of the rest?

7. Is it well to make the preliminary training of a nurse so hard, her hours so long, her running up and down stairs so incessant, her allotted time of rest so disregarded, the number of patients under her care so large that she must either neglect them or drive along until she herself begins to waste the hospital's time, by dropping into one of the cots for repairs? Are there not, in most hospitals where nurses are taught, too large a proportion who break down before graduating?

8. If it should be answered to the last question that nobody is wanted as a nurse whose constitution will not bear such strains, on the principle of those Indians who subject their children to great hardships, arguing that the strong will stand it and that the weak should die, we still might ask—Is it not possible that the Indian treatment often plants the seeds of future feebleness, even in those who survive? And may it not be that many young women who would have proved capable of the care of any cases they were likely to meet outside, are broken in strength by the tests, unnecessarily severe, to which they are subjected in their preliminary training?

Eliza S. Turner.

THE COMBINATION OF ANTIPYRINE WITH SWEET SPIRITS OF NITRE.

To the Editor of The Medical News,

Sir: The combination of antipyrine with sweet spirits of nitre, as you are aware, has the effect of producing a precipitate, which causes a loss of activity in proportion as the antipyrine is affected by the chemical change. It has been reported that this precipitate is not poisonous, and that the combination may be used without injury to the patient, the sole effect being upon the antipyrine. Through information gained from a friend, who is now a student in pharmacy, and has had occasion to investigate the matter, I have learned that this chemical change can easily be avoided, and I desire to lay the matter before the readers of this journal.

Upon the addition of antipyrine to sweet spirits of nitre a dull, greenish precipitate is thrown down, which, for want of a better name, has been called "iso-nitroso-antipyrine," a substance which has been demonstrated to be insoluble in water, alcohol, or any of the stronger acids. Ordinarily, when antipyrine is added to sweet spirits of nitre, and the precipitate falls to the bottom, the supernatant liquid is at first yellowish, then bluish, and after keeping for some time it turns a deep red, the same color as that produced by the addition of ferric chloride to antipyrine. The cause of this discoloration may be attributed to the acidity of the nitre, due to the decomposition of the ethyl nitrite by the slow absorption of water from the atmosphere, and this is apparently prevented by neutralizing this acidity of the nitre (nitrous acid?) by the addition of ammonia water, in the proportion of two drops to the ounce of nitre, before the addition of antipyrine. The solution thus prepared is colorless, and will remain so until the volatilization of the ammonia water, and it is believed that no deleterious effect is produced from a therapeutic standpoint, as will be the case when this precaution is omitted.

In order to test the question practically, I have had a solution of antipyrine and sweet spirits of nitre prepared in the proportion of half an ounce of the latter to fifteen grains of the former, together with one drop of ammonia water, and although it has been standing where the temperature is about 80° F., I have noticed no change at the end of a week, except a slight, colorless sediment; the solution still gives the odor of nitre and of ammonia, and I am disposed to think that if properly corked, it would remain in its present condition for weeks. Where antipyrine and sweet spirits of nitre are ordered together, it will be advisable to have the acidity of the nitre neutralized before the addition of antipyrine, and then caution the patient that the medicine should be kept in a well-stoppered bottle and in a cool place, so as to postpone the evaporation of the ammonia as long as possible.

John Aulde, M.D.

1910 Arch Street, Philadelphia,
March 29, 1890.

NEWS ITEMS.

Adirondack Sanitarium.—The results of the "cottage plan" of the treatment of phthisis pursued at the Adirondack Sanitarium, at Saranac Lake, New York, as shown in their last report, are such as should encourage the founding of similar institutions in other equally favorable localities. Of the 96 patients under treatment during the past nine months, 1 died, 11 who continued to lose ground were returned to their homes, 17 have somewhat improved, a similar number have been restored to lives of usefulness, and 8 are thoroughly cured. The patients now under treatment number 42. The financial condition of the institution continues very satisfactory.

Southwestern Ohio Medical Society.—The semi-annual meeting of the Southwestern Ohio Medical Society will be held at Springfield, O., on April 17th and 18th. An excellent programme is announced. Physicians of that section of the State should certainly attend.

Revision of the United States Pharmacopœia.—The following has been received from Robert Amory, M.D.:

The convention for the revision of the United States Pharmacopœia will be held in the city of Washington, May 7th, at noon. As it is necessary that some preliminary arrangements should be prepared in advance of the convention I have taken upon myself the responsibility of appointing the following delegates to act as a Committee of Arrangements:

Dr. Samuel C. Busey, Dr. C. H. A. Kleinschmidt, Dr. Robert T. Edes, of Washington; Mr. P. W. Bedford, of New York, and a committee appointed by the National College of Pharmacy of the following members: W. S. Thompson, J. A. Milburn, and S. E. Waggaman, M.D.

As soon as arrangements are completed, a circular will be mailed to each organization whose credentials are received by me before April 10th, and to any delegate who will forward his address on a stamped envelope enclosed to me.

Medical Association of Missouri.—The thirty-third annual meeting of the Medical Association of Missouri will be held at Excelsior Springs, Clay County, Mo., May 6, 7, and 8, 1890. The officers for the year are: President, L. I. Mathews, of Carthage; Vice-presidents, Jacob Geiger, A. B. Miller, N. Guhman, J. F. Robinson, and W. C. Tynee; Recording Secretaries, J. C. Mulhall and Joseph Sharp; Corresponding Secretary, J. R. Fritts; Treasurer, C. A. Thompson.

State Medical Society of Arkansas.—The fifteenth annual meeting of the State Medical Society of Arkansas will be held at Little Rock, May 14th, 15th, and 16th.

Liabilities for Injurious Patent Medicines.—The Supreme Court of Georgia has just rendered a decision, says the *New York Herald*, which is likely to attract widespread attention, and to have a salutary effect on the preparation of patent medicines. It holds that the proprietor of such a preparation is liable to damages for injury done to any person who takes the medicine according to directions.

This liability does not fall upon the druggist who sells the medicine, but upon the proprietor, even when the consumer buys not from him directly, but from the druggist. Here is the view the court takes of the matter:

"These proprietary or patent medicines are secret or intended by the proprietors to be secret as to their contents. They expect to derive a profit from such secrecy. They are, therefore, liable for all injuries sustained by any one who takes their medicine in such quantities as may be prescribed by them.

"There is no way for a person who uses the medicine to ascertain what its contents are ordinarily, and in this case the contents were only ascertained after an analysis made by a chemist, which would be very inconvenient and expensive to the public.

"Nor would it be the duty of a person using the medicine to ascertain what poisonous drugs it may contain. He has a right to rely upon the statement of the proprietor, printed and published to the world; and if, thus relying, he takes the medicine, and is injured on account of some concealed drug of which he is unaware, the proprietor is not free from fault, and is liable for the injury thereby sustained."

Invitation for a Medical and Scientific Exhibition at the Approaching International Congress.—In connection with the Tenth International Medical Congress to be held in Berlin, between the 4th and 10th of August, there is to be an International Medical and Scientific Exhibition. The exhibits will be of an exclusively scientific nature, as follows:

New or improved scientific instruments and apparatuses for biological and strictly medical purposes, inclusive of apparatuses for photography and spectral analysis as far as applicable to medicine.

New objects and preparations in pharmacological chemistry and pharmacy.

New foods.

New or improved instruments subservient to any of the departments of medicine, including electrotherapy.

New plans and models for hospitals, convalescent homes, and disinfecting and bathing institutions and apparatuses.

New arrangements for nursing, including transportation baths, etc.

New apparatuses in hygiene.

Applications or inquiries inscribed "Ausstellungs-Angelegenheit," and accompanied with a printed card containing the name and address of the firm thus applying, should be directed to the Secretary General, Dr. O. Lassar, Carlstrasse, No. 19, Berlin, N. W., Germany.

R. Virchow, President.

E. von Bergmann, E Leyden, W. Waldeyer, Vice-presidents.

O. Lassar, Secretary General.

An Investigation of the Use of Electricity in Uterine Fibromata.—The Philadelphia County Medical Society has appointed a committee, consisting of Drs. Parvin, Hirst, Montgomery, Massey, and Baldy, to conduct a series of observations relative to the effect of electricity in fibroid tumors of the uterus.

The Committee requests the profession at large to send any case of the kind to the Gynecological Out-Patient Department of the Pennsylvania Hospital, Mondays, Wednesdays, or Fridays, at 12 o'clock.

Iowa State Medical Society.—The thirty-ninth annual session of the Iowa State Medical Society meets at Des Moines, April 16th, 17th, and 18th. Judging from the announcement, the meeting will be very interesting.

Professor Henoch.—Professor Henoch, who has been for thirty years at the head of the clinic for children's diseases at the Charité Hospital, Berlin, will celebrate his seventieth birthday on July 16th. His friends propose to make the event memorable by the presentation of a bronze bust to the clinic.

The Successor of von Troeltsch.—Dr. W. Kirchner will succeed the late Professor von Tröltsch at the otological

clinic at the University of Wurtzburg. He is the author of a handbook of aural surgery.

University of California.—The legislature of California has voted to appropriate the sum of $80,000 to build a new college for the medical department of the University of California, in San Francisco.

Professor von Nussbaum.—Professor von Nussbaum, of Munich, was a victim of the influenza, and has not yet recovered sufficiently to enable him to resume his official work. He has improved, however, and has announced that he will resume his clinic during the summer semester.

Insurance Losses from the Influenza.—Mr. Smee, an actuary for a large London insurance society, has made an estimate that the losses in England from the influenza epidemic will amount to one million of pounds, cash paid out by companies and beneficial societies, and another million in the losses of time and wages and disorganization of trade.

Obituary.—Dr. Charles J. Nordquist was fatally injured by a railroad train on the Harlem Railroad, not far from his home at Tuckahoe, Westchester County, N. Y. He was the son of Dr. Lars Peter Nordquist, who early in the present century was surgeon to the King of Sweden. Dr. Nordquist served with great credit in the late war as regimental surgeon and as medical inspector in the First Army Corps. He had only recently been reëlected to serve a second term as coroner of his county.

Appointments in the New York Post-Graduate Medical School.—The following additions have been made to the Faculty of the New York Post-Graduate Medical School and Hospital: Charles B. Kelsey, M.D., Professor of Rectal Diseases; Charles H. Knight, M.D., Professor of Laryngology and Rhinology; Reynold W. Wilcox, M.D., Professor of Clinical Medicine; S. Lustgarten, M.D., formerly Privat Docent in Vienna University, Instructor in Syphilis and Dermatology.

Western Pennsylvania Medical College.—The fourth annual commencement exercises of the Western Pennsylvania Medical College were held in the Grand Opera House, Pittsburg, on March 27th; the degree of M.D. was conferred on 29 graduates, being about 25 per cent. of the class in attendance during the past term.

In the evening of the same day the Alumni Association of the college, now numbering 120, was entertained by the Faculty at a banquet provided at the Seventh Avenue Hotel.

Chicago Polyclinic.—A special course of nine lectures on "abdominal and pelvic surgery," with demonstrations on dogs and cadavers, was given at the Chicago Polyclinic, by Drs. N. Senn, Charles T. Parkes, Christian Fenger, and W. T. Belfield, beginning March 24, 1890, and lasting two weeks.

Association of American Physicians.—The preliminary programme of the fifth annual meeting of the Association of American Physicians to be held at the Army Medical Museum Building, Washington, D. C., on the 13th, 14th, and 15th of May, 1890, is as follows:

1. The President's Inaugural Address, by Samuel C. Busey, M.D., of Washington.

2. Consideration of the Revised Constitution.

3. Disturbances of Sleep. Referee, S. Weir Mitchell, M.D., of Philadelphia. Co-referee, Charles F. Folsom, M.D., of Boston.

4. Methods of Diagnosis in Diseases of the Stomach. Referee, Francis P. Kinnicutt, M.D., of New York. Co-referee, A. F. Shattuck, M.D., of Boston.

5. Inflammations of the Appendix and Cæcum, and the Duty of the Physician regarding them, by Norman Bridge, M.D., of Chicago.

6. Anæsthetic and Non-anæsthetic Hysteria, by Charles L. Dana, M.D., of New York.

7. Seizures Characterized by Shock and Loss of Consciousness, by Israel T. Dana, M.D., of Portland, Me.

8. The Diathetic Causes of Renal Inadequacy, by I. N. Danforth, M.D., of Chicago.

9. Antisepsis in Midwifery, by William T. Lusk, M.D., of New York.

10. Varicose Aneurism of the Arch of the Aorta, by William Pepper, M.D., and J. P. C. Griffith, M.D., of Philadelphia.

11. Natural History of Typhoid Fever, by James E. Reeves, M.D., of Chattanooga.

12. What can and should be done to Limit the Prevalence of Tuberculosis in Man, by Edward O. Shakespeare, M.D., of Philadelphia.

13. Migraine, by Wharton Sinkler, M.D., of Philadelphia.

14. Etiology of Pleurisy, especially in its Relation to Tuberculosis, by A. A. Smith, M.D., of New York.

15. Report of Cases of Angio-neurotic Œdema, by Samuel B. Ward, M.D., of Albany.

16. Notes of a Case of Acromegaly, by J. E. Graham, M.D., of Toronto.

17. A Case of Acute Pancreatitis, by R. H. Fitz, M.D., of Boston.

18. Demonstration of Pathological Specimens, by W. T. Councilman, M.D., of Baltimore.

Those who are to contribute papers may send to the Secretary, Dr. Henry Hun, 33 Elk St., Albany, N. Y., the names of members whom they wish to have invited to participate in the discussion; and by sending their papers to the Recorder, Dr. J. Minis Hays, 266 South 21st st., Philadelphia, as early as possible and at a reasonable time prior to the meeting, they can receive five or six copies in type, which they can forward to those members whom they wish to have participate in the discussion.

There will probably be time at the meeting for the reading of two or three papers more than those on this programme. Members who desire to contribute such papers are requested to send the titles of them to the Secretary.

The constitution provides that papers shall not exceed twenty minutes in the reading.

Foreign Physicians in France.—The French Minister of Foreign Affairs attended a recent meeting of a commission appointed to devise regulations governing the med-

ical practice of foreign physicians residing in France. He urged the expediency of removing all restrictions from foreign practitioners who practise among their fellow countrymen at the health resorts in the south of France and at the watering places; and advocated the granting of a special form of license to meet the cases of those foreigners who are desirous of practising some special branch of medicine.

The Society of the Alumni of Bellevue Hospital.—The ex-internes of Bellevue Hospital propose, this year, to have a special reunion, covering parts of three days. The regular monthly meeting will be held April 8th, at which a surgical subject will be discussed by Dr. Charles Phelps and other prominent surgeons. On the following morning, Dr. Sayre will give a surgical clinic at Bellevue; in the afternoon a meeting will be held at the Mott Library, when papers will be read by Dr. R. A. Vance, of Cleveland, on the results of injury to the hip-joint, and by Dr. Brandreth Symonds on glycosuria and the delicate tests for sugar; to be followed in the evening by an elaborate banquet. A clinic by Dr. Lusk, on the morning of the 10th, will close the reunion.

Death from Nitric Acid Fumes.—A very unusual form of fatality occurred in New York recently. A young man, aged twenty-five years, who was employed in an electro-plating works, dropped a tool into a vat containing nitric acid, and in spite of warnings remained too long bent over the vat, while trying to recover his lost tool. He inhaled the acid fumes, was taken sick soon after, and removed to a hospital, where he died about twenty-four hours later.

An Irregular Medical College.—The Medical and Surgical College of New Jersey, by many supposed to have been suppressed or suspended, has been reported in the daily papers to have held on March 20th a "commencement" at Cooper's Hall, Jersey City. The diploma of this "college" has no standing at the Board of Health, and the County Medical Society has condemned the undertaking.

Bogus Medical Diplomas.—The *Boston Medical and Surgical Journal* calls attention to the diploma issued by the "Druidic Banchoreion" of New York State, as liable to mislead the unwary public. As described by the *Buffalo Advertiser*, these diplomas are used by designing persons as licenses to practise medicine.

An American Merchant's Bequest.—An old New York merchant, Mr. Thomas Hope, has bequeathed to his native town of Langholm, Scotland, the sum of $400,000, to found a hospital and dispensary. Langholm has a population of about 4000, so that this gift will make abundant provision for all who require hospital treatment.

Condemnation of Cheap Lodging-houses in New York.—The New York City Board of Health has ordered a number of the cheap and low lodging-houses, in the lower parts of the city, to be vacated on or before May 1st. Of these, twenty or more have been condemned because of sanitary defects in regard to light and ventilation.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM APRIL 1 TO APRIL 7, 1890.

By direction of the Secretary of War, leave of absence for six months, on surgeon's certificate of disability, with permission to leave the Division of the Pacific, is granted ARTHUR W. TAYLOR, *Captain and Assistant Surgeon.*—Par. 10, *S. O. 78, A. G. O., Washington*, April 3, 1890.

SKINNER, J. O., *Captain and Assistant Surgeon* (Fort Ontario, New York).—Is hereby granted leave of absence for one month, to commence forthwith, as his services may be required with troops to change station early in May.—Par. 5, *S. O. 75, Division of the Atlantic*, April 2, 1890.

By direction of the Secretary of War, a Board of Medical Officers, to consist of: EDWARD P. VOLLUM, *Colonel and Surgeon;* GEORGE M. STERNBERG, *Major and Surgeon;* HENRY MCELDERRY, *Major and Surgeon;* and JOHN J. COCHRAN, *Captain and Assistant Surgeon*, is constituted, to meet in New York City, on the 28th day of April, 1890, or as soon thereafter as practicable, for the examination of Assistant Surgeons for promotion, and of candidates for admission into the Medical Corps of the Army. The Board will be governed in its proceedings by such instructions as it may receive from the Surgeon-General.—Par. 6, *S. O. 78, A. G. O.*, April 3, 1890.

TAYLOR, MARCUS E., *Captain and Assistant Surgeon.*—The leave of absence for one month, granted by Par. 3, S. O. 26, *c. s.*, Headquarters Department of the Columbia, is hereby extended one month, on surgeon's certificate of disability.—Par. 1, *S. O. 19, Division of the Pacific*, March 27, 1890.

By direction of the Secretary of War, leave of absence for two months, to take effect on or about April 15, 1890, is granted CHARLES F. MASON, *First Lieutenant and Assistant Surgeon.*—Par. 3, *S. O. 76, A. G. O., Washington*, April 1, 1890.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE TWO WEEKS ENDING APRIL 4, 1890.

AMES, H. E., *Passed Assistant Surgeon.*—Ordered to the Museum of Hygiene, Washington, D. C.

FEREBEE, N. MCP., *Surgeon.*—Ordered to the U. S. S. "Essex."

ANDERSON, FRANK, *Passed Assistant Surgeon.*—Detached from the U. S. S. "Dolphin," and ordered home.

GRIFFITH, S. H., *Passed Assistant Surgeon.*—Detached from the Museum of Hygiene, and ordered to the U. S. S. "Dolphin."

HEFFENGER, A. C., *Passed Assistant Surgeon.*—Ordered to temporary duty at Navy Yard, Portsmouth, N. H.

SIMONS, MANLY H., *Surgeon.*—Ordered to superintend repairs at Widow's Island Hospital, in addition to present duties.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL LECTURES.

PSORIASIS.

A Clinical Lecture.

BY HENRY J. REYNOLDS, M.D.,

PROFESSOR OF DERMATOLOGY IN THE COLLEGE OF PHYSICIANS AND SURGEONS, OF CHICAGO; CHIEF DERMATOLOGIST AND GENITO-URINARY SURGEON TO THE WEST SIDE FREE DISPENSARY, ETC.

GENTLEMEN: In the case of the patient before us to-day, we have a disease wherein the diagnosis is usually a comparatively simple matter. You will remember, in recently considering eczema, that we had a disease wherein we generally not only failed to find any well-pronounced or pathognomonic diagnostic points, but in various cases almost every known form of lesion, or a host of different kinds of objective symptoms may be present, on no one of which could a diagnosis be made—a disease so variable in its behavior that probably upward of one hundred different names have been used to designate its various forms.

In the disease we are now about to consider, however, we not only always have the same chain or combination of symptoms present by which a diagnosis can always be made with positiveness, but we have several features or symptoms which are met with in this disease alone, any one of which may be regarded as almost pathognomonic. The name of the disease to which we shall now confine our remarks, and which is fairly well illustrated in the case of the man before us, is *psoriasis*.

Let us, however, before directing our attention to this particular case and the symptoms found therein, as is imperatively essential to an intelligent study of any disease, and particularly the diseases of the skin, first get a clear understanding of the characteristics by which the disease is recognized.

This disease, though not so frequently met with as acne or eczema, is comparatively common, ranking next in frequency to the diseases already mentioned. It is not contagious, it may occur in both sexes at almost any age, and is probably more frequently encountered in winter than in summer. When first seen the lesions are usually in the form of small, slightly elevated macules, covered by very fine pearly scales, which lesions may be very numerous, covering a large portion of the body, or may be very scanty. Owing to the peculiar manner in which these lesions are distributed, several names have been employed to signify the different manifestations, such as psoriasis guttata, psoriasis diffusa, psoriasis punctata, etc. As the disease progresses to its full development the lesions become larger and more pronounced, and the scales become more numerous. Usually when first seen the lesions vary in size from that of a silver ten-cent piece to a silver quarter, are round, with well-defined margins and with perfectly healthy skin between the lesions. The patches are always covered by a mass of white, shiny, pearly scales. Though the pearly, shiny scales are not always visible at first glance, by gently scratching with the finger-nail they at once take on the shiny, pearly character. These scales invariably cover the entire lesion to its very margin, so that no portion of the reddened patch, which is always found underneath the scales, can be seen until the scales are removed. On their removal we find a bright red patch, on the surface of which may be seen in several places pin-point oozings of blood. Just here I wish to call your attention to a characteristic that is not laid down in the books: Upon removal of the scales we sometimes fail to find these pin-point oozings of blood, but the fact is, while the scales appear to be all off, there still remains a very thin, transparent film which covers the entire patch. While this may also be regarded as a scale, the point I wish to call your attention to is the fact that we always find this very thin film, and that it is sometimes necessary to scratch almost down into the lesion before getting off the lowest scale or film, which, when once removed, always shows the pin-point oozing. One reason why I wish to call your attention particularly to the presence of this film is because while other diseases, as some forms of syphilitic eruption, for instance, may have scales very closely resembling those of psoriasis, we never in any of them find this characteristic broad, uniform, thin film. The eruption is not only always symmetrical, but general in its tendency, in well-marked cases usually involving the entire surface of the body. By symmetrical we mean an eruption that tends to involve both sides of the body equally, and in psoriasis we almost invariably find this characteristic. When we speak of it as a generalized eruption it must not be implied that the lesions are necessarily very numerous, but that, however few in number, they are sure to be distributed here and there over all parts of the body, usually affecting both upper and lower extremities equally. Now, while the disease tends to involve the entire surface of the body, there are certain localities which it seems to have a preference for. The parts where it is oftenest found are the extensor surfaces. This peculiarity is usually so well marked that we may at times find only a patch on each olecranon process, with perhaps also a patch over each shin or patella. It must not be understood, however, that the disease never affects the flexor surfaces, but merely that it has a preference for the extensor surfaces, and is to be found in greatest abundance on these parts. There are localities, however, where the disease is rarely seen. It almost never affects the palms of the hands or soles of the feet, and it very rarely affects the face to any extent. Even when the scalp is extensively involved, after creeping down slightly over the margin of the forehead the eruption generally terminates there, sparing the face. This point that I now refer to is sometimes very useful in

differentiating it from other scalp diseases. The disease is quite chronic in its tendency and is never characterized by moisture during any period of its existence, being always dry from first to last. There is almost never any itching or other subjective sensation of any consequence; there is no essential constitutional disturbance, and when cured it is very liable sooner or later to return.

Turning now to the patient, we find that he is fifty-two years of age, Bavarian by birth, and that his general health is good. He has been troubled with the eruption on and off for three or four years, having been treated and cured several times during this period. We find, as you see, several patches on the front of each leg, some on each arm, affecting the back or extensor surface more than the front, and particularly the vicinity of the olecranon process. We also find a few spots over the sacrum, and others on the chest. As he passes around amongst you, you will please examine and carefully study the characteristics which we have already described. You will notice that the lesions are round, varying in diameter from one-quarter of an inch to one inch, that the patches are entirely covered by scales, and that the scales are white, shiny, and pearly, which appearance you may more fully develop by gently scratching with the finger-nail. Upon removing the scales you will notice the bright red patch with pin-point oozing of blood. You will notice that the skin between the lesions is entirely healthy, and that the disease terminates abruptly at the margin of the patch, instead of fading off gradually as the redness in eczema and certain other diseases does. You will notice it is both symmetrical and general in its distribution, that there is an entire absence of moisture, and from the fact that the parts are entirely undisturbed and are covered with scales you may at once make up your minds that the finger-nails have not been used for the relief of itching, and, consequently, that the symptom of itching is entirely wanting. You will also notice the points I referred to in regard to the extensor surfaces being principally involved. While the disease involves a considerable surface of the body, you fail to find any lesions upon the palms, soles, or face, and from the fact that the disease has already existed three or four years its chronic character may be established.

Etiology.—As to the etiology of the disease very little is known. It is, however, neither hereditary nor contagious, and may occur at any age in either sex. Inasmuch as it seems to be more frequently met with in cold weather, it is probable that the influence of cold or the dryness of the skin is in some way concerned in its etiology.

Diagnosis.—The diagnosis of this disease is, as I have already intimated, usually not a difficult matter. The pearly character of the scales, the pin-point oozing of blood, and the thin film immediately covering the red patch are almost pathognomonic symptoms of psoriasis.

In obscure cases we must differentiate it from *eczema* on account of the great frequency of the latter disease and its somewhat similar appearance; *syphilis*, owing to the fact that there is the same tendency to general distribution, circular shape of lesion, etc.; *tinea favosa* (favus), *tinea tonsurans* (ringworm of the scalp), and *seborrhœa sicca*, inasmuch as psoriasis when confined chiefly to the scalp, as is sometimes the case, is not distinctly pronounced in its symptoms. By carefully considering, however, the following differential diagnostic table which I have arranged, one need never fail in the diagnosis of psoriasis:

Psoriasis.	*Eczema.*
1. No itching.	1. Usually intense itching.
2. Always dry.	2. Always a history of moisture.
3. Prefers extensor surfaces, the elbows and knees in particular.	3. Prefers the flexor surfaces.
4. Usually a generalized eruption.	4. Never a general eruption.
5. Symmetrically distributed.	5. Never a symmetrical eruption.
6. Scales white, shiny, and silvery.	6. Scales never white, shiny, or silvery.
7. Crusts never form.	7. Always a tendency to the formation of crusts.
8. Lesions uniform.	8. Lesions multiform.
9. Lesions round and well defined.	9. Patches irregular and ill defined.
10. The skin between the lesions always healthy.	10. Always a tendency to diffuse redness between the lesions.
11. Pin-point bleeding on removal of the scales.	11. Never pin-point bleeding when scales are removed.

Psoriasis.	*Syphilis.*
1. May occur at any age.	1. Generally occurs after puberty.
2. No history of syphilis.	2. Generally a history of syphilis.
3. Prefers the extensor surfaces.	3. All parts affected about alike.
4. The lesions are entirely covered by the scales.	4. In the squamous syphilide the red patch is almost never completely covered by scales, but is apt in every case to show, at least, at the margin.
5. Scales white, shiny, or silvery.	5. The scales, though sometimes somewhat lustrous, are generally dirty, yellowish, grayish, or ashy in color.
6. Scales very abundant.	6. Scales generally scanty.
7. Generally a thin adherent film underneath the scales, covering the entire patch.	7. Never a broad thin film under the scales covering the entire patch.
8. Never crusts.	8. Generally crusts, sooner or later.
9. The superficial scales are loose.	9. The scales are all more or less adherent.
10. The redness is bright or inflammatory in color.	10. The redness is dark or copper-colored.
11. Pin-point bleeding on removal of the scales.	11. The bleeding when the scales are removed is never decidedly pin-point in character.
12. Lesions uniform.	12. Lesions multiform, and even in the squamous variety the lesions tend to the papular type.
13. Never destructive.	13. Always destructive, sooner or later.
14. Never affects the palms or soles.	14. Frequently affects the palms and soles.

Psoriasis.	*Syphilis.*
15. Always dry.	15. Generally pus or other moisture, sooner or later.
16 Characterized by frequent recurrences for years.	16. When once cured, rarely recurs, and when it does it is of a destructive character, bearing no resemblance to psoriasis.
17. Patient generally in good general health.	17. Patient generally shows constitutional symptoms.
18. Not affected by syphilitic treatment.	18. Generally cured by syphilitic treatment.

Psoriasis.	*Favus.*
1. No evidence of contagion.	1. Usually a history of contagion.
2. Shiny scales.	2. Never scales, but sulphur-yellow cup-shaped crusts.
3. Not confined to the scalp, but fringes the brow; also usually found on other parts of the body.	3. Almost invariably confined to the scalp.
4. Symmetrically distributed.	4. Not symmetrical.
5. Lesions numerous and coin-sized.	5. Generally only one or a few patches.
6. Hairs normal.	6. Hairs brittle, broken off, and loose.
7. Never any baldness as a result.	7. Generally in all cases some thinning of the hair on the patches.
8. May disappear and return.	8. Never gives a history of having disappeared and relapsed.
9. Disappears readily under appropriate treatment.	9. Very stubborn to cure.
10. No parasite to be found with the microscope.	10. The parasite always readily seen with the microscope.

Psoriasis.	*Tinea Tonsurans.*
1. No history of contagion.	1. Generally a history of contagion.
2. The eruption rarely so scanty but that it may be found on other parts of the body, as elbows, knees, etc.; and in any event is always sure to fringe the brow below the hair.	2. Usually confined to the scalp, but if found on non-hairy skin assumes the well-marked ringworm appearance.
3. Symmetrically distributed.	3. Not symmetrical.
4. Lesions numerous and coin sized.	4. Generally only one or a few patches.
5. Scales white and shiny, and more or less adherent.	5. Scales loose and not lustrous.
6. Hairs normal.	6. Hairs loose, brittle, and broken off.
7. Never results in baldness.	7. May produce some thinning of the hair in the patches.
8. May disappear and return.	8. Never gives a history of having disappeared and relapsed.
9. Easy to cure.	9. Very stubborn to cure.
10 No parasite to be found with the microscope.	10. The parasite always to be found with the microscope.

Psoriasis.	*Seborrhœa Sicca.*
1. White, shiny, dry scales.	1. Thick greasy scales or small crusts.
2. Rarely confined to the scalp, but fringes the brow, and generally found on other parts, as elbows and knees, etc.	2. Generally confined to the scalp.
3. Symmetrical, but not diffuse.	3. Symmetrical and diffuse.
4. Distinct coin-sized lesions, with healthy skin between them.	4. No lesions other than, at times, some general hyperæmia.
5. Hairs generally normal.	5. Usually some general falling of the hair.
6. Never produces thinning of the hair.	6. If not arrested early, produces some permanent general thinning of the hair.

Treatment.—As the disease is more or less chronic in character, with a tendency to return, naturally very many remedies, both internal and local, have been made use of at various times with a view of curing and eradicating the disease. The disease, as already stated, is always characterized by the same symptoms, regardless of the case or stage of the disease, so that the treatment may be more or less uniform, and I need only occupy a few minutes of your time in considering this part of the subject. As in most other scaly eruptions, the first thing to be done is to get rid of the scales. This is best accomplished by the use of (two or three times a day at the beginning of the treatment) some oleaginous preparation, as any simple ointment, combined with the daily use of plenty of hot water and soap, with a rough towel or flesh-brush for the purpose of getting rid of all the scales that have already been softened by the oiling process. When the scales have been pretty thoroughly removed, the best remedy or local application is ten grains of chrysarobin to the ounce of lard, vaseline, or other similar substance. This remedy, to be effectual, must be thoroughly worked into every individual patch on the surface of the body once or twice a day. In two or three days the oiling, soaping, and washing process must again be resorted to to get rid of the scales which have re-accumulated. By following up this process, almost every case of psoriasis may be cured in the reasonably short space of a few weeks. The other remedies which may be used are pyrogallic acid, citrine ointment, naphthol, etc. As to constitutional treatment, I think the majority of dermatologists favor the use of some form of arsenic, psoriasis being the disease of all others wherein arsenic is said to be necessary or beneficial. Arsenic may be given in the form of Fowler's solution, beginning with a dose of five drops and gradually increasing till the full dose is reached. I mention arsenic, however, in the treatment of psoriasis, not because I think it is essential or useful, but because it is usually recommended and used. In my own practice I have not used arsenic for six years in the treatment of psoriasis, and, as far as I am capable of judging, I am able to cure the disease just as well without it, or other constitutional treatment, as with it. It may have a tendency to prevent the return of the disease, but I think even this is doubtful.

THE TYPES OF INSANITY.

A Clinical Lecture,
delivered before the Class of the Woman's Medical College at the Cook County Insane Asylum.

BY DANIEL R. BROWER, M.D.,
PROFESSOR OF DISEASES OF THE NERVOUS SYSTEM, DIDACTIC AND CLINICAL, IN THE WOMAN'S MEDICAL COLLEGE; PROFESSOR OF MENTAL DISEASES AND LECTURER ON THE PRACTICE OF MEDICINE IN RUSH MEDICAL COLLEGE, CHICAGO, ILL.

LADIES: Through the kindness of Dr. John A. Benson, Superintendent of this Asylum, we have before us to-day a number of cases illustrating the several types of insanity to which your attention has already been called. First, we have four cases of *melancholia*, cases of insanity that show mental depression. This boy's case is a comparatively recent one, and his attitude is that common to the disease. You notice that he sits with his head bent upon his chest. He has no inclination to straighten himself up and show us his facial expression, which would reveal the mental misery he has endured. These cases of melancholia show not only depression of mind but great depression of all the functions of the body. The temperature is below normal, the circulation is feeble, the skin is cold and clammy, the tongue is coated, the digestion is impaired, the bowels are constipated, the assimilation is defective, the pupils are dilated, and in the beginning there is more or less discomfort in the head, a sense of fulness or an absolute pain. They steadily lose flesh in the early stages of the disease. This patient is suicidal in his tendencies, as are many cases of melancholia, and requires, therefore, the closest possible observation and care to prevent him from taking his life.

I now show you another case of melancholia, of longer duration. This patient has had the disease for the last two years, and the profoundness of the mental depression has disappeared. You notice that he does not show, in as marked a degree, the attitude spoken of as characteristic of the recent cases, or the profound depression of mind as manifested by the facial expression. Melancholia is of variable duration, say from two to twelve years, and then, if recovery does not occur, the patients gradually drift into a condition of mental enfeeblement or secondary dementia. We are informed by Dr. Rund that this patient is now failing in mental power, and gradually passing into this condition of dementia. Now, in the early history of melancholia there is no failure of mind, but the patient is simply under a delusion that gives rise to the characteristic symptoms of the disease, this delusion of course being based upon the malnutrition of the brain; but the memory and all the ordinary faculties of the mind are as vigorous as before.

The next case of melancholia I present is of shorter duration, and you will see in this patient the usual attitude and facial expression, and the evidences of general psychical disorder. She refuses to eat, for she has the delusion that her food is poisoned. Many cases of melancholia have this delusion to a greater or less degree, and require forcible feeding by means of a stomach or nasal tube to prevent their carrying out the suicidal proclivities. She answers no questions. Some melancholic patients are under the delusion that if they speak, great calamities will befall them or their friends, consequently they will say nothing. She probably has such a delusion.

Melancholia is a very interesting type, from the standpoint of the etiology and treatment of insanity, because almost every case of insanity begins as melancholia, the period of depression lasting in some cases only a few days, in others a few weeks, and then the condition of mania, or other permanent form of insanity, ensues.

Now, if we had the history of these cases, we would probably find that there had been a period of several weeks or months when sleep was imperfect, appetite poor, digestion impaired, and assimilation defective. This being the pathogenesis of most cases, the treatment becomes evident. If you can catch the patients, as will often be your opportunity as family physicians, in the very beginning, when the insomnia, the digestive and assimilative disturbances have commenced, then by the judicious use of sleep-producing remedies, digestive agents, nutritious food, etc., you may be able to arrest the progress of the disease and thus abort insanity. It is your duty as family physicians to watch carefully the digestion, assimilation, and elimination of those who have a neurotic or insane diathesis, for by doing this you may avert the storm.

The medical profession to-day is more fortunate than ever before in the number of sleep-producing remedies. Sulphonal is a comparatively recent remedy of great value. It does not interfere with the digestion, the circulation, or the heart's action as chloral, the bromides, and opium frequently do. We have also the still more recent remedy chloralamid. It has some advantage over sulphonal in that it acts more rapidly, and when dissolved in wine has but little taste. Sulphonal, on the contrary, probably by reason of its great insolubility, often acts slowly, its effects being more manifest the next day than on the evening of its administration. You can often administer either of these remedies without the patient's knowledge, as they have but little taste.

These patients require an abundance of food, and are much benefited by the judicious use of alcoholic stimulants; alcohol, as you are aware, in moderate doses, being a food. A very desirable way to administer it is as eggnog, and three or four, or even five or six, eggnogs in twenty-four hours can be administered to them with benefit. You must also pay attention to their elimination. They need mild laxatives and mild alteratives. Small doses of aloin and blue mass will assist you very materially in keeping the alimentary tract in good condition.

MANIA.

We have before us now a series of cases which illustrate the state of mental exaltation called *mania*. You notice how they differ from the melancholics in their facial expressions and attitudes. They hold their heads up; the corners of their mouths are not drawn down. These patients do not suffer the untold agonies of the other class, and, indeed, are more or less happy. There is but little derangement of the digestive organs. They often smile, and they are in a more or less constant state of movement. Here is activity, while in the other cases you just saw we had the opposite condition. Melancholic patients sit still; they scarcely move a muscle; maniacs are in a state of continual activity.

In all of these cases of mania there is no enfeeblement of mind, but simply a disorder of mind. Probably most of these cases began with melancholia. For a few days or weeks they were depressed, and then they passed into this condition of activity. These cases, like the others, finally pass into a condition of mental enfeeblement, but more rapidly. They gradually lose their memory, reason, judgment, and power of instituting comparisons as to likenesses and differences of things. Cases of mania usually reach the condition of dementia in a year or two; cases of melancholia may remain as such for five, six, or a dozen years. As a rule, maniacs eat well, but do not sleep well. There is but little derangement of the digestive organs. This condition of continual activity means a great deal of tissue waste, which, associated with poor sleep, causes them to drift more rapidly into a condition of mental enfeeblement than do the others, who spend their time in such quietude of body.

CIRCULAR INSANITY.

The next type of insanity to which I call your attention consists of cases characterized by alternating changes in the mental state, or *circular insanity*, as it is sometimes called. These cases have their periods of depression, followed by intervals of comparative lucidness of mind, to be followed again by a period of depression, and then a period of excitement. We have, therefore, alternations of depression, of excitement, and of lucidness. One form of this mental alternation is called katatonia. The case I now show you illustrates this condition. You see how her arm remains in a fixed position. She is now in what is called the cataleptic state, which every case, of katatonia has for a time. This cataleptic state only lasts for a few days, and we are informed that she sometimes becomes violent. This condition of mental depression will become more and more pronounced as the cataleptic state advances, and after a while she will pass into a condition of violent excitement; then that period of violent excitement will pass away and she will return to her usual mental condition.

Here is another case passing into the cataleptic condition. After a while the catalepsy will pass away and the arms will resume their proper function, when we will have excitement and a period of comparative freedom from manifestation, and then the circle will be completed. The patient has three days of depression, and then three days of excitement, with great regularity. The next patient which you see is in a state of exaltation. This will be followed by depression, which will last for some days or weeks and then pass away, and he will again become excited. Thus do these cases of mental alternation go on completing the round, with little or no prospect of complete recovery.

MONOMANIA.

I will now show you some cases of *monomania*, that form of insanity in which the patients have fixed and limited delusions. Cases of monomania are sometimes very perplexing. The area of delusion may be very slight. There is a large number of these cases going about attending to their business in a fair way. It is only when the delusions become of such a character and of such a range as to make them dangerous to themselves or to the community in which they live, or to interfere with their daily avocations, that it will be necessary for them to come here. Such cases are perplexing, and it is usually almost impossible to make a correct diagnosis, their delusions being limited and the remainder of their mental operations being normal. They can conceal their delusions so that it requires considerable knowledge or expertness to make a diagnosis.

I had one of these cases of limited delusions at my house last night. He talked to me on general topics as well as a man with his education could talk, but with a slight nervousness in his manner and twinkling in the eye. No one would suppose that there was anything the matter with him. But as soon as I touched on religious topics, he assured me that he was the Lord Jesus Christ, and was going to reform the world. He talked for a long time on religious subjects in an insane way, but on any other matter his conversation did not differ from the majority of people. So it is with all these cases of fixed and limited delusions; unless you strike their delusions, you may labor with them for days without success.

The woman on my right has the delusion that she is Prince of the Roman Catholic Order; while the one on my left has communications with spirits. A third regards herself as the King of Sweden.

I have a patient under my care who is perfectly well, except that he will not walk. You cannot get him to walk for fear somebody will knock against his legs and break them.

Here is a patient who thinks her soul will be damned. Upon all other questions she is rational, and there is no special amount of depression in her face.

TERMINAL DEMENTIA.

I will now direct your attention to cases of *terminal dementia*, a disease that begins as mania or melancholia and continues thus for a variable period of time, and then passes into the state of dementia. It takes cases of melancholia a long time to reach this condition of mental fatuity, while cases of mania reach the condition rapidly. Two or three years will be sufficient for a case of mania, while eight or ten years may be necessary for a case of melancholia to undergo the change.

This case now before you was at first one of acute mania, then became one of chronic mania, and then dementia. Her excitement is gone, and with it the mind. Sooner or later she will be in a condition of fatuity. The mental state of these cases of terminal dementia is much like idiocy or imbecility, forms of mental enfeeblement that are the result of an arrest of development. Here there has been a destruction of the brain cells and brain fibres: in idiocy there is insufficient development of cells and fibres.

IDIOCY AND IMBECILITY.

We will now present to you cases of mental enfeeblement due to an arrest of brain growth either before or after birth. Of this form of insanity there are two types, *idiots* and *imbeciles*. The difference between the two conditions is simply one of degree. According to the standard of the English law, an idiot is a person who cannot count ten. These cases of mental enfeeblement have reached this condition because of an arrest of brain growth, not necessarily as a consequence of disease.

The patient on the right is an extreme case of imbe-

cility, and we might call her an idiot. This woman on my left has manifestly more intellectual capacity than the other and may fittingly be called an imbecile. Many cases of congenital or acquired enfeeblement are characterized not only by failure in the growth of the brain, but by an arrest in body development as well. Some cases of imbecility and idiocy show very marked congenital defects in the growth of the fingers, arms, legs, and teeth.

GENERAL PARESIS.

I now ask your attention to another interesting form of insanity, a type that has a positive pathological basis. Just what the pathological changes of the manias, the melancholias, and of the monomanias are we do not know; but these cases of *general paresis* have a positive pathological substratum on which they rest.

Here is a case of general paresis, paretic dementia, or general paralysis of the insane, a disease that is almost always characterized by grand delusions. This man says he feels first-rate. Notice the peculiarity of his articulation, the thickness of his speech, the excessive movements of his lips in speaking, and the tremor of his tongue. These patients are happy in their delusions as a rule. A few cases of paretic dementia begin with melancholia, and you must remember this in your diagnoses. As a rule the latter are females, and usually of a tubercular diathesis.

Notice the pupils of the patient on my right; one pupil is contracted almost to a pin-point, the other is dilated, and neither responds normally to light. The pupillary condition of the patient on my left is different. Both pupils are dilated, but neither of them responds to the action of light. Some of these cases of general paresis have no pupillary reflex whatever.

The next patient says he has three professions combined in one. He is a decorative painter, a lawyer, and a doctor, and thinks he has cured a great many cases of insanity, and was successful as a lawyer. He believes that he is the richest man in the world. We find in his case diminished pupillary reflex, and one pupil a little more contracted than the other. There is also loss of patellar-tendon reflex, the same peculiarity in articulation, and more pronounced grand delirium.

Here are some cases that show more enfeeblement of both the body and mind. There is more pronounced muscular paresis in this case than in any of the others which I have shown you. This process of deterioration goes on until they become bedridden and completely paralyzed.

The characteristics of these cases of general paresis we may enumerate as grand delirium, delusions of an exalted character, disturbance in articulation, excessive movements of the facial muscles in articulation, usually contracted or dilated pupils not responsive to light, then gradual, progressive enfeeblement, loss of power of mind and body, etc.

These patients, as I have before remarked, have a positive pathological history. They are all cases of *meningo-encephalitis* involving the motor territories of the brain. Some of them in the early stages, I believe, can be greatly benefited by treatment, but when they pass on to this condition of paresis so manifest in two of the cases you have seen, there is nothing whatever that can be done except to make them comfortable. Many of them have a syphilitic history, and if they are treated vigorously with the iodide of potassium and a judicious selection of tonics, mental rest, and counter-irritation by means of blisters the size of a silver dollar over the territory that is the seat of this inflammatory process, some will be greatly improved and a few may recover.

DEFECTIVE INHIBITION.

Here are two cases which illustrate another and very important type of insanity, to which I will ask your attention very briefly, that of *defective inhibition*, a state that is characterized by irresistible impulses. Both of these patients have epilepsy and are homicidal. Without any reason, such patients commit violations of law of various kinds. During this state they are entirely unconscious of what they do. They may manifest their disease by an irresistible or uncontrollable impulse to kill, burn, or steal.

Cases of irresistible impulse are of very great importance from a medico-legal standpoint, and they are often extremely difficult to diagnose. It is common when a person commits some criminal act to plead irresistible impulse, and you will time and again be called upon to determine this condition. If this irresistible impulse is due to disease, surely such persons should not be held responsible for their crimes, but should be carefully put away so that their uncontrollable impulse will not again damage society. Every now and then you will be called upon to determine whether, in a given case, the murder was the consequence of this defective inhibition, the outgrowth of disease, or whether it was simply want of proper moral capacity—a crime and not a disease. I believe that many of these cases of defective inhibition showing a violent fury and uncontrollable impulse are simply a manifestation of the epileptic condition. I have often seen cases in which this impulsiveness took the place of the ordinary convulsive seizure; just about the time when the patients should have a convulsion they do something of an impulsive character. The nerve explosion simply went out through the emotional territories rather than through the motor centres, and instead of having a convulsion they had this manifestation of emotional activity. In making a diagnosis, each case must stand by itself. If a person goes around in broad daylight stealing things that are of no earthly value or service to him, it is certainly not a criminal act. For instance, a man went into a lawyer's office a short time ago and carried off his books and chair. The lawyer went after him, and when he was questioned about it afterward he was entirely unconscious of the act. That man was not responsible for what he had done, for the theft was committed when he was in an epileptic condition.

Here is another case of defective inhibition. The interesting feature about it is the treatment he has had. Notice the color of his skin; he has chronic argyria. The nitrate of silver was given him as a cure for epilepsy. There have been a few cases of epilepsy benefited by the nitrate of silver, which is a stomachic tonic and alterative. This patient, however, took too much of it, hence the blueness of the skin which you notice. He took it for six or seven years. Nitrate of silver is a good remedy, but I do not believe it should ever be given

continuously for more than ninety days. I am somewhat fearful of its administration for even sixty days. Sixty grains of nitrate of silver are as much as is absolutely safe to give without interruption. The third of a grain is the ordinary dose, and if he took nitrate of silver at that rate for years, he must have taken a large quantity.

The treatment of epilepsy with nitrate of silver is not much in fashion to-day. Nitrate of silver is confined now to such diseases of the nervous system as sclerosis of the spinal cord, especially locomotor ataxia.

THE OIL-SILK JACKET IN THE TREATMENT OF BRONCHIAL ASTHMA.

By SAMUEL C. BUSEY, M.D., LL.D.,
of Washington, D. C.

The investment of the chest in a jacket made of oil-silk or other impervious fabric, and wadded or not with absorbent cotton or other form of cotton-wool, in the treatment of bronchial and pulmonary diseases, more especially bronchitis and pneumonia, has been in quite common use for many years, but I am not aware that any one has previously suggested such investment of the chest as a method of treatment in cases of bronchial asthma.

The object, therefore, of this brief paper is to present the value of the continuous wearing of an oil-silk jacket as a method of preventing the recurrence of attacks of that form of bronchial asthma which is ascribed to atmospheric conditions, and usually complicated, sooner or later, with more or less bronchial catarrh. To illustrate the effect of this use of this jacket I cite the following cases, which comprise about one-half of the cases to which it has been applied by me with equally beneficial results:

Case I.—Mrs. M., aged forty-three years, the mother of five children, was seized during the winter of 1884 with her first attack of bronchial asthma. During the autumn of 1885 her second attack occurred, and in the winter of 1886 the third. In October, 1886, with the beginning of the first "cold snap," the premonitory symptoms of a fourth attack began. The chest was immediately invested in a jacket, which had been previously prepared at my suggestion. The attack was aborted and no recurrence took place during the autumn and winter months of 1886 and 1887, when the jacket was continuously worn. In like manner she was protected from any attack during the following seasons of 1887–88 and 1888–89. In October, 1889, whilst on a visit to New York, and whilst standing on the high bridge over the East River, her respiration became very laborious, which proved to be the precursor of a pronounced and very severe attack of bronchial asthma. The jacket had not been replaced since the previous spring, and was not put on until near the close of this attack. It was afterward continuously worn until about January 1, 1890, when it was removed because of discomfort incident to the unseasonable and warm weather. Since its last removal she has had numerous very slight attacks of dyspnœa, coming on during the early morning hours, but disappearing after sunrise. None during the time it was worn.

This lady was passing through the period of menstrual decadence, and suffered from some of the usual and other extraordinary nervous conditions, which were mainly referable to the cerebral and circulatory functions, and incident to the change of life, but the asthmatic attacks did not seem to be directly connected with the nervous perturbations.

Only a few days ago she told me that she never had had an attack while wearing the jacket, and that since leaving it off she was frequently very uncomfortable, but would persist in her present course until a more severe seizure occurred. She stated also that the attack last October was induced by the elevation, and that for several years she always has had difficult breathing upon making a visit to Capitol Hill, an elevation of about eighty feet above her residence, and that the attack would be relieved by returning to her home.

Case II.—W. B., aged thirty-two years, was born and lived until he reached maturity in a neighboring county in the State of Maryland, and in a locality near extensive marshes and surrounded by lowlands subject to overflow during heavy rainfalls. At the age of three years, after sudden and prolonged exposure to falling temperature, he was taken with a very bad cold, characterized mainly by great difficulty in breathing. From this date he has been subject to frequent similar attacks, usually occurring during the autumn and winter seasons, and increasing in frequency with growth and age. At the age of twenty years he removed to Baltimore and two years later to this city. While residing in the country he lived an active outdoor life on a farm, but since coming to Washington has passed a sedentary life as a freight clerk in one of the railroad offices, subject to great hardships and exposed to the vicissitudes of the weather and fluctuations of temperature night and day. Since leaving the country the attacks have increased in frequency, duration, and severity, and in June, 1889, for the first time during the summer season, he had a very protracted and distressing attack, and another, equally severe, in September. During the interval between these he had several slight attacks, which did not confine him to the house. In his earlier life the asthma was usually preceded, for a day or two, by sneezing, then a slight cough followed by laborious breathing, usually lasting several days or a week, with remissions during the daytime and recurring paroxysms during the night. Since residing in this city the remissions have been less marked and the night paroxysms more pronounced and distressing. During the last two

attacks, June and September, 1889, there was no marked difference between day and night, and when they began to subside the improvement was progressive during day and night. During the past five years I have attended him in many attacks, but did not see him in the beginning of any, except those in June and September, 1889. They presented similar clinical pictures of aggravated bronchial asthma, characterized by great dyspnœa, a harassing cough, cyanosis, immobility of chest walls, inability to lie down, sleeplessness, anorexia, with diffuse sibilant and sonorous râles, audible hissing and wheezing sounds, copious fluid expectoration, and bronchial catarrh. During the September attack I had him fitted with an oil-silk jacket, which he has since worn continuously, with renewals every four or six weeks, as has been necessary. He has not had a subsequent attack, notwithstanding greater exposure during a more inclement season and the remarkable prevalence of the recent disastrous epidemic. Thus, for the first time in twenty-nine years, he has escaped an attack of asthma during the late autumn and winter months.

Case III.—J. M. D., aged five years, a vigorous boy, in good general health, and with a good family history, had, during the spring of 1888, an attack of difficult breathing, with cough, recurring in nightly paroxysms during several consecutive nights, which the physician in attendance pronounced asthma. During the autumn and winter seasons of 1888 and 1889 similar but more aggravated attacks recurred several times, and in October, 1889, he had the last, and the only one that I have seen. At my first visit I ordered the oil-silk jacket, which, with the usual and necessary renewals, has been continuously worn. No attack has occurred since. He has suffered with a moderately severe attack and a less severe relapse of the influenza, but has continued free from any asthmatic conditions.

The etiological relation of atmospheric conditions to bronchial asthma are capricious and variable. Asthmatics are differently affected by apparently similar conditions; some suffering more, some less, and others not at all during the same seasons and when exposed to the same fluctuations of temperature and weather changes. For instance, I know a gentleman who secures absolute relief by changing his sleeping apartment from his residence in this city to the adjoining city of Georgetown, whereas resident asthmatics of the latter city are at the same time suffering; and a second who never had an attack after removing from one residence to another, two squares distant; and a third who was permanently cured by removal from a house, in the cellar of which was a flowing spring of drinking water. It is, I believe, admitted that some city asthmatics find relief by removal to the country, and that country asthmatics sometimes secure relief by city residence. Seasonable conditions are equally variable. During some seasons in the same locality all asthmatics will suffer, at other periods some will suffer and some escape. Some suffer frequently, some annually, and some bi-annually, without apparent cause of difference.

These circumstances point to individual peculiarities and differences in personal and domiciliary hygiene as exciting causes, which must necessarily invalidate the claim of any method of prevention which has not been tested by its application to a large number of victims, during a sufficiently long period of years to include every variety of atmospheric condition and to eliminate all other causes.

It may, therefore, have so happened that the method of treatment was applied to patients during periods when they would have been free from any attack. It is, however, submitted for further and more extensive trial, which will certainly establish its value or prove its uselessness.

THE TREATMENT OF COMPOUND FRACTURES, BASED ON AN ANALYSIS OF ONE THOUSAND CASES.[1]

By FREDERIC S. DENNIS, M.D.,
of New York.

The subject of this paper is not of my own selection, but is one which has been assigned to me by the esteemed President of the Philadelphia County Medical Society. It is a subject, however, which may be designated as the touchstone of surgery, because a discussion of the treatment of compound fractures includes all the great principles involved in every department of the science. It embraces a consideration of cerebral, thoracic, and abdominal surgery; it includes a discussion of the great principles of antisepsis, it covers operative technique, it embraces the study of surgical pathology, it touches upon the higher departments of the science, and opens up the field where surgery must be considered as an arena for the exercise of sound judgment, for the display of clear foresight, and for the exhibition of accurate knowledge and ripe erudition. Finally, a full discussion of this subject inevitably leads to a consideration of the progress of surgery during the present century and its precise status at the present day.

In considering the management of compound fractures, I shall confine myself to the salient points which an extensive clinical experience has taught me to be the most essential for success. The 1000 cases from which I shall derive material for discussion have occurred during the past decade in four metropolitan hospitals devoted to the treatment of acute surgical cases, and also in private practice. The accumulation of so vast an amount of clinical material has been attended with great clerical labor.

[1] Read by invitation before the Philadelphia County Medical Society, April 9, 1890.

The conscientious treatment of these serious cases has been attended with a sense of great responsibility, and the results which I shall report have been attained only by close attention to the minutest details in the management of each individual case. There are some points in the treatment of compound fractures that deserve special consideration, and it is only by a study of these cases in groups that clinical facts of essential importance can be established. I have carefully watched the results of the same plan of treatment in many cases at the same time, and it has been by a process of evolution that some of the opinions which I shall enunciate have become fixed laws in routine practice. To see in one day nineteen cases of compound fractures in the same ward with a normal temperature is not a coincidence. The number might possibly be, but the same condition in all is the result of the application of fixed principles which have been established as the result of long study and observation. To see upon another day twelve cases in the same ward and all with normal temperatures, as happened during an unexpected visit of the President of the Philadelphia County Medical Society, removes all question of coincidence. These circumstances make it evident that the application of fixed rules is necessary to arrive at certain and uniform results.

Before entering upon a description of the manner in which the first dressing of a compound fracture should be applied, I desire to call attention to the management of the fracture preparatory to its first dressing in the hospital. The fate of a patient with a compound fracture often hangs upon the surgeon who first touches it. Whenever the circumstances are within the control of the surgeon, I would go still further, and recommend that ambulance surgeons should exercise great care in the transfer of a compound fracture to the hospital. I have made it a rule of practice at the Harlem Hospital that antiseptic irrigation should be employed at the station-house or upon the sidewalk before the temporary splint is adjusted, and that at once after the irrigation, a clean antiseptic dressing be applied before the patient is lifted into the ambulance. I feel sure that the success of treatment in the present list of compound fractures is in great part due to a strict adherence to this important rule. Contrary to my expectations, I have found these directions willingly and cheerfully obeyed by the ambulance surgeons, who now realize how important is their position in the matter of antiseptics.

The patient having been carried either to the hospital or to his home, the temporary dressing is now to be removed, the fracture adjusted, and the first dressing applied. I cannot emphasize too strongly the point that the *first and aseptic dressing will largely influence the prognosis*. This dressing, therefore, should be made in the operating room, because the germ-laden air of the hospital ward is not a safe place to expose a compound fracture. The instruments, sutures, ligatures, drainage-tubes, and everything possibly required for the operation should be immersed in carbolic acid solution (1 to 40). Several towels wrung out in a solution of bichloride of mercury (1 to 500) should be prepared for use about the table and around the limb, in order to protect the fracture from any possible contact with a surface not rendered aseptic. The wound itself should be covered by antiseptic gauze, while the limb is washed with soap and water, then shaved and irrigated. Upon the limb is then poured a saturated solution of naphthalin in ether. This application removes all the fat, and the solution crystallizes upon the surface and protects the parts.

Having made aseptic all the adjacent parts, the wound itself requires attention. All blood and débris should be washed away by a stream of warm bichloride of mercury solution (1 to 4000). The interior of the wound should be thoroughly irrigated with the same solution, and all hæmorrhage completely arrested. Loose pieces of bone not attached to periosteum should be removed. All pieces of fascia, fatty tissue, muscular shreds, and lacerated integument should be cut away with scissors, and then a final ablution made. The drainage-tube should be introduced into the bottom of the wound, and if the wound is so situated as to drain well, there is no necessity for a counter-opening. The tube is then cut off flush with the surface of the skin, and fastened by a safety pin. The wound is now closed by catgut sutures, which completes the operative technique. The towels should now be changed and clean ones substituted, which should also be wrung from bichloride solution. The limb is now in readiness for the application of the antiseptic dressings. This dressing, above described, can be done without an anæsthetic, and as a rule with little or no pain. When the compound fracture is extensive, it is necessary to administer ether, so that the dressing can be completed from the beginning to the end while the patient is under the influence of an anæsthetic. The fragments can now be adjusted, and if the displacement is great, a silver wire can be introduced to keep them in place. Again, it may be necessary to introduce, besides the wire through the bone, some deep catgut sutures, which are carried through the muscles. Deep sutures are necessary in all extensive and gaping wounds of the soft parts, especially when such muscles as the biceps and triceps, or the quadriceps extensor, are divided. These sutures must be independent of the superficial set. Such wounds as just described require free drainage, and counter-open-

ing is necessary in order to meet the requirements of the case.

Another class of compound fractures is often met where the wound is very small, and with these cases a different plan should be adopted. The irrigation should be made around and in the wound, and then it can be hermetically sealed by sprinkling iodoform over the perforation, and painting styptic collodion over the iodoform, and then irrigating with an antiseptic solution. This mixture will soon coagulate, and the medium of sealing is surgically clean, and then the fracture is ready for the antiseptic dressings. Thus it is evident that the small wounds can be hermetically sealed : the medium sized wounds closed by sutures and drained through the existing opening ; and the large wounds drained by a counter-opening and sewed with deep sutures, and the fragments held together by silver wire.

Having completed the operative technique, in one of the three ways mentioned, the parts are now prepared for the antiseptic dressings. Iodoform gauze, or a small piece of oil-silk protective, should be placed over the wound, with a hole cut in it to allow the mouth of the tube to drain into the dressings. Iodoform gauze is used, because bichloride gauze irritates the wound. The bichloride gauze is next applied in loose pieces over the iodoform gauze and around the wound. This dressing is moist because dry antiseptic dressings next to a wound are sources of infection. The loose and wet gauze is held *in situ* by the application of a moist bandage. Over this deep dressing, absorbent cotton is placed and retained by a dry bandage.

The last dressing affords a means of securing equable and uniform compression around the limb and over the fracture. The cotton by its elasticity expands and contracts so as to accommodate itself to the swelling of the parts in the vicinity of the fracture. This part of the dressing is very important as a means of preventing inflammatory swelling and of affording comfort to the patient. Four strips of sheet iron about one inch in width are now adjusted. One strip is to pass down on the posterior part of the limb, and over the heel and upon the sole of the foot. Two strips are placed upon the sides of the leg, and one upon the front of the leg, and bent so as to conform to the shape of the dorsum of the foot. Over these strips, plaster-of-Paris bandages are now applied, and the dressing is completed. The strips prevent any backward as well as any lateral displacement of the fracture, and also do away with the necessity of a heavy splint.

In three days a fenestrum is cut over the wound and under continuous irrigation the drainage-tube is removed.

The question of how long this first dressing should remain is a pertinent one. My experience in the treatment of this injury has taught me that no splint should be left on a limb longer than eight days without an inspection of the compound fracture. I have seen several bad results arising from a neglect of this rule. In one case I saw a fracture which was skilfully dressed with plaster-of-Paris examined at the expiration of six weeks, during which time the patient's condition was in every way satisfactory. Upon removal of the splint the bone was protruding, and considerable union had taken place. An osteotomy corrected the deformity, and in six additional weeks a perfectly satisfactory result followed. If this fracture had been examined the protrusion of the bone would have been detected, and the faulty position rectified. While this result is exceptional, such unfortunate complications can always be obviated by an inspection of the fracture after eight days.

There are some new questions which have arisen, that are of interest when discussed in the light of recent revelations in surgical pathology. Among the many subjects for special study and observation, I have selected a few which seem to me to possess unusual interest in connection with the report of these compound fractures :

1. Meningeal hæmorrhage, and fractures of the base of the skull.
2. Fat embolism.
3. Insanity following fracture of the skull.
4. Malignant disease.
5. Tenotomy.
6. Healing by Schede's method.
7. Amputation.
8. The conversion of simple fractures into compound or complicated fractures.
9. Compound fractures involving the major joints.

1. *Meningeal Hæmorrhage.*—This variety of hæmorrhage occurring in compound fractures of the skull is a subject about which much diversity of opinion exists. It has been the routine treatment for many years to ligate the common or external carotid artery in case of severe hæmorrhage from the middle meningeal artery or one of its large branches.

Among the cases in my list of compound fractures of the skull is one which is of great practical interest as bearing upon a new method of arresting hæmorrhage. In the case referred to, a man received a severe compound fracture of the skull upon the right side of the head, followed by paralysis of the left side of the body. The accident was caused by a stone weighing 700 pounds falling upon his skull. I trephined the seat of fracture, and removed over forty pieces of bone, which were loose in the wound, of which two fragments were larger than a twenty-five cent piece. I also found a large epidural blood-

clot, nearly the size of the palm of my hand. I removed the blood-clot, and found the middle meningeal artery bleeding to an alarming extent. The hæmorrhage was controlled temporarily with sponges and tampons, until I was able to remove more bone in order to secure the open vessel. Having removed bone to the extent of six inches, I attempted with artery forceps to seize the bleeding point. Every attempt failed, and I was unable to grasp the artery because, whenever the ends of the forceps were applied to the dura, this membrane was pushed down, and the forceps could not be made to catch hold of the bleeding point. The idea suggested itself to me in this crisis to introduce the point of a tenaculum through the membrane in such a way as to include the bleeding vessel in the curve of the tenaculum. With this instrument I now raised up the dura from the brain on a level with the bone, and then applied the artery forceps. The membrane, which before receded from the grasp of the forceps, and formed a tense, concave surface, was now held firmly, and that part between the curve of the tenaculum was lax, and permitted the forceps to seize tissue and artery. The vessel was tied with catgut, and the hæmorrhage was arrested. The paralysis upon the left side of the body disappeared. The wound healed in an aseptic manner, and the patient recovered so far as the operation was concerned. He died some time after the injury, and I was enabled to secure an autopsy, which was made by Dr. Grauer. There was nothing in the brain, or in its coverings, which could have caused death; the patient had died from exhaustion and inanition, with no local brain lesion. The use of the tenaculum in the manner described—to seize a torn middle meningeal artery through an opening made in the skull—seems to me a better operation than ligation of the external or common carotid artery in its continuity. Besides the question of the arrest of hæmorrhage by ligation of the meningeal artery by means of a tenaculum, another question has arisen in connection with these cases of meningeal hæmorrhage; that is, the possibility of a surface clot by *contre-coup*, the existence of which has been denied by many surgeons. I have three specimens, which I believe will settle this long-disputed question.

In the first of these cases, a policeman found the man in a condition of what was supposed to be intoxication. He walked to the station-house with the officer and was locked up for the night, and upon the following morning was brought before the police justice and sentenced to ten days' confinement on account of intoxication. At eleven o'clock he was returned to the station-house, awaiting the time to be sent to the Island. While in the cell, a few minutes after his arrival, he became unconscious; an ambulance was summoned, and he was taken to the Ninety-ninth Street Hospital. I saw the patient that day, and from the peculiar history of the case and the presence of paralysis, I diagnosed meningeal hæmorrhage. The patient was anæsthetized, and the uninjured scalp was incised, exposing to view a linear fracture. The trephine was applied, and an epidural clot was discovered. The dura was torn, and the brain substance lacerated. The wound was dressed antiseptically. In fourteen hours the patient died. The autopsy revealed the presence of a second epidural clot, which was almost opposite, and was the result of *contre-coup*. The scalp over the skull corresponding to this clot was normal, as was the scalp upon the opposite side, and the bone over the *contre-coup* clot was not injured.

The second case was brought to the hospital in an unconscious condition with general paralysis. The case was supposed to be a fracture at the base of the skull. The patient died the next day, and the autopsy showed a linear fracture of the parietal bone upon one side and extending to the middle fossa. Under the fracture was a large epidural clot, and upon removing the calvarium another surface clot was found at a point directly opposite to the fracture. This fracture did not extend upon the other side of the skull, and the clot here was also the result of an injury by *contre-coup*.

I have seen during the past winter another case similar to the two just described. These three specimens settle the important question whether a meningeal hæmorrhage may be produced by *contre-coup*. The diagnostic points of epidural meningeal hæmorrhage by *contre-coup*, or by traumatism without fracture, suggest operative interference in these cases.

The presence of symptoms of cerebral irritation followed by unilateral paralysis, with a slow, full pulse, the Cheyne-Stokes respiration, accompanied by a sudden rise of the temperature due to disturbance of the heat centre, form a group of symptoms which, if preceded by a short interval of lucidity after the injury in which no serious manifestations of brain lesion were present, make it extremely probable that an intracranial meningeal hæmorrhage has occurred.

These symptoms appearing at the time, and in the order mentioned, with or without any fracture, would indicate the application of the trephine over the seat of pressure, the removal of the clot, and the ligation of the middle meningeal artery through the opening made in the skull by means of a tenaculum applied in the manner already described. To some this may seem too bold; but when the fact is considered that formerly nine-tenths of these cases perished under the expectant plan of treatment, and further when it is considered how safe the operation of trephining is with antiseptics, it would seem that a surgeon might be derelict in his duty if

he did not remove a portion of the skull to take away the clot and arrest the bleeding. Within ten days I have trephined and removed a clot from the right ventricle. This is the first time that a clot from the ventricle has been removed, and I trust that this case may be a precursor for the relief of apoplexy.

Fracture of the base of the skull has been one of those injuries which the surgeon has treated purely upon the expectant plan, and with the conviction that death is sure to follow. This view of the lesion has been entertained for years by hospital surgeons, and there is certainly a consensus of opinion among surgical writers in regard to the prognosis. All standard text-books and monographs are in accord in reference to the mortality. During the past few years my attention has been especially directed to a study of these cases of basilar fracture, and I shall endeavor to demonstrate here that fractures of the base of the skull are amenable to surgical treatment. I shall also endeavor to point out the clinical fact that the great majority of these cases die from causes which can be wholly prevented by the surgeon. There has been but little encouragement to the surgeon to attempt any treatment in these cases of basilar fracture, when one reads in the latest edition of a large standard work on surgery, "that any treatment directed to the lesion itself is out of the question." I trust that I can demonstrate the incorrectness of this view, which represents the opinions of most surgical authors. This is not the time or the place to enter upon the discussion of the signs and symptoms of fracture of the base, which would require too great a digression from the title of the present paper.

With a view to simplifying the general subject of basilar fractures, I shall advance two propositions, and shall attempt to prove the correctness of these propositions:

First. That fractures of the base of the skull should be considered in the same category as compound fractures of the vertex of the skull or of the long bones.

Second. That since fractures of the base of the skull possess the same essential characteristics as other compound fractures, they should therefore be treated by the same exact principles of aseptic surgery.

Some surgeons may dissent from the first proposition, viz.: that a basilar fracture should be considered in the same light as a vertex fracture. It is evident, however, that every compound fracture has air admitted to the seat of the fracture, and that this is the case in fractures of the base of the skull. If the anterior fossa is the seat of lesion, air gains entrance to the fracture through the nasal cavities. If the middle and posterior fossæ are involved, air gains access either by the external auditory meatus, or by the Eustachian tube through the pharynx and nasal cavity. The entrance of air to the seat of fracture, which is a *sine qua non* for the existence of a compound fracture, is not the only point that basilar fractures possess in common with all other compound fractures. The basilar fracture is associated with hæmorrhage, laceration of nerves, venous thrombosis, septic phlebitis, fat embolism, cerebro-spinal shock, pyæmia, septicæmia, and abscesses; and, in fact, with all the complications that arise in connection with other compound fractures. Even the cerebral lesion is not confined to basilar fractures, because it occurs in fractures of the vertex. It is thus evident that fractures of the base do not differ in any essential particular. The view may be even advanced that the cerebral lesions in vertex fractures may be more severe than in basilar fractures, because in the latter the cerebro-spinal fluid, in a measure, protects the brain from concussion and thus diminishes the shock.

A discussion of the second proposition brings us to a consideration of the treatment of compound fractures in general. The technique is simple. Every patient suffering from fracture of the base, if the immediate shock is not too profound, should be removed to the operating-room. Every outside preparation having been made to make the toilet aseptic, the head should be held firmly and the entire scalp shaved, after which it should be thoroughly washed with soap and water, and then irrigated with a 1 to 500 bichloride of mercury solution. Attention should next be directed to the irrigation of the external auditory canal and the nasal cavities. Both of these should be rendered thoroughly aseptic, after which the ears should be packed with iodoform or bichloride gauze, and some absorbent cotton plugs placed in the nose. The air can filter through cotton, but microörganisms cannot pass through it. In irrigating the nasal fossæ the surgeon must exercise great care, lest the fluid enter the stomach and produce toxic effects. There remains now only one other possible channel of infection to the seat of fracture, and that is the Eustachian tube. This may carry sepsis to the interior of the cranial cavity in a fracture of the base. The arrangement of the ciliæ in the tube is such as to propel air and mucus *toward* the nasal cavity; but during the act of deglutition the current may be reversed, and infection thus reach the base of the brain. In the ordinary form of fracture of the base, where the membrana tympani is ruptured, the discharges make their exit through the auditory canal. In the exceptional cases where the membrane is not ruptured, the serum, blood, and cerebro-spinal fluid find their way into the nasal cavity and the pharynx, and thus these cases are most exposed to sepsis. If

the unruptured membrana tympani is examined in a basilar fracture, the membrane will be seen puffed out on account of the presence of fluid behind it, and the membrane will have lost its natural lustre. These are the circumstances under which it may be wise to puncture the membrana tympani, and thus allow the blood and the cerebro-spinal fluid to escape through the external auditory canal. The diversion of the discharges from the Eustachian tube into the ear makes it possible to keep the fluids permanently aseptic. Having now rendered the head and all the avenues of approach to the intracranial cavity surgically clean, it remains to apply a dressing that will keep these parts permanently free from any source of infection. This object is best accomplished by the use of a cap made of wet, loose bichloride gauze or carbolized wool, over which absorbent cotton and a plaster-of-Paris bandage are applied. The cap should completely surround the entire head, cover in the ears, and protect every channel leading down to, and communicating with, the seat of fracture. The cerebral viscera are thus protected from the entrance of septic germs. This same dressing should be made from time to time during the repair of the fracture, and under the same strict and rigid rules of antiseptic surgery.

The reasons for dressing fractures of the base of the skull with a scrupulous attention to the minutest detail in antiseptic surgery are at once obvious. If a patient survives the immediate shock of the fracture, and lives twenty-four hours, he is almost certain to die from causes which can be directly attributed to sepsis. Among these causes may be mentioned basilar meningitis, cerebral abscess, pyæmia, suppuration in the petrous portion of the temporal bone, septic phlebitis, encephalitis, leptomeningitis, and other complications due to infection.

If the surrounding parts and the discharges are kept aseptic then sepsis cannot occur, and this removes at once all the causes of death due to septopyæmia. I do not pretend to state that it is impossible for a patient with fracture of the base to die except from a cause due to sepsis; but I do state that nearly all these cases terminate fatally from causes which are due to sepsis. A reference to statistics will demonstrate that deaths occurring in fractures of the base of the skull, independent of shock or sepsis, are extremely rare, and that nearly all these cases die, therefore, from causes which can be prevented by the surgeon. I would go even further, and recommend that all cases of head injury with hæmorrhage from the ear, or from the nose, be treated with antiseptic precautions. I have seen many cases where a fracture of the base of the skull did not exist, but where a hæmorrhage was present from the ear or the nose, and in the course of ten days a fatal meningitis developed. Every practical surgeon can recall such cases as I have mentioned, and I believe that the meningitis has its origin in septic contamination of the hæmorrhagic or other discharges. The old and good rule in surgery, "Never to look lightly on any injury of the head, however trifling it may appear," is one that, if strictly observed, may be a means of saving life where otherwise that life may be sacrificed. During the past few years I have seen a large number of cases of basilar fractures. Most of these cases died from shock within twenty-four hours; but recently, I have had the satisfaction of seeing six cases recover under the plan of treatment just described. By placing basilar fractures in the same category as compound fractures, and treating them as such, there is a prospect of recovery in cases which have been hitherto considered fatal. If fractures of the base can be saved, it is another triumph of antiseptic surgery, which but recently was thought impossible. These six cases of fracture of the base are not included in the list of one thousand cases, as they have been separately published in the *Transactions of the New York Academy of Medicine*. If, however, these cases were introduced, under the same conditions as the other compound fractures, the mortality would be affected only in favor of its fractional diminution.

2. *Fat Embolism.*—This interesting complication was first fully described by Wagner and Zenker. Fat embolism means the entrance of fluid fat from the medulla of the bone into the veins in the immediate vicinity of the fracture, and through these channels into the capillaries of the brain, spinal cord, lungs, kidneys, and other essential organs. The presence of fluid fat in the blood was described in 1836 by Dr. R. W. Smith, but the clinical importance of this condition was not investigated until recently by Bergmann, Czerny, and Scriba. Dejerine has experimentally produced fat embolism in the lower animals by inserting laminaria-tents into the medullary cavity of the bone. The symptoms of fat embolism are present within the first three days as a rule, and resemble those of secondary shock. They occur before the time at which venous thrombosis or pulmonary embolism would be expected to appear. Great dyspnœa associated with the Cheyne-Stokes respiration, irregularity of the heart with a sudden rise of temperature, together with twitching of the muscles, as well as paralysis of certain muscles, have been observed in these cases. There have been no metastatic abscesses discovered where an autopsy has been made. I have found an abundance of fat globules following the train of symptoms just mentioned. This group of symptoms must not be mistaken for shock following fracture, nor for pulmonary embolism. Shock may

be said to be present *three hours* after the fracture, fat embolism *three days* after, and pulmonary embolism *three weeks* after. For convenience, I have arranged these complications in the order in which they are most likely to occur, and by associating these conditions, which simulate each other, with the time at which they appear, no mistake in diagnosis is likely to arise.

3. *Insanity following Fracture of the Skull.*—There have been a good many cases of insanity following traumatism of the head, and this is generally accepted by specialists in nervous diseases. I have at present under observation a case of insanity, one of imbecility, and one of idiocy, all resulting from traumatism of the skull; also a case in which there was severe and persistent headache, extending over a period of six years, in which I trephined over the site of a previous fracture, and found the dura thickened and the seat of a pachymeningitis. I removed the depressed bone, which relieved the intracranial pressure, and the patient has never had any return of the agonizing pain in her head, and her mental condition seems normal. In cases of traumatic epilepsy attended with more or less mental disturbance, I have used the trephine with most excellent results. I am aware that trephining is not uniformly successful in epilepsy, and my own experience has led me to expect little from the operation in those cases where there is not a well-marked depression produced by a fracture. There is a case reported by Dr. MacDonald, in which insanity followed a compound fracture of the skull, and also a case reported by Dr. Macewen, of Glasgow. Both of these patients recovered after trephining. Schroeter mentions a case where a patient became insane on account of a fracture of the skull. Dr. Spitzka gave me the notes of another patient who became insane after a depressed fracture of the skull produced by the explosion of a shell at the battle of Bull Run.

Many other cases might be found where the cause of insanity is due to an old and unrelieved depressed fracture. In all these cases depression existed, hence the importance of elevating at the time of the accident, even though no symptoms exist.

The kind of insanity which follows in these traumatic cases is that form which is attended with great irritability and mental excitement, and which is also accompanied by fits of violent temper and passion. These phenomena are suggestive in depressed fracture, and call for surgical interference in a class of cases where, until recently, no relief could be extended to the sufferers.

The part of the head injured seems to exert a causative influence upon the development of insanity. Dr. Garmany has pointed out the interesting clinical fact, that insanity follows in fifty per cent. of the cases of traumatic epilepsy where the injury involves the frontal or parietal regions. The same writer has also demonstrated that an irritative, rather than a destructive, lesion is the cause of insanity. As irritative lesions are largely due to the effects of traumatism, it follows that all cases of compound fractures of the skull should be treated by rendering the wound aseptic by operative interference, even in the absence of any symptoms.

The suggestion of enlarging the field of operative surgery of the skull, so as to trephine in cases where there are no symptoms, for the purpose of preventing insanity, may seem at first too radical. When, however, it is considered that the operation of trephining in this list is attended with a mortality of a fraction of one per cent., it seems justifiable in all cases to trephine in order to prevent insanity, if for no other reason. A still further extension of the field of operative surgery of the head has been recently made by Mr. Horsley to include trephining for the relief of general paresis. The object is to remove some of the arachnoid fluid, and thus relieve intra-cranial pressure. To what extent this operation will afford relief is at yet *sub judice*.

4. *Malignant Disease.*—The question of the development of malignant tumors at the seat of fracture is an exceedingly important one in surgical pathology. The late Dr. S. D. Gross pointed out the important fact, that almost half of the cases of malignant bone disease can be traced to traumatism. His valuable contribution upon this point is worthy of careful study. I have been able to verify in my own experience his conclusions.

I recently operated upon a child with an immense sarcoma upon the occiput. The child had sustained a heavy fall upon the back of the head six months previous, followed at once by the development of a large hæmatoma. The hæmatoma was not incised, and a linear fracture existed beneath it. For some weeks after the injury there was nothing special excepting the presence of the hæmatoma; but the tumor then began to grow very rapidly, and in less than six months from the receipt of the injury the sarcoma was much larger than the child's head. The patient died some weeks after an incomplete operation for its removal. I have many beautiful specimens illustrating the clinical fact that a fracture may be the starting-point of this variety of tumor.

The prognosis of sarcoma affecting bone as a result of fracture, while grave, is not necessarily fatal, provided the tumor is recognized before glandular swelling appears and the operation is performed early and includes the tissues far from the seat of disease. This subject of the influence of fracture upon the development of sarcoma is one on which no extensive investigation has as yet been made,

and it is one which offers a rich field for original research.

Epithelioma also may develop indirectly as a result of a compound fracture; but this malignant growth has its origin from the soft tissues in connection with a sinus leading down to necrosed bone. If a sinus is not healed it becomes lined with epithelium, and a discharge of ichorous pus through it from time to time sets up an irritation with a proliferation of epithelial cells, and epithelioma may in this way secondarily develop. While the epithelioma is not directly connected with the seat of fracture, as is the case in sarcoma, nevertheless, the disease may have its origin in conditions arising from sequestration in a compound fracture. The closure of sinuses in connection with necrosis following a fracture should always be aimed at by the surgeon.

5. *Tenotomy.*—Six years ago I called attention to this procedure in the treatment of compound fractures, and in a number of cases since then I have been impressed with the value of the operation in all oblique compound fractures. Tenotomy relieves at once any contraction of the muscles, permits the fragments to be placed in accurate coaptation, and secures physiological rest to the fracture. It affords also great comfort to the patient, and is a valuable means of fixation during the first ten days. Tenotomy may be employed upon the tendo-Achillis, upon the hamstring muscles, upon the tendons of the arm and forearm, and even upon the sterno-cleido-mastoid muscle in fractures of the clavicle. I believe there is much to be gained by the adoption of this simple procedure in overcoming muscular spasm in compound fractures of the extremities where there is difficulty in reduction, and I cannot too highly commend it as a means of overcoming the obstacles to the reduction of fractures. In several cases of compound fracture of the tibia, where the solution was parallel with the long axis of the bone, with considerable separation, I found that a horseshoe tourniquet was a most valuable instrument in closing the long fissure. The instrument by pressure overcomes the vertical separation, just as tenotomy by relaxation overcomes the oblique displacement. The pad can be applied upon one side of the bone and pressure be made by applying the other pad over a thick plaster bandage. The screw can be gradually tightened, and in a few days the bone can be approximated and the instrument discarded. This is a safe and more satisfactory instrument than the apparatus devised by Malgaigne. I have found that muscular spasms can in most cases be overcome by position. Relaxation of the muscles will always relieve the spasm. The use of sulphonal, as well as many other drugs, has been suggested, but I have never seen a case where relaxing the muscles did not relieve the condition.

6. *Healing by Schede's Method.*—In a number of severe cases of compound fractures of the leg and skull I have observed some beautiful illustrations of this newly described method of repair. It has usually been taught that blood-clots in wounds are obstacles to repair by primary intention, and that these clots act as foreign bodies. In one case of severe compound fracture there was great hæmorrhage between the fragments, and the large space between them was filled with fluid blood and clots. I divided the tendo-Achillis to overcome the contraction of the muscle, which permitted the fragments to be brought into perfect apposition. The wound was then dressed with the most rigid aseptic precaution, and the blood-clots became organized and furnished a most valuable medium of union. The fracture healed by primary intention, and the patient made an excellent recovery.

Fluid blood and clots, if perfectly aseptic, are valuable adjuncts to the repair of compound fractures. They are, however, most potent sources of evil if any infection reaches the clot through carelessness of the surgeon. It is a most valuable contribution to the treatment of compound fractures, if the blood which escapes between the ends of the fragments can be in the future utilized as a means of hastening and perfecting union by primary intention. The reason why so important a principle in surgical pathology has been so long unknown, is explained by the fact that blood-clots, until rigid asepsis was established, were recognized sources of septic inflammation. If all the surrounding parts in every compound fracture are made aseptic, clots and fluid blood can be utilized for the purpose of healing. Anything short of absolute surgical cleanliness will convert these clots and the blood into dangerous agents of infection.

7. *Amputation.*—Amputation of the limb in compound fracture was formerly resorted to with great frequency in hospital practice. Before the introduction of antiseptics, pyæmia destroyed the life of almost every patient suffering from compound fracture who was brought to a large metropolitan hospital. The time is within my own recollection when, in Bellevue Hospital, amputation was immediately performed as a routine treatment to prevent blood-poisoning, upon the admittance of a compound fracture; and this operation was considered by surgeons as offering to the patient the only chance of recovery. At the present time limbs are saved which would then have been sacrificed, and it is a rare event to witness an amputation in compound fracture. Extensive fracture of the bone with protrusion of the fragments through the soft structures would not now form an indication for

amputation, unless the soft structures were badly lacerated. Formerly the loss of a few inches of the bone called for primary amputation; but this no longer offers an indication, for the bones are brought together by silver wire, and though the limb may be shorter than its fellow, the member is still retained, and elevation of the shoe compensates for any slight irregularity in the gait. In one case which I treated, where four inches of the tibia were removed, the patient made an excellent recovery.

The limits to which amputation in compound fracture may be resorted to are exceedingly narrow and restricted, and this conspicuous clinical fact is one of the most notable steps in the advance of modern surgery. Another important point in reference to amputation in compound fracture is the proper line of treatment to be pursued up to the time of the operation. It often happens that a patient is suffering too profoundly from shock to make it expedient to amputate. In these cases great benefit is to be derived from deferring the amputation even many days, until the condition is such as to justify the operation. Formerly this could not be practised without subjecting the patient to a greater risk from septic infection than would be incurred by an amputation during shock. If the wound is at once made aseptic, and compresses be placed over the fracture to control the hæmorrhage, and these compresses do not extend higher than the wound itself, the amputation can be deferred. It is important that these compresses be applied only over the wound, and that no tourniquet or any other form of compression be applied to the limb in the continuity of the artery above the injured part, for if this is done, there is danger of gangrene in the flaps after the amputation. In one case gangrene followed an amputation of the leg where a tourniquet had been placed over the femoral artery. This patient was brought to the hospital from a neighboring town with a tourniquet upon the femoral artery for the purpose of arresting hæmorrhage in a compound fracture of the leg. There can of course be no blame attached to the hospital authorities for a mistake which occurred before the patient was received into the hospital, but I call attention to the case in order to emphasize forcibly this point.

8. *The Conversion of Simple Fractures into Compound or Complicated Fractures.*—By this is not meant the conversion of a simple into a compound fracture on account of the bone thrusting itself through the integument at the time of the accident. This may happen, especially when the muscular spasm is great, or during the transportation of a patient suffering from a simple fracture. What is meant, however, is the spontaneous conversion by means of the necrosis of a small fragment. An abscess subsequently forms and pus is set free, and the seat of fracture is exposed to the atmosphere. I have seen, for example, a Pott's fracture—that is to say, a fracture of the fibula three inches above the tip of the external malleolus, with a laceration of the deltoid ligament—converted after several weeks into a typical compound and complicated fracture, owing to the necrosis of the distal fragment. Suppurative arthritis of the ankle-joint ensued with caries of the astragalus. The ankle-joint was opened, the carious fragments removed, the joint freely irrigated, and an antiseptic dressing applied. The patient recovered in a few weeks with a useful joint. The possibility of nature transforming a simple fracture into a complicated one must not be overlooked. In such cases prompt surgical interference may arrest the progress of the disease, and effect perfect restoration of a joint, otherwise this complication leads to irreparable damage, if not to loss of life.

9. *Compound Fractures Involving Major Joints.*—The treatment of compound fractures involving major joints has been entirely revolutionized since the introduction of aseptic surgery. The criticism I would offer upon the general management of these cases, is, that too little conservatism of one kind, and too great radicalism of another kind, are simultaneously practised. The bad results in fracture-dislocations are due in a large measure to a want of rigid asepsis on the one hand, and a too extensive operative interference on the other. For example, the joint may not be rendered thoroughly aseptic at the beginning, but may be extensively interfered with as regards operative procedures.

In the one hundred and seventy-one compound fractures involving joints, recorded in my one thousand cases, the results as regards the usefulness of the joint have been in nearly all the cases perfect. To have a compound fracture-dislocation of the ankle-, knee-, elbow- or shoulder-joint, repair with complete restoration of function, is the aim of the surgeon. In one of my cases, the astragalus extruded from the joint and was re-inserted, and perfect movement of the joint followed. These ideal results are to be obtained only by the exercise of great care. In all fracture-dislocations the joint should be immediatly rendered absolutely aseptic by thorough irrigation. The drainage should be entirely across the joint, otherwise a pocket for the retention of inflammatory exudates is sure to form in the fold of the capsule. These products under certain conditions are sources of great danger. A careful study of cases of fracture-dislocation reveals the history of an abscess formation weeks after, upon the side of the joint opposite to the original wound. This complication, so often reported, is obviated by free drainage. It is not sufficient to drain one side only, and that side through the original opening into the joint; but the tube must pass entirely

through and across the joint. Physiological rest for many weeks must then be secured, and no passive motion employed for at least six weeks. Passive motion too early employed has often excited inflammation which has led to suppurative arthritis. Active motion must follow in its turn, but not for some time after the employment of the passive motion and massage. A proper sequence in the employment of these different agencies is most important in order to reach an ideal result.

The complete history of the one thousand cases of compound fractures I have here before me. Each case is given in full with the name of the patient, the date of his or her admittance to the hospital, the age, a description of the injury, the treatment in full, and the result, together with the name of the house-surgeon on duty at the time as a matter of reference. I have also most of the temperature charts, and in bottles the pieces of skull which have been preserved, and labelled to correspond to the cases given in the table.[1] It is obvious that time will not permit the detailing of these histories, and therefore I can only give a summary.

The general summary in the one thousand cases is as follows:

Skull	178
Nasal, malar, maxillæ and patellæ	89
Arm	40
Forearm	41
Fingers and toes	97
Ilium, clavicle	2
Thigh	87
Leg	295
Fractures involving shoulder-, elbow-, or wrist-joints as a result of disease or accident	39
Fractures involving hip, knee-, or ankle-joints as a result of disease or accident	85
Fractures involving carpal or metacarpal, tarsal or metatarsal joints as a result of disease or accident	47
	1000

Now, following the example of surgical writers who have carefully tabulated the results of treatment in compound fractures, I shall eliminate all those cases in which primary amputations were performed, because they do not concern the point at issue; and I shall also, according to the practice of writers, reject all those cases which died of hæmorrhage, collapse, shock, etc., within forty-eight hours, although most of the cases died within a few hours after injury. I shall also leave out cases of compound fractures of the hand and foot, as too insignificant to be classed with compound fractures of the long bones or of the skull.

In the total of one thousand consecutive and, of course, unselected cases of compound fractures, produced by traumatism or by operation, there were 101 deaths, 60 primary amputations, and 4 cases where the results were unknown on account of the removal of the patients from the hospital, at their own request, immediately after their admittance. In the 101 deaths, 82 died within forty-eight hours after the accident and during shock, and consequently these deaths should not be included in any figures to ascertain the percentage of mortality, because the patients died before any plan of treatment could be adopted having reference to the repair of the fracture or to the prevention of septic infection.

The remaining nineteen deaths occurred from the following causes: One from tuberculous meningitis following some weeks after a resection of the hip-joint, so that this case died from other causes than septic infection; another from uræmia in chronic Bright's disease one week after wiring the patella. The wound was, however, healed and perfectly aseptic, so that this case died from other causes than septic infection. Another died one month after trephining, from exhaustion and inanition, with the wound perfectly healed by primary intention, and, as shown by the autopsy, with no evidences in the brain of the pathological changes of sepsis, so that death in this case cannot be attributed to septic infection. Two other cases died from irreparable damage to the brain, in one of which the lock of a gun was driven through the skull into the brain, and in the other a fracture at the base was found at the autopsy in addition to the fracture of the parietal bone, so that death in neither of these two cases was due to pyæmia or septicæmia. Four other cases died from cerebral softening, which was situated at a distance from the original wound.

In reference to these cases of cerebral softening following injuries, a word of explanation seems pertinent. The circumscribed areas of softening in every respect resembled the changes which are found after apoplexy. There was no local evidence of septic infection, and in all the four cases the autopsies were made by experienced pathologists. The situation of the softened areas at a point distant from the original wound, the changes, *i. e.*, hæmorrhage and softening, and the perfect aseptic and healed condition of the external wounds, indicate that these cases are not of septic origin from the wound, but that they are changes identical with those which are found in cases of cerebral apoplexy. The cerebral softening appears to be due to a molecular disintegration or laceration of brain tissue from traumatism, and this disturbance of the nutrition produces a metamorphosis and liquefaction. The external surface of the dura seems to possess power to prevent the entrance of septic microorganisms into the cerebral substance; while the

[1] Dr. Dennis exhibited some of the bones of the leg, thigh, arm, and forearm in which amputation was performed, also the pieces of bones from the joints, which pieces were removed by resection.

internal surface of the dura, owing to its prox mity to the arachnoid space, is exceedingly delicate and affected by the slightest amount of septic material. Experimental work in this direction indicates that such points of softening may have their origin in traumatism, and are not necessarily due to sepsis. To convince myself further of the accuracy of this conclusion I trephined the skull of a dog, and planted upon its dura septic micrococci, which were furnished to me from cultures by Dr. Biggs. Though the microörganisms were septic, they were incapable of developing cerebral abscess through the dura or even producing a meningitis.

Such an experiment, while it is not conclusive, of course carries additional evidence in favor of the non-septic origin of such cerebral softenings, though they may be due to the presence of some such micro-organism as the bacillus tuberculosis; but at the same time the traumatism may have acted as an exciting cause to develop an abscess in tissue already impregnated with pathogenic germs. This explanation places a higher value upon antiseptic surgery, and it also serves to illustrate that an operation like trephining may be a brilliant success, so far as the operation is concerned, but that the patient may perish from causes which are as yet beyond the complete control of the surgeon.

This is still an unoccupied field for investigation and research, and surgeons must turn the direction of their studies to those causes of death which are not connected with the details of antiseptic surgery. Perfection has been almost reached in the technique of the operation of trephining, but as yet there are circumstances which are not controlled by the practical surgeon, and in a study of these causes future scientific surgery must engage.

Returning again to the list of nineteen deaths after this brief digression, one case died from diphtheria after the external wound of the compound fracture had healed. The wound was aseptic and was never the seat of any disturbance, and as the diphtheria affected the larynx and trachea the cause of death was in no way connected with the fracture, although, of course, the time was too short to have the bone firmly united. One case of compound fracture of the skull died on the fifth day, but in this case the patient was suffering from a fracture of the spine which caused his death by myelitis. One case died within forty-eight hours after admittance, from cerebral abscess connected with a punctured fracture of the skull, which had been operated upon two weeks previous by a surgeon in a neighboring town. During the patient's sojourn in the hospital, he was trephined and seven ounces of pus were evacuated from the brain, but he died a few hours later. This case is excluded on the ground that the patient's injury was not treated in the hospital, and that he did not enter the hospital until within forty-eight hours of his death. The death was clearly due to sepsis, but the circumstances were such as to relieve the hospital surgeon from all responsibility.

One case died after forty-eight hours, but it was a case of primary amputation. The patient was run over by a locomotive; both feet were crushed and the hanging toes were removed as soon as his condition would permit. One case similar to the last died from a crushed foot ninety hours after the accident. The patient was over sixty years of age, and never reacted from the shock. The remaining case of death was due to leptomeningitis, which occurred fifty-two hours after trephining. This case was due to sepsis.

Finally, in order to arrive at the mortality in this list of one thousand compound fractures, there must be deducted from the original one thousand cases 60 primary amputations, because no treatment of the fracture itself was undertaken; 82 deaths from shock occurring within forty-eight hours, because no treatment was begun; 4 cases where the result is unknown because the patients left the hospital of their own accord; 155 cases of compound fractures of the fingers and toes, because they are too insignificant; also 18 cases just mentioned in detail. There then remain 681 cases of compound fractures with *one death due to sepsis.* This gives a death-rate of about one-seventh of one per cent. In order to appreciate fully what aseptic surgery has accomplished in reference to the management of compound fractures, it is necessary to compare the results obtained prior to the introduction of antiseptic surgery. In the Pennsylvania Hospital, Norris has made a statistical report of the compound fractures treated between the years 1839 and 1851. During that time there were 116 cases of compound fractures of the leg and thigh (excluding those cases requiring amputation) with 51 deaths, thus giving a rate of mortality of forty-four per cent.

In the New York Hospital during the same period there were treated 126 cases of compound fractures of the leg and thigh (excluding those cases requiring amputation) with 61 deaths, giving a rate of mortality of forty-eight per cent. If a comparison is now made between the tables just mentioned and my list of one thousand cases, the mortality falls from forty-eight per cent. to a cipher. In the Obuchow Hospital Reports of St. Petersburgh there are 106 cases of compound fracture with a mortality of sixty-eight per cent. No particulars are given in this high death-rate.

In Guy's Hospital, from 1841 to 1861, there were reported 208 cases of compound fractures, with 56 deaths, giving a mortality of about 28 per cent. Billroth reports from the surgical clinics of Vienna

and Zurich 180 cases of compound fractures (excluding cases of amputation), with a mortality of 31 per cent. from septo-pyæmia. Now, after the introduction of antiseptics, a study of Billroth's table of compound fractures shows a reduction in the death-rate to about 3 per cent. The influence, therefore, of antiseptics has caused the death-rate to fall from 26 to 68 per cent. to about 3 per cent. In the present report of one thousand cases, if we compare the fractures of the extremities only, as has been done in all of the above tables, there is no death from septo-pyæmia, and thus the rate of mortality from blood poisoning is now reduced from 68 per cent. to a cipher. It may be said, therefore, that pyæmia and septicæmia, which formerly destroyed as many as 68 per cent. of compound fractures, have been practically eliminated. The science of surgery has at last demonstrated to the world that it has fairly met these demons of destruction, and that it has conquered them. Without doubt, the means of warfare have been found in the establishment of bacteriological laboratories, for without these institutions the great discoveries that affect the happiness and mortality of the human race could not have been made. For my own part, I remained a sceptic to the germ theory of inflammation until the Carnegie Laboratory afforded me an opportunity to work out my own salvation. The reduction of the death-rate from 68 per cent., which half a century ago was considered a brilliant achievement, and a result which was thought worthy of publication, to that of a cipher, represents what surgery has done for the amelioration of human suffering and the preservation of life. Humanity, indeed, owes a debt of gratitude to the science of surgery, which has annihilated pain and suffering, and has preserved and prolonged human life. To Pasteur and to Lister the profession are indebted for this great work—the former as the discoverer of the means, and the latter as the one who applied the discovery to surgery. Surely their names can never be disassociated with the march and progress of the grandest profession in the world.

HOSPITAL NOTES.

OPERATION FOR INGUINAL HERNIA IN A CHILD. THIERSCH'S METHOD OF SKIN-GRAFTING. STRICTURE OF THE URETHRA. FISTULA IN ANO. REMOVAL OF A FLOATING CARTILAGE FROM THE KNEE-JOINT.

Abstract of a Clinical Lecture delivered at the Roosevelt Hospital, New York.

By CHARLES McBURNEY, M.D.,
ATTENDING SURGEON.

Case I.—The first patient presented to the class was a little boy, who, at the time of his admission to the hospital, was reduced almost to a skeleton. Urination had been constant and painful. He was found to be suffering from a calculus, which was removed by suprapubic cystotomy. All the bladder symptoms were removed by this operation; but there was in addition an inguinal hernia induced by the calculus in the bladder. This was operated upon a week previously, and the sac found filled with such a large mass of intestine that reduction was accomplished with difficulty. It is not an easy matter to secure proper antisepsis in children on account of their restlessness, so that Dr. McBurney had been in the habit of dressing such cases with a plaster-of-Paris double-spica bandage; with this heavy dressing the child can be kept lying immovably on one side, so that the stream of urine is directed away from the wound. This was the method adopted in the present instance, and the patient's temperature only once reached 101° F., having been most of the time below 100° F. There have been no symptoms that would lead one to suppose that the wound had become infected. On removing the dressing, there was found some swelling of the testis, but the wound itself was in excellent condition with the exception of a drop or two of pus in the scrotal incision. The operator said that personally he had no objection to operating upon such young children, and that he had done so in a number of cases without the development of any unpleasant symptoms. The plaster-of-Paris bandage is no longer needed, and the subsequent dressings—consisting of powdered iodoform, iodoform gauze, rubber tissue, and a roller bandage—will be changed on alternate days. The little patient's general condition is remarkably improved.

Case II.—The next patient was a man who had received a slight injury to the knee, which was followed by a suppurative inflammation of the bursa, and extensive burrowing of pus. The suppurating sac had been opened and treated in the usual way, yet during two months of careful treatment, there had been no real attempt at repair, and large chronic ulcers remained. A week ago, he had been subjected to the operation of skin-grafting by Thiersch's method, which Dr. McBurney has frequently used, and considers much the best method. The grafts were obtained by shaving off with a very sharp razor, large thin sections of healthy skin from the thigh. The surfaces of the ulcers were excised, and, after controlling the hæmorrhage, the grafts were applied. They were covered with India-rubber tissue, and the dressings kept moist with salt solution. The surface from which the grafts were taken was simply dusted with iodoform and firmly bandaged. On removing the dressings, it was found that a small ulcer on the lower part of the leg presented only one minute point of granulation; a second ulcer in the middle of the leg, about three inches in diameter, which had been covered by two grafts, had cicatrized, and the same result had been attained in a still larger ulcer in front of the knee. On the latter ulcer were one or two dark points, showing where hæmorrhage occurred soon after the application of the grafts. These will probably slough. The most remarkable feature of this method is the rapid elevation of the surface after the application of the grafts. Those who saw the operation, recalled the fact that the ulcers had sharply cut edges, and seemed to be about one-sixth of an inch in depth, whereas they were now level with the surrounding surface. There is an entire absence

of any tendency to cicatricial contraction, and the tissue will remain as it is with the exception of a little thickening. By this simple operation, one week has sufficed nearly to heal the ulcers, whereas two months of previous treatment had accomplished nothing. In all probability the patient will be up and around in another week.

CASE III.—Dr. McBurney called attention to a complicated case of urethral stricture, which required very extensive cutting. He divided every stricture so that a No. 32 sound readily passed into the bladder. To guard against infection of the deeper part of the canal, he introduced, as was his custom, a drainage tube through the perineum into the bladder. The tube is usually removed in three or four days, but is at once re-inserted if there are fever, chill, or other symptoms indicating infection.

CASE IV.—A case of fistula in ano was then freely incised, the redundant skin removed, and the surface lightly touched with the Paquelin cautery. Dr. McBurney frequently makes use of the cautery in this way, and he thinks that more rapid granulation follows than can be obtained by any other method. For the first week after the operation, the wound is packed with iodoform gauze; but after this, the progress will be more rapid if balsam of Peru be substituted for the iodoform.

CASE V.—The next case was that of a man, twenty-four years of age, who presented an unusual history in that, up to about two months ago, he was not conscious of any difficulty with the knee. Even at this time, there was no marked interference with the functions of the joint, and it was only three weeks ago that he felt under the skin a small movable body. Since then, there have been occasional pain and interference with complete extension of the joint, and also a serous effusion into the joint. It looked like an ordinary case of mild serous synovitis, but further examination revealed the presence of a floating cartilage, being, in all probability, a portion of redundant synovial membrane separated from its attachment, in which a gradual deposit of calcareous material had taken place. A few months ago Dr. McBurney operated upon a case in which the cartilage was found in the process of formation and still attached. In some portions it was harder than in others, owing to the deposit of calcareous material which was taking place. A little later the cartilage would have been set free, and have given rise to further symptoms. It is remarkable that in the present case the cartilage should be free and yet give the patient so little trouble. The risk of removing such bodies under proper precautions is very slight; and if left alone, the joint will unquestionably suffer from their presence, rendering the patient predisposed to a chronic synovitis, and he may at any time be thrown down by the cartilage slipping in between the joint surfaces.

On the previous day the cartilage was found in the extreme lower and outer part of the synovial pouch, and now it is upon the inner side; but the presence of the fluid made the exact location difficult to determine.

After spending some time in ineffectual attempts at locating the body by palpation, an incision about one and one-half inches long and parallel to the axis of the limb, was made on the outer side of the knee, extending down to the synovial membrane, which was then opened. The body was very smooth and slipped from the grasp several times, but was finally removed from the lower part of the joint and found to be nearly circular, and measuring about three-quarters of an inch in diameter.

Dr. McBurney was of the opinion that the introduction into the joint of any foreign material, even an antiseptic fluid, was injudicious; therefore the cavity was not irrigated, but the wound in the synovial membrane was brought together with four sutures. The capsule was similarly treated, and the superficial tissues were united by a continuous catgut suture. A small rubber drainage-tube was introduced through the skin only. The external parts were then irrigated with corrosive sublimate solution (1 : 2500), the usual antiseptic dressing applied, and the limb bandaged from the toes upward. Immobilization was secured by two lateral wire splints, left in position for about two weeks.

Dr. McBurney said that he usually found it impossible from an examination of the specimen after its removal to determine its origin; but he thought it was only in very rare instances caused by a fracture. In the present case there was no history of traumatism, nor had there been in any case which he had seen.

MEDICAL PROGRESS.

The Uses of Ichthyol.—PROFESSOR NILS GADDE reports his results with the internal and external use of ichthyol in a number of different diseases (*Therapeutische Monatshefte*, March, 1890). With urticaria, both acute and chronic, the internal administration was of decided benefit. He has treated a number of cases of chronic alcoholism by the same means with success, tremor quite rapidly disappearing, appetite returning, and sleep becoming normal and undisturbed. In one case marked tremor disappeared in ten days. The depression and anxiety of chronic gastric catarrh were also much diminished by the drug.

In chronic rheumatism, either articular or muscular, the external and internal employment of ichthyol was followed by good results. The pain of arthritis deformans was also considerably diminished.

The author has administered the drug in cases of chronic nephritis and diabetes, but considers his observations too few to permit positive deductions. In one case of diabetes the sugar was reduced from six per cent. to one-half per cent. in about one month, but in connection with the administration of ichthyol the diet was regulated. The doses in which the drug was administered are not stated.

DR. FREUND, of Strassburg, employs ichthyol in the treatment of many diseases of the genito-urinary organs in women (*Berliner klinische Wochenschrift*, March 17, 1890), and advocates its use in chronic parametritis, chronic and subacute perimetritis with exudations or adhesions, inflammation of the ovaries and tubes, erosions of the cervix, and pruritus of the external genitals, in all of which diseases it has given the author suprisingly good results. He administers the drug internally in doses of 1½ grains three times daily at the beginning of treatment; later, this dose is doubled. For intra-vaginal use a mixture of ichthyol (sulph-ichthyolate of ammonium) 5 parts, glycerin 100 parts, is employed by saturating cotton tampons, which are introduced into

the vagina. In addition to this an ichthyol ointment (equal parts of ichthyol and lanolin) or soap (ichthyol 1 part, green soap 10 parts) may be rubbed into the abdominal walls with the view of hastening absorption, or the drug may also be used in enemata of olive oil or in suppositories.

Cervical erosions the author usually treats by painting with the pure ichthyol. For pruritus it may be used in the form of an ointment or a ten per cent. solution in water.

In all cases, according to Freund, the internal administration is followed by improvement in the general condition, the appetite increasing and the stools becoming more regular. In no case were disagreeable symptoms of any kind produced.

Treatment of Exophthalmic Goitre.—Professor Nothnagel states that digitalis and drugs with similar effects are entirely useless in Graves's disease. An effective agent against the palpitation is cold, in the form of an ice-bag applied either over the cardiac region or over the neck. The patients should live quietly, and avoid coffee, beer, tobacco, and mental and bodily excitement. Little or nothing is to be expected from medicinal remedies. According to the most recent observations, galvanism through the medulla oblongata and cervical sympathetic is the best treatment; but this treatment must be regular and long continued, and should be associated with a hydro-therapeutic course—the patient being systematically treated with tepid half-baths, irrigations, wrapping in moist linen cloths, and the cold spinal bag. By these means an improvement in the condition is in many cases brought about. Iron may be given if indicated; in other cases, when patients are much excited, bromide of sodium or potassium may be exhibited in doses of fifteen grains twice or thrice daily. An important means of treatment, but one that can only be carried out in the case of well-to-do patients, is to send them to mountain regions, especially to the higher altitudes.—*Practitioner*, March, 1890.

Orexin.—According to the *Therapeutische Monatshefte*, orexin hydrochlorate, the new stomachic, is quite soluble in warm water, is very irritating to the nasal mucous membrane, and when applied to the tongue has a bitter taste and causes a burning sensation.

Professor Penzoldt prescribes it in the form of pills, as follows:

℞.—Orexin hydrochlorate . . . 20 grains.
Extract of gentian } of each
Pulverized althæa } sufficient quantity.

Mix and divide into 20 pills, which should be gelatin-coated. Three to five pills may be taken once or twice daily, with a cup of broth.—*Medical Chronicle*, March, 1890.

The After-effects of Chloroform.—A new phase of the chloroform question is touched upon in a paper by Ostertag, published in the *Deutsche medizinal Zeitung*, January 16, 1890. In the literature of the fatal cases of the administration of chloroform as an anæsthetic a few are on record where death was only produced a number of hours after the production of the narcosis. Thus Langenbeck published, in 1850, a case of death after extirpation of the shoulder, which occurred seventeen hours after the operation. Berend also published cases in which death did not occur until sixty hours after the production of narcosis. Ungar and Strassmann called attention to the fact that chloroform inhalation in certain instances had produced fatty degeneration of internal organs, especially of the heart and liver, but without producing any detectable alteration in the blood. These results seem to have attracted but little notice, though it is evident that they should draw attention to a possible phase of chloroform death which is worthy of a careful study.

The author's experiments were made on rabbits, guinea-pigs, rats, cats, dogs, and pigeons, in all of which the prolonged administration of chloroform was followed by fatty degeneration of the heart and other organs, and by changes in the blood. He claims that it is quite conceivable that the preliminary stages of fatty degeneration, even although not having passed to a complete degeneration, may be concerned in the reduction of the functional activity of the heart. Fatty degeneration of the skeletal muscles, which was especially noted in the diaphragm, may likewise prove an important factor in the disturbance of respiration; while, of course, the depressing action on the respiratory centre is likewise of prime importance. Further than this, the interference with the respiration leads to the accumulation of carbon dioxide in the blood, and this may act as a depressant on the heart muscle.

The author formulates his conclusions as follows: 1. After prolonged inhalation of chloroform, fatty degeneration of different organs, especially of the heart, liver, skeletal muscles, kidneys, and stomach occurs in animals of widely different species. 2. The fatty degeneration is the result not only of the action on the blood and the structure of the red blood-corpuscles, but also of a direct local action on the tissue cells themselves. 3. Certain individuals show such great susceptibility to the action of chloroform by inhalation that they rapidly succumb to its influence. 4. The fatal after-effect of chloroform is attributable to paralysis of the heart, due to an anatomical degeneration of the myocardium, although in certain cases this may only with difficulty be detected, and to a gradual accumulation of carbon dioxide in the blood.—*Therapeutic Gazette*, March 15, 1890.

Prescription for Chilblains.—According to the *Monatshefte f. praktische Dermatologie* of March 15, 1890, Dr. Baelz uses the following as an application to chilblains and chapped hands:

℞.—Liquor potassæ . . . ½ part.
Glycerin } of each . . . 20 parts.
Alcohol }
Water . . . . . 60 " —M.

To be used once daily after washing the hands in warm water. If desired, the mixture may be made more agreeable by the addition of a perfume.

Some Therapeutic Uses of Cannabis Indica.—In a short paper (*Lancet*, March 22, 1890) Dr. J. Russell Reynolds describes the conditions in which he has found cannabis Indica useful. In senile insomnia, where an

elderly person, probably with brain-softening, goes to bed, gets up again, thinks he has an appointment to keep, etc., and yet is quite rational during the day, Reynolds considers cannabis indica the most satisfactory of all drugs, and gives from one-fourth to one-third of a grain of the extract at bedtime. In such cases it has been useful for months, or even years, without increasing the dose. In melancholia it is of less service; in alcoholic delirium and in mania it is valueless. Neuralgia, even after it has existed for years, he has often seen relieved by the drug. In neuritis it is very valuable, but only as an adjunct to mercury, iodine, or other remedies. Many victims of migraine have kept the attacks in abeyance for years, by taking hemp when an attack threatens. In sciatica, and in myalgia wherever situated, it has proved of no value. The same may be said of its use in gastrodynia, enteralgia, tinnitus aurium, and the so-called hysterical pains. On the other hand, it has relieved the lightning pains of tabes, and the disorders of sensation so frequently found in gouty subjects.

In many cases of clonic spasms, whether epileptiform or choreiform, such as are seen from a variety of causes in children, Reynolds has successfully relied upon hemp alone; but in true epilepsy an extensive experience has shown him that it is absolutely useless. The author believes that there are many cases of so-called epilepsy in adults which are either eclamptic or due to gross lesions in the nerve centres, and in these Indian hemp is a most useful agent. In tonic spasm, such as torticollis, in writer's cramp, general chorea, paralysis agitans, the ataxic movements of spinal sclerosis, and in tetanus the remedy is of no benefit. It relieves some cases of spasmodic asthma, and is of great service in cases of simple spasmodic dysmenorrhœa.

Reynolds explains the toxic effects occasionally observed by the fact that the drug varies greatly in strength, and that there are individuals peculiarly susceptible to its action, as is observed with other agents. As a commencing dose for an adult he never exceeds one-fifth of a grain; or for a child, one-tenth of a grain. But by gradually increasing the dose, adults may take with impunity, and often with advantage, two, three, or even four grains at a dose.

The Danger of Iodides in Acute Nephritis.—PROFESSOR PRIMAVERA (*L'Abeille Médicale*) declares that it is dangerous to prescribe the iodide of potassium or sodium in acute nephritis. In support of this opinion, he cites the following, one of many similar cases he has seen:

A boy, fourteen years old, developed acute nephritis fifteen days after an attack of scarlatina. The urine was scanty and albuminous, and contained large quantities of hæmoglobin and numerous casts. A milk diet was prescribed, but no drugs. Some days later, after the albumin had greatly diminished, another physician prescribed iodide of sodium, which was immediately followed by an increase of the albumin and casts and the appearance of blood. The iodide was stopped and the albumin and blood rapidly diminished. On giving the iodide a second time the same symptoms were produced, and again disappeared when the drug was withdrawn.

Primavera is convinced that the iodides are dangerous in acute nephritis. They may be used in syphilitic nephritis, but even here must be carefully watched.

The Treatment of Gleet.—PROFESSOR FESSENDEN W. OTIS (*Physician and Surgeon*, March, 1890) writes as follows upon the treatment of gleet:

As large a sound as can be used without undue force having been passed, either Ultzmann's short silver catheter with slit openings, or an ordinary silk catheter *coudé* is introduced just beyond the compressor urethræ muscle so that the eye lies in the neck of the bladder, and as much fluid as can be comfortably borne by the patient (usually from eight to ten ounces) is injected into the bladder by means of a large hand syringe. The patient then empties the bladder in the natural manner, the catheter having been withdrawn, thus thoroughly washing the urethra from behind forward. That the catheter is in the correct position is known by the fact that, when the injection is made, the fluid does not flow outward along the sides of the catheter, as it would were it not prevented by the action of the compressor urethræ; nor, when the syringe is removed, does the fluid flow out through the catheter as it would if it were in the bladder—this being prevented by the sphincter internus. The internal sphincter is so weak, however, that it makes but little resistance to the entrance of the fluid into the bladder. The first injections are extremely weak, increasing in strength day by day as the dilatation progresses. On the first day after the passage of the sound (lubricated with glycerin), a solution, consisting of zinc sulphate, carbolic acid, and alum, of each 1 part, water 2000 parts, is injected. On the second day, the strength of this is increased by reducing the water to 1500 parts, on the third day to 1000 parts, and, on the fourth day, to 500 parts. On the fifth day a change is made to a solution of the permanganate of potassium, 1 to 2000 of water; on the sixth day, 1 to 1500; on the seventh, 1 to 1000, when the solution is changed to the nitrate of silver, 1 to 1000, which is gradually increased in strength to 1 to 100. If the discharge still continues after the silver solutions have been used, they should be supplemented every three or four days by the injection of a few drops of a 5 per cent. solution of silver nitrate into the deep urethra by means of the drop-syringe. After a time it will be found that the large injections, if they have not cured the discharge, will cease to act beneficially and become irritating; they should then be stopped and the applications with the drop catheter alone relied upon, the dilatation being continued.

Laryngeal Tuberculosis as a Cause of Globus Hystericus.—LANGREUTER (*Centralblatt für Nervenheilkunde*) reports the case of a laboring woman, forty-four years of age, who was admitted to hospital with the typical symptoms of hysteria, functional paresis of lower extremities, paræsthesia, sensation of fulness in head, etc. The patient repeatedly said that there was a foreign body in the throat, made efforts to expel it, and signified that it should be removed. Her manner was so hysterical that organic disease was not suspected, but on the fourteenth day after admission she died. At the autopsy extensive tubercular deposits were found in the larynx, though the lungs and other organs were normal.

Langreuter thinks that such cases should always be borne in mind in making a diagnosis when there are hysterical laryngeal symptoms.—*Centralblatt für klinische Medicin*, March 22, 1890.

SATURDAY, APRIL 19, 1890.

RETENTION OF URINE.

The profound pathological effect of retention upon the urinary organs is so well formulated from a clinical standpoint, and the *rationale* of the process thus originated has been so carefully elaborated, that further investigation upon this subject, even from the point of view of the experimental therapeutist, would apparently give little promise of fruitful result. Yet Guyon (*Annal des Mal. des Org. Génito-urin.*, March, 1890) has by a series of experiments so controlled the observations of the clinicians that he has materially added to an exact knowledge concerning the secondary effects of obstruction to the outward flow of the urine from the bladder.

Though it is not always stated in surgical textbooks, still it has long been observed that retention of urine, no matter what its cause may be or the length of time it has continued, is not accompanied by fever unless a septic element is introduced. When the urine contains no microörganisms, as determined by culture-experiments there is no elevation of temperature. These observations were confirmed by observing animals, the urethræ of which had been ligated. Hyperpyrexia was observed only in those animals whose bladders had been infected before ligation.

All cases of retention, both complete and incomplete, are characterized by polyuria, though this is especially marked where the condition is partial and chronic. Experiments fully verify this observation. Congestion of the entire urinary apparatus is another consequence of retention; if this be acute and prolonged, a brown or even red coloration of the urine, from admixture with blood, is not rare. As a result of this congestion, if, in chronic retention accompanied by cystic distention the bladder be completely and rapidly evacuated of its contents, a hæmaturia nearly always results. In acute retention the prostate and kidneys have both been observed to diminish in size when the bladder was emptied, and many cases of hæmaturia have been immediately cured of this complication by simply drawing off the retained urine. In animals Guyon has observed this congestion, involving not only the kidneys and the prostate gland, but also the renal pelves, the ureters, and the bladder. In the bladder and kidneys there is not only blood-stasis but interstitial hæmorrhages are found. As a result of this the bladder epithelium is detached in places, thus exposing areas fitted for rapid absorption; the gorged vessels form a conspicuous scarlet network, ecchymotic plaques are distributed irregularly over the inner aspect of the organ, and the urine contains blood. The kidneys are a sixth larger than normal, the extravasated blood percolates between the tubes and penetrates into their interior, causing a mechanical destruction of their epithelium, and hence the appearance in the urine of blood and epithelial tube-casts. In chronic retention of long duration dilatation of the canaliculi is observed, with flattening and granular degeneration of the epithelium.

The polyuria accompanying and dependent upon retention is not excited by the distention of the bladder; since, if this organ is subject to excessive tension there is a lessening of urinary secretion with diminution of urea, especially in that part of the water taken from the ureters, provided the flow of urine is not obstructed. In the normal condition of the parts the constant flow of the urine through the ureters provides a protective irrigation against septic inoculation of the kidneys, even though the bladder be infected. In retention, if prolonged, this flow is first diminished, then entirely suppressed. The chemical difference in composition between the urine of the bladder and that of the ureters, together with the fact that in the vesical hæmaturia of prolonged retention the water of the ureters is free from blood, shows that the bladder urine does

not pass backward into the ureters. Nevertheless minute particles of inert substances, such as charcoal, can ascend to the pelvis of the kidney when a continued flow from the ureters is interrupted, though these inert particles pass upward very slowly and do not penetrate beyond the renal pelvis. Microörganisms, however, reach the kidney quickly, and penetrate to all parts of the organ. The urinary stasis is complete in proportion to the amount of distention-atony from which the bladder and ureter suffer. The bladder loses its muscular power somewhat earlier than the ureter. If the retention has lasted not longer than twenty-four hours, the ureteral contractility may be restored by the evacuation of a portion of the bladder contents or by electrization, to be followed shortly by returning power of the cystic muscles. A more prolonged dilatation produces atony which cannot be remedied. The practical deductions from these experimental confirmations of clinical fact are: the importance of promptly relieving an over-full bladder, and the extreme care necessary as to the asepsis of all instruments used for the relief of either acute or chronic retention.

TARIFF ON BOOKS.

It is with great pleasure that we notice that books and pamphlets printed in languages other than English are placed upon the free list in the new Tariff Bill, and we sincerely trust that many of our subscribers will be sufficiently interested in the matter to write to Chairman McKinley commending his action in this matter, and also to their representatives and senators urging that the clause making these books free shall be permitted to become a law. At the present time, owing to the craze for taxing not only proper substances but those things which by their free importation would improve the mental condition of the population of the United States, medical men are unable to receive even a pamphlet in the German or French language without having to pay a small, but nevertheless annoying, custom fee. These amounts are so small that even in the aggregate they can be of but little advantage to the Government; while, on the other hand, to an individual whose funds are limited the constant addition of 25 or 40 cents, or perhaps a dollar, to the value of a European work readily prevents a general purchase of the standard medical publications of firms upon the Continent. It does not protect American industries, because no American publisher would ever think of reprinting a book in a foreign tongue, and even if he prints a translation the purchaser of the German copy would probably be glad enough to buy the English version. Fortunately, there is little doubt that the clause we mention will pass the "House," and that these books will be given a free entry, not because the national legislators take enough interest in such matters to push the law through, but rather because they do not care to deal with what to them seems so small and unimportant a matter.

REVIEWS.

A German-English Dictionary of Medical Terms. By Frederick Treves, F.R.C.S. Eng., and Hugo Lang, B.A. 12mo., pp. 402. Philadelphia: P. Blakiston, Son & Co., 1890.

For years English and American students have keenly felt the need of a complete German-English medical dictionary. Cutter's dictionary, good ten years ago, is now extremely unsatisfactory. Billings's "National Medical Dictionary" is beyond the reach of many a purse. Adler and Grieb are very imperfect in medical terms and definitions. For these reasons, we have examined the work before us with great interest. After careful comparisons with the above-mentioned lexicons, and, after using it constantly for a brief period, we feel fully justified in saying that it is surprisingly satisfactory and complete.

The care and thoroughness with which it has been prepared, is shown by the fact, as stated in the preface, that over one hundred and fifty German volumes were perused from beginning to end, and all medical words extracted and provided with an English equivalent—a labor covering a period of five years. The authors estimate that the work contains about 16,000 words which are not to be found in any German-English dictionary. Much space has been saved by omitting words the definition of which is obvious, such as *patellarreflex*, *nephrektomie*, etc., and by the judicious separation of compound words.

We most heartily commend the volume to all students of German medicine, and doubt not that in a very short time it will be on the table of every one.

Principles and Practice of Surgery, being a Treatise on Surgical Diseases and Injuries. By D. Hayes Agnew, M.D., LL.D. Profusely illustrated. Second edition, thoroughly revised and with additions. Three volumes. Philadelphia: J. B. Lippincott Company, 1889.

To attempt to give anything more than a book notice of the second edition of a Surgery which is one of the monuments of American medicine would be absurd, unless many pages of this journal were devoted to the consideration and criticisms of the statements made by its distinguished author. It is but a few years since the first edition was completed in its third volume and placed before the profession, and we are glad to find that the

teachings of Dr. Agnew have not only been gladly received by the students whom he has taught, but by his professional brethren all over the world. In the present edition, conservative notice is taken of the rapid advances which have been made in the practice of surgery since the first edition appeared, and while several things have been omitted which we think should have found a place, we cannot but recognize that the book before us is intended as a trustworthy and absolutely reliable guide to the surgeon or physician wherever he may be in practice, and that it is not designed to bring before him the latest fad or untried operation.

The important subject of antisepsis, which was, comparatively speaking, in its infancy at the time that the first edition appeared, has of course received proper attention; but we feel sure there can be little doubt that the statistics, which are given in various portions of the work would be very considerably modified if they were divided into parts in which cases were treated with and without antiseptic precautions. These are the most notable changes which have been made by the author, and we feel confident that with them the work will go on to a still more successful career, and Dr. Agnew may rest assured that he has placed a stamp upon the history of American medicine which many years cannot efface.

CORRESPONDENCE.

NEW YORK.

To the Editor of The Medical News.

Sir: The increasing interest that is shown in all matters pertaining to preventive medicine, both by the medical profession and by our civil authorities, is full of good omen; and the efforts now being put forth in this direction must surely bear good fruit in the near future. Our Health Board has been remarkably active in the enforcement of the law regulating vaccination. The law is not a new one, but for a number of years its provisions have been carried out in such an indifferent manner that many of our citizens are greatly surprised at what they are pleased to style "the new rule made in the schools." But even now there is no attempt made to determine whether the school-children are properly *protected* by vaccination, the fact of their being vaccinated at some time, no matter how remote, being accepted as a compliance with the requirements of the law. I do not mean to speak disparagingly of the Board of Health, for it has arisen from its former condition of "innocuous desuetude," and seems to be honestly striving to secure that hearty coöperation of the medical profession which is necessary to carry out properly its important and legitimate work. Attention has already been called to the fact that our people are almost panic-stricken when they hear of the possibility of typhus fever, smallpox, or cholera getting a foothold here; but they look with an apathy born of long familiarity with its horrors, and a mistaken notion of its nature, upon the constant ravages of diphtheria. This disease yearly counts among its victims more than many an epidemic of cholera. Great praise is due our health authorities, who have undertaken the difficult task of staying the march of this dread enemy. They have issued an order to the dispensaries requiring persons who come to these places, and are found to be suffering from diphtheria, to be detained and quarantined until the Board of Health can remove them to the hospital. It will be no easy matter to make the people believe that this is a beneficent measure, and that a due regard for the safety of all, demands that it shall be rigidly enforced. To those who have seen a tenement-house "wake," there is no mystery about the spread of contagious diseases; and the difficulties in the way of enforcing the law requiring private funerals in such cases can be easily imagined. The health inspectors have met with violent opposition in endeavoring to perform this duty; and he would, indeed, be rash who would venture, single-handed and unprotected, upon such a mission. Some of your readers may remember the experience of a poor man who, in his anxiety to avoid carrying diphtheria to his own home, dared to refuse "to kiss the corpse." He was seized by the excited people at the "wake," and but for timely aid would have been thrown out of a window.

The Pædiatric Section of the Academy of Medicine has devoted part of an evening to the discussion of the prophylaxis of diphtheria, with reference to the physician as a means of carrying contagion, and to the means to be employed for the better protection of nurses and others exposed to the disease.

Dr. W. P. Northrup thought that in addition to the usual precautions to secure cleanliness and disinfection of the person of the physician, he should remove his coat before entering the sick-chamber and wrap himself in a sheet. Dr. A. Caillé believed most thoroughly in the efficacy of systematic and thorough irrigation and disinfection of the oral and nasal cavities, not only of the patients but of those exposed to the disease. Dr. W. H. Thomson felt sure that the physician was rarely the carrier of contagion, and he asked in vain for the members of the Section to produce any well-authenticated case. While it is probable that the disease is not very frequently carried from one patient to another in this manner, those who have seen physicians visit such cases and then continue on their way without even taking the precaution to wash their hands, naturally ask themselves, By what good fortune do these physicians and their patients escape?

A great change has come over the opinions of medical men on the subject of heart disease. The student of a few years ago was confused by descriptions of various murmurs, their supposed origin, and their significance; and he often emerged from this labyrinth with the general notion that a murmur and heart disease were almost synonymous, and that the treatment could be summed up in the words "rest and digitalis." It was therefore gratifying, in a discussion at the Academy of Medicine on the therapeutics of heart disease, to see that a much more comprehensive view was taken of the subject, and that, as the President, Dr. Loomis, aptly remarked, "We have left the discussion of valvular diseases, and have grouped them according to the condition of the heart muscle, regarding that as the great factor in our study and treatment."

The discussion was directed more particularly to the consideration of the mechanical and dietetic treatment of heart disease.

Dr. H. N. Heineman said that the mechanical treatment, although not original with Oertel, had been placed by him upon a sound scientific basis. The proper ex-

ercise of a muscle led to its hypertrophy; and even muscular fibres which had undergone partial fatty degeneration, would improve and some of its fibres might ultimately hypertrophy, and by their proliferation overcome the degeneration which had taken place.

Dr. W. H. Thomson thought that we should not lose sight of the vital importance of oxygen to a muscle. Throughout the whole animal kingdom muscular power was found to be dependent upon the activity of respiration. This was particularly noticeable in the insect tribe, where the muscular power was phenomenally greater than that of any other class of living creatures. The muscle cell, unlike the nerve cell, used oxygen as its chief stimulant, and almost as its food. We had learned that animal heat came from the muscular tissue, independently of its contraction; and experiments had shown that the blood coming from a muscle by its vein, was more venous than the blood in the right side of the heart, and that more carbonic acid was generated by muscle than by any other tissue, which was another proof that the muscles used a great deal more oxygen. From these facts it followed that in the presence of muscular degeneration, a free supply of oxygen was urgently indicated, and this could best be obtained by giving iron, and securing for the patient an out-door life. He did not recommend muscular exercise *per se*. There was nothing better for these patients than camping out; and it was worthy of remark that the nomad races suffered the least from heart disease. Oxygen dilated the capillaries, and lowered arterial tension; and by eliminating the nitrogenous element as far as possible from the diet, the kidneys were relieved of much work and the vascular tension still further diminished. Therefore, in fatty degeneration of the heart, fresh air and a liberal diet of fermented milk were the most important elements in its successful treatment. There was a practical unanimity throughout the discussion as to the importance of diet and exercise in the treatment of heart disease, and drugs were relegated to a very subordinate position.

The usual routine of medical meetings was somewhat broken at a recent meeting of the New York County Medical Society, as it was found necessary to prefer charges against two of the members who had been guilty of flagrant violations of the code of ethics. The censors received information from the Medical Society of the County of Erie that one of these offenders was engaged in extensively advertising a patent medicine business. The evidence proved to be satisfactory, and he was expelled by a unanimous vote. The other member had not only been guilty of repeatedly advertising himself in the daily papers as a specialist, but conclusive evidence was furnished of his practising under an assumed name. After hearing the charges in detail, the Society unhesitatingly and unanimously voted to expel him.

On the evening of February 27th, the Alumni of the University of the City of New York held their annual dinner at Delmonico's, and the attendance was unusually large.

Dr. C. B. Kelsey, as is well known, was at one time a strong advocate of the treatment of hæmorrhoids by the injection of carbolic acid, but he has experienced a most decided change of faith on this point. At a meeting of the Society of the Alumni of Bellevue Hospital, he said that it had been the cause, on more than one occasion, of his eating "humble pie." When his article on the treatment of two hundred consecutive cases by this method without a mishap was still in press, he met with his first unfortunate case. The operation, he said, was sometimes followed by an unusually large slough, or by a periproctitis, or an ischio-rectal abscess. Whenever an irritating fluid was injected into a vascular tumor, one was unable to limit its irritant action, and bad results might follow either a weak or a strong solution. He had seen profuse and dangerous hæmorrhage follow the injection of a ten per cent. solution of carbolic acid into a hæmorrhoid, owing to the slough opening into a vein. But the most serious objection to the employment of this method was that the results were not permanent, and, after a period of two or three years, the hæmorrhoids were pretty sure to return. The method should be unequivocally condemned. He considered the operation, *par excellence*, for the relief of hæmorrhoids, was the clamp and cautery operation recommended by Mr. Smith, of London.

LONDON.

The Gulstonian Lectures. The New University of London Scheme. The Royal Medical and Chirurgical Society.

To the Editor of THE MEDICAL NEWS,

SIR: The annual Gulstonian lectures fell this year to the lot of Dr. G. N. Pitt, of Guy's Hospital, who took cerebral lesions for his subject and devoted his first lecture to the consideration of a series of fatal cases of ear disease. The records of his hospital during the last twenty years furnished him with fifty-seven cases, thirty-four being males, and two-thirds of the entire number were under twenty years of age. The two chief causes of death were abscess of the brain and thrombosis of the lateral sinus with subsequent pyæmia. Of cerebral abscess, there were eighteen cases, equally divided between the two sides of the brain. He found that abscesses in the temporo-sphenoidal lobe, which was by far the most common situation, were often associated with an inflamed or sloughing dura over the anterior surface of the petrous bone, or with a collection of pus beneath it; other complications were infrequent except meningitis, which was generally due to the extension or rupture of the abscess. The abscesses were almost always situated very close to the roof of the tympanum. A foul discharge was often a source of danger, and frequently, if not invariably, the spread of the mischief was due to imperfect drainage of the middle ear. Mastoid suppuration often involved the posterior surface of the petrous bone, but might be associated with disease limited to the middle fossa of the skull. His conclusions in regard to other points were, that cerebral abscesses occurred only when the otorrhœa had lasted for years or months; that the symptoms usually came on insidiously; that rigors, pyrexia, and optic neuritis were infrequent in uncomplicated cases, but that they all occurred occasionally; that a headache of intense severity and a dull, sluggish mental state were the two most characteristic symptoms; and that cerebellar abscesses were less common and were probably associated with disease of the dura mater behind the petrous bone, or with thrombosis of the sinus. Of thrombosis

of the lateral sinus, he had had twenty-two cases; in some, but not all of these, there was well-marked phlebitis; in considerably more than one-half the thrombus was suppurating, but pyæmia existed in several cases in which no suppuration had taken place in the thrombus. His conclusions were as follows: 1. The disease more often spreads from the posterior wall of the middle ear than from the mastoid cells. 2. The otorrhœa is generally, but not always, of long standing. 3. The onset is sudden, the chief symptoms being pyrexia, rigors, pain in the occipital region and in the neck, associated with a septicæmic condition. 4. Well-marked optic neuritis may be present. 5. The appearance of acute local pulmonary mischief, or of distant suppuration, is almost conclusive of thrombosis. 6. The average duration is about three weeks, and death is generally due to pulmonary pyæmic abscesses.

The following very interesting and remarkable case of recovery after thrombosis of the lateral sinus was narrated: A boy, ten years of age, who had had otorrhœa for years, was admitted with a temperature of 102° F., earache, tenderness, and œdema; a week later he had a rigor and developed optic neuritis on the right side. The mastoid was explored without result. The rigors and pyrexia continued, and two days later the lateral sinus was explored, a mass of foul clot was removed from it and the jugular vein tied, the boy making an uninterrupted and permanent recovery.

With the exception of the University of London scheme, there is nothing much of interest going on in the medico-political world, nor, as far as I can make out, is any very great progress being made toward providing a reasonably accessible degree for London medical students. The scheme which the Senate put forth has met with almost universal condemnation, particularly in several important particulars, and it seems quite possible that the difficulties of reconciling the conflicting and opposing interests of the various bodies concerned will be found to be insuperable. The subject is engaging the attention of a committee of the College of Physicians and Surgeons, and it may be hoped that before long the result of their deliberations will be made public, but when all the teaching and licensing bodies have succeeded in agreeing there will still remain the formidable opposition of the Scotch and other universities, who are so largely benefited by the inaccessibility of the existing London degree.

The Royal Medical and Chirurgical Society has at last settled down in its new home in Hanover Square, and is indisputably in possession of most suitable premises. The alterations necessary to accommodate the very large library owned by the Society, and to provide a suitable debating room, have been completed, and the Fellows of the Society are once more able to use the library. The meeting-room, which has been built on what was formerly the garden, will hold two hundred people without inconvenience, and more, if necessary, though it is hardly likely that the number at any of our numerous medical society meetings will ever reach, much less exceed, that figure. The Clinical, Pathological, Obstetrical, and British Gynecological Societies will also be housed under the same roof, and perhaps some other scientific, but not professional, societies also.

THE EFFECT OF HEAT UPON THE RED CORPUSCLES.

To the Editor of The Medical News,

Sir: In your issue to-day it is stated, in an editorial upon "The Effect of Heat upon the Red Corpuscles," that the changes produced are very similar to the hæmatozöon malariæ. Doubtless they are to any one unfamiliar with that organism. The changes of which you speak are perfectly well recognized, and are seen every day by men who use Ehrlich's methods, or who watch continuously the behavior of corpuscles in the warm stage. Even without this apparatus the deformations, chain-like bodies, undulating flagella, etc., can be studied with an immersion glass on a blood-slide surrounded with paraffin and kept warm for twenty-four hours.

Only a tyro could confuse these with any known pathological alterations, and to speak of them as "singularly like" the remarkable series of forms characteristic of, and peculiar to, malaria indicates an absence of practical knowledge of the now well-known blood-changes in this disease.

Very truly yours,
William Osler, M.D.

Baltimore, April 12, 1890.

THE INTERNATIONAL MEDICAL CONGRESS.

To the Editor of The Medical News,

Sir: In a letter dated Berlin, Karlstrasse 19, March 22d, Dr. Lassar, the Secretary-General of the Tenth International Congress, directs me to inform the medical profession of America that a programme of the Congress and other communications will be distributed two months before the meeting amongst *those who will have registered previously and received their tickets of membership.*

The latter can be obtained by sending application and five dollars to Dr. Bartels, Leipzigerstrasse 75, Berlin, S. W. By so doing the members will save much crowding and time during the first days of the Congress.

For the American Committee of the Tenth International Medical Congress, A. Jacobi, M.D.

OBITUARY.

Dr. Henry Hollingsworth Smith died on Friday, April 11th, of pneumonia, after ten days' illness. Dr. Smith was born in Philadelphia, December 10, 1815, and was the son of James S. Smith, a distinguished lawyer. He received his medical education in the University of Pennsylvania, from which he was graduated in 1837.

He was resident surgeon in the Pennsylvania Hospital for two years, and in 1839 visited the London, Paris, and Vienna hospitals, where he spent eighteen months in study. On his return he began practice, and gave instruction in surgery to private classes. In 1849 he became surgeon to St. Joseph's Hospital, soon afterward surgeon to the Episcopal Hospital, and in 1854 surgeon to the Philadelphia Hospital. Between 1855 and 1871 he was Professor of Surgery in the medical department of the University of Pennsylvania, and in the latter year became Professor Emeritus.

When the war of the Rebellion broke out he was made Surgeon-General of Pennsylvania, and organized the

hospital department of this State. At the first battle of Winchester, Va., he originated the plan of removing the wounded to the large hospitals in Philadelphia and other cities, and established the custom of embalming the dead on the battle-field. He also organized and directed a corps of surgeons with steamers as floating hospitals at the siege of Yorktown, and served the wounded after the battles of Williamsburg, West Point, Fair Oaks, Cold Harbor, and Antietam. In 1862, after thoroughly organizing the department of which he was in charge, he resigned his commission, and had since been actively engaged in the practice of his profession. He was for three terms President of the County Medical Society, and at the International Medical Congress of 1887 he was Chairman of the Executive Committee.

Dr. Smith contributed largely to medical literature. Among his works were the following: *An Anatomical Atlas*, to illustrate William E. Horner's *Special Anatomy* (Philadelphia, 1843); *Minor Surgery* (1846); *System of Operative Surgery, with a Biographical Index to the Writings and Operations of American Surgeons for 234 Years* (2 vols., 1852); *The Treatment of Ununited Fractures by Means of Artificial Limbs* (1855); *Professional Visit to London and Paris* (1855); *Practice of Surgery* (2 vols., 1857–63), and numerous surgical articles in medical journals. He translated from the French *Civiale's Treatise on the Medical and Prophylactic Treatment of Stone and Gravel* (Philadelphia, 1841), and edited the *United States Dissector* (1844).

In October, 1843, he married Mary Edmunds, oldest daughter of Professor William E. Horner. A widow and three children survive him.

NEWS ITEMS.

Medical Examining Boards of Florida.—It is said that one of the medical examining boards of Florida recently rejected 35 per cent. of the applicants desirous of practising medicine in the State; a general average of 80 or more being required.

The Sims Monument.—It is stated that the committee in charge of the J. Marion Sims Fund have closed a contract with a German firm for a full-length bronze figure of the celebrated American gynecologist. The statue will be completed within a year, and, it is thought, will be placed in Central Park, New York.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM APRIL 8 TO APRIL 14, 1890.

By direction of the Secretary of War, PAUL R. BROWN, *Captain and Assistant Surgeon*, now at the Army and Navy General Hospital, Hot Springs, Arkansas, is relieved from station at Fort Thomas, Arizona, and will report in person to the commanding officer Little Rock Barracks, Arkansas, for duty at that post, reporting by letter to the commanding general Department of the Missouri.—Par. 3, *S. O. 84, A. G. O.*, April 10, 1890.

By direction of the Secretary of War, leave of absence for two months, on surgeon's certificate of disability, is granted JOSEPH C. BAILY, *Lieutenant-Colonel and Assistant Medical Purveyor*, with authority for his admission to the Army and Navy General Hospital, Hot Springs, Arkansas, for treatment therein.—Par. 10, *S. O. 85, A. G. O.*, April 11, 1890.

By direction of the Secretary of War, the following changes of stations of officers of the Medical Department are ordered:

LAUDERDALE, JOHN V., *Major and Surgeon*.—From Fort Davis, Texas, to Fort Ontario, New York.

SKINNER, JOHN O., *Captain and Assistant Surgeon*.—From Fort Ontario, New York, to Fort Davis, Texas.

PERLEY, H. O., *Captain and Assistant Surgeon*.—From Fort Wayne, Michigan, to Fort Mason, California.

BURTON, H. G., *Captain and Assistant Surgeon*.—From David's Island, New York, to Vancouver Barracks, Washington Ty.

HOPKINS, WILLIAM E., *Captain and Assistant Surgeon*.—From Fort Mason, California, to Fort Columbus, New York Harbor.

STEPHENSON, WILLIAM, *Captain and Assistant Surgeon*.—From Fort Verde, Arizona Territory, to David's Island, New York.

WILLCOX, CHARLES, *First Lieutenant and Assistant Surgeon*.—From Fort Columbus, New York Harbor, to Fort Bowie, Arizona Territory.—Par. 2, *S. O. 83, A. G. O., Washington, D. C.*, April 9, 1890.

By direction of the Secretary of War, the leave of absence granted NATHAN S. JARVIS, *First Lieutenant and Assistant Surgeon*, in S. O. 34, March 20, 1890, Department of the Missouri, is extended fifteen days.—Par. 22, *S. O. 81, Headquarters of the Army, A. G. O.*, April 7, 1890.

By direction of the Secretary of War, MARSHALL W. WOOD, *Captain and Assistant Surgeon*, is relieved from duty at Fort Randall, South Dakota, and will report in person to the commanding officer Fort Meade, South Dakota, for duty at that post, reporting by letter to the commanding general Department of Dakota.—Par. 24, *S. O. 82, Headquarters of the Army, A. G. O., Washington*, April 8, 1890.

By direction of the Secretary of War, the leave of absence granted ROBERT M. O'REILLY, *Major and Surgeon*, in S. O. 24, October 16, 1889, amended by S. O. 252, October 29, 1889, both from this office, is extended one month.—Par. 30, *S. O. 81, A. G. O.*, April 7, 1890.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING APRIL 12, 1890.

WHITE, S. S., *Assistant Surgeon*.—Detached from the "Minnesota," and wait orders.

HARRIS, H. N. T., *Assistant Surgeon*.—Ordered to the "Minnesota."

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FROM MARCH 24 TO APRIL 5, 1890.

BAILHACHE, P. H., *Surgeon*.—To represent Marine-Hospital Service at the meeting of the California State Board of Health, April 4, 1890.

WYMAN, WALTER, *Surgeon*.—To proceed to Wilmington, Delaware, on special duty, March 27, 1890.

CARRINGTON, P. M., *Passed Assistant Surgeon*.—Granted leave of absence for thirty days, on account of sickness, March 28, 1890.

PETTUS, W. J., *Passed Assistant Surgeon*.—Promoted, and commissioned Passed Assistant Surgeon by the President, February 26, 1890. Granted leave of absence for sixty days, with permission to go abroad, April 2, 1890.

HEATH, F. C., *Assistant Surgeon*.—To rejoin station, Detroit, when relieved at Cleveland, April 3, 1890.

KINYOUN, J. J., *Assistant Surgeon*.—To proceed to Wilmington, Delaware, on special duty, March 28, 1890.

STONER, J. B., *Assistant Surgeon*.—Relieved from special duty on floating-hospital "Stevens"; ordered to assume command of the Service at Pittsburg, Pa., March 28 and April 4, 1890.

CONDICT, A. W., *Assistant Surgeon*—To proceed to Cleveland, Ohio, for temporary duty, April 2, 1890.

GUITERAS, G. M., *Assistant Surgeon*.—When relieved at Pittsburg, Pa., to proceed to Marine Hospital, New York City, for duty, April 3, 1890.

ORIGINAL LECTURES.

STRICTURE OF THE RECTUM; INTESTINAL OBSTRUCTION; INGUINAL COLOTOMY.

A Clinical Lecture
delivered at the New York Post-Graduate Medical School Hospital.

BY CHARLES B. KELSEY, M.D.,
PROFESSOR OF DISEASES OF THE RECTUM.

GENTLEMEN: The case I shall show you to-day is one of great interest, being an example of the most serious form of disease of the rectum you will ever encounter except cancer. The disease is generally incurable and often fatal, but only after long suffering.

The patient is forty-two years old, married, and the mother of one child twenty-one years of age. She first came under my observation nine years ago, at which time she gave the following history: She had always suffered from obstinate constipation, and several years before had been relieved of an impaction by artificial means. The rectal symptoms began six years after marriage, or seven years before I saw her, and sixteen years ago.

Nine years ago she was in much the same condition as you now see her—emaciated, nervous, and nearly worn out with obstruction. There was at that time, as now, a constant discharge of foul-smelling pus from the anus, an entire loss of control by the sphincters, and great difficulty in securing a movement of the bowels, even by cathartics. There were then several fistulous openings around the anus, and one track in the recto-vaginal septum which communicated with both cavities.

At an inch and a half from the anus there was a stricture admitting the end of the index finger, and above and below this much ulceration. The stricture was not of very great extent, nor was it very unyielding; and, in fact, the mechanical obstruction was of less grave moment than the exhausting suppuration and incontinence.

Her condition to-day is much the same as then. There is still a stricture at the same point which will admit my index finger after slight pressure. Above the stricture as far as I can feel, the rectum is denuded of its mucous membrane and ulcerated. There is an abscess cavity behind the anus with an external opening in the median line. But there are other grave conditions present now which did not exist then.

The patient calls my attention to the distended condition of the abdomen and begs me to allow her to take her customary cathartic that she may reduce it. She tells me it is always so before she purges herself; but that after the medicine has acted it is perfectly flat, as you would expect it to be in a person so emaciated. She tells me that she usually does this twice a week, taking her medicine in the evening and spending from twenty-four to thirty-six hours in unloading the bowels, often sitting on the commode for two or three hours at a time. The movements at such times are at first solid, and often pieces will come away as large as her thumb, though sometimes the evacuation is moulded into the tape-like shape so often spoken of. After the solid matter has passed the fluid movements begin and continue for many hours, ending in the evacuation of a large amount of retained fæces and in great exhaustion of the patient. Note what she says about the size of the solid fæcal masses she passes, as I shall refer to it again.

The patient also refers to a lump, the size of two eggs, which occasionally appears in the left inguinal region and causes her a good deal of pain. This, she says, comes and goes and is not now present, but when I examine I find immediately under the abdominal wall a hard, nodular tumor, the size of my closed fist, which is somewhat movable, is tender on pressure, and is yet too resistant to be indented with the fingers. This is probably a fæcal impaction in the sigmoid flexure, and, from its hardness, one of long standing.

One other point of difference between her condition now and nine years ago. The physician who has had her in charge for the past two years tells me she has Bright's disease. Her urine has already been examined in the hospital several times, and on two occasions a trace of albumin has been found. I know that at one time a year ago the albumin was very marked. We can go further, and say that the patient probably has the waxy kidney so often found associated with prolonged suppuration.

This, then, is the history of the patient's disease and her present condition: sixteen years of suffering with incontinence of fæces, and with a foul discharge from the rectum; constant pain; and, in the end, chronic intestinal obstruction—what I judge to be an impacted colon—and waxy kidneys.

Let us now study the cause which has produced this result, and I wish to lead you to separate in your minds, as far as possible, the condition of ulceration of the rectum from that of stricture. It is true they are generally associated, that either may be the cause of the other, and yet the point I wish most strongly to impress upon you now is, that in just such a case as this, where we have both stricture and ulceration, the two conditions may be of vastly different relative importance. You saw me a few weeks ago exsect a stricture of the rectum though it had not advanced far enough to cause any obstruction and there was but slight ulceration. We were then dealing with malignant disease. You have also seen here a congenital stricture, which was so tight as to threaten complete obstruction at any moment, and associated with which there was no ulceration. You see to-day a stricture tight enough to make trouble, and yet through which solid fæces the size of the thumb will pass; and this stricture, grave as it is, is a matter of almost trivial importance in comparison with the ulcer-

ation and suppuration which are associated with it, and in all probability caused it. In fact, I am not at all sure that the stricture we feel is the only one, for the same process which has caused this may as easily have caused another; and a stricture as low down as this, with a calibre admitting the index finger, will not generally give rise to the degree of intestinal obstruction from which this patient is suffering.

As to the nature of the ulceration which is killing this patient I do not think there is much doubt. There was no venereal history for six years after marriage and up to the time when this trouble began. There are none of the other usual causes of ulceration such as cancer, tuberculosis, or dysentery. The disease in all probability began as a simple erosion, possibly only a fissure, due to chronic constipation, made worse by impaction, accelerated by unsurgical treatment, and steadily advancing from the day of its formation till now.

You will see many such strictures as this in my service, though a smaller proportion perhaps than in private practice, and you have already learned not to jump to the conclusion that a patient must have had syphilis because she has a stricture of the rectum which is not cancerous. Any ulcerative process, if sufficiently extensive, may result in stricture, and there are many causes of ulceration besides venereal disease. I have seen ulceration, deep and extensive, result from the mere pressure of hardened fæces in the rectum, and such a mass as is now impacted in this patient's sigmoid flexure may easily lead to fatal perforation. I have seen also severe stricture result from neglected hæmorrhoidal ulceration, and to one of these causes, or both combined, I have no doubt the extensive disease in this case is due.

I will give you now a short account of the treatment this patient has had in the past. For the first seven years, the only time when a cure was possible, nothing radical was done, though the usual applications were made. Then nine years ago she was brought to me, as I have said, in much the same condition as now, and at that time it was a grave question whether a colotomy should not be done. In place of that I did a posterior linear proctotomy, dividing the stricture and the anus down to the tip of the coccyx; hoping to cure the stricture by subsequent dilatation, and the ulcer by the rest given to the parts and by subsequent applications. At that time the entire ulcer could be reached, and our efforts were in great measure successful. Six weeks after the operation I find that the following note was made: "The patient has gained much in flesh and general condition, and returns to her home with the incision not yet healed, but she is perfectly comfortable in every respect. Has natural, full-sized, painless passages, and has not been troubled by incontinence since operation." Six months later she again returned to me for treatment. The general condition was excellent. There was a marked decrease in the stricture tissue, and there had been no pain on defecation since the operation. But she was still troubled by the discharge of pus from the bowel, and the incision had not entirely healed. Treatment was, therefore, begun to cure the ulceration—rest in bed, fluid diet, and local applications. After three months she again left the city with the ulceration entirely healed except in the line of the incision.

Two years later I find the following note: "Some contraction, general and local condition excellent." Three years and a half ago I find the last note of her condition: "Tight annular stricture at one inch from anus. Patient to return for treatment." This she has now done. Her history for the past three and a half years has been that of steady progress in the disease. The stricture was cut again two years ago, but whether thoroughly divided or only partly I do not know. Fresh abscesses have formed and added greatly to her suffering, and she is now in the condition I have described.

In such a case as this there are three possible courses of treatment to choose from—incision, excision, and colotomy, and it is for us to consider which will do the greatest good.

I can again divide this stricture completely down to the sacrum in the median line behind, open up the abscess cavity, divide the fistulæ, and treat it as an open wound. This means many weeks of confinement to bed, much exhaustion, fresh suppuration, and no little danger, with the kidneys in the condition they are. But, worse than all this, I fear it would not mean a cure of the extensive ulceration. The stricture without the ulcer could be easily handled, though in her present condition any such operation is attended by considerable danger; but dividing the stricture would do little good unless the ulcer could be made to heal by subsequent treatment, and of this I have no hope.

We have now in the hospital a case which you have seen me operate upon where such a stricture as this has been completely excised, and I could do that operation in the present case. But in that case the mucous membrane both above and below the disease was sound, and the sphincters were unimpaired, so that after removing the cicatricial tissue it remained only to unite the two healthy ends of the gut and the disease was cured. Leaving out of consideration the great immediate risk of such an operation in this case, we could hope for no such result, for we could hardly remove the entire ulcerated surface, and even if we did, we should still be left with incontinence of fæces, for the sphincters have been irreparably ruined.

By colotomy, on the other hand, we shall hope to do this: Relieve the sufferer of the pain and danger which now necessarily attend the discharge of fæces, put an end to the formation of abscesses, and cause the ulceration to heal merely by doing away with the irritation of fæcal matter. And this we shall hope to accomplish with the least possible risk of surgical accident; for I consider that the operation of left inguinal colotomy would be attended by less shock than either of the other operations.

You may ask, Would the patient's condition with an artificial anus in the left groin be better than it is now? and I answer, unhesitatingly, Infinitely better. You cannot possibly be any more prejudiced against this procedure than I once was, but that prejudice has been entirely removed by clinical experience. The idea that an artificial anus properly made renders the patient loathsome to herself and friends, can hardly find support amongst those who are called upon to see many of these cases. I have too many patients now alive and comfortable, attending to their various duties in life—some of them having only one passage a day, and others having a passage only after a laxative—upon whom

I have done this operation, for me to hesitate now from any sentiment.

I am asked as to the proper treatment of the fæcal impaction. With a colotomy the answer is easy, for if on cutting down to the gut I find it best to open it below the fæcal mass, I shall do so, probably breaking up the mass at the same time and allowing it to escape through the artificial anus when the gut is finally opened. If, on the other hand, it seems better to open the gut above the mass, I shall subsequently break it up and wash it out through the rectum by working at it from above. By either of the other two operations proposed the mass in itself increases the danger. I have already referred to the fact that it might by its presence cause a fatal perforation. We also know that in every such case of chronic obstruction the bowel above the disease is dilated and thinned, sometimes to a remarkable extent. To attempt, therefore, the removal of such a mass, either by cathartics to increase peristalsis, or by injections of large quantities of water to soften it, would be an operation by no means free from danger. In fact, the patient's habit of taking frequent purgatives may at any time cause a fatal result. I have known this to happen in one case identical with this, while the patient and myself were trying to arrange a convenient time for a colotomy. Sunday was his day for evacuating his bowel, and he had taken strong purgatives every Saturday night for months. But the effort was made once too often; the dose was taken as usual, and in a few hours he was dead from rupture of the bowel above the disease.

We will now etherize this patient, make a more thorough examination under ether than is possible without it, and will then operate by the method which seems best.

The patient being under ether in the lithotomy position, you observe first these fistulous openings behind the anus. The director does not pass into any abscess cavity; on the contrary, the tracks are found to be superficial, and as I lay them open one after the other we have a resulting incision only about two inches long and half an inch deep in the median line behind the anus. In other words, the sphincter has once more been cut, but this is evidently not as grave a condition as I had been led to suppose.

Next I examine the rectum. At one inch from the anus I find a tight stricture but of limited extent, and as I gently force my finger through it I find extensive ulceration above, but not to any such degree as would account for the patient's history. Where does this perpetual discharge of foul pus come from, and why is she suffering from intestinal obstruction? As I force my finger higher up the bowel, I find that there is no rectal pouch, but that the rectum is occluded by a round, smooth mass pressing upon it from in front. I find it impossible to get beyond this mass, but as I place my left hand on the abdomen and practise conjoined manipulation I find that my supposed fæcal impaction resolves itself into an immense abscess in the region of the left broad ligament; and pressure in the pelvis causes the tumor to decrease in size while there is a flow of six or eight ounces of fetid pus from the rectum, forced out by the pressure on the abdominal tumor. In this way, then, are the doubtful points in this case explained. There is a second stricture to account for the obstruction, and the fæcal impaction resolves itself into a large pelvic abscess which opens into the rectum, furnishes the foul discharge which I supposed to be due to ulceration, and obstructs the rectum by pressure.

And now what shall we do for the patient? She has an old stricture of the rectum. She has fistulæ which I have just cut. She has a pelvic abscess on the left side which is exhausting her by suppuration. She has chronic intestinal obstruction and amyloid degeneration of the kidneys. What can we do? The answer is, Very much can be done. Let us take the conditions in their order.

The fistulæ are already cured by the incisions you have seen me make.

The stricture is rendered harmless, though not cured, by the dilatation of my finger in this examination.

The ulcer above the stricture is by no means as extensive as I believed; and could be cured, as it was nine years ago, by local treatment.

This leaves us with an abscess in the left broad ligament occluding the rectum by pressure, and for this I shall at once do colotomy. The abscess is for the present incurable. It cannot be made to heal, it exhausts the patient, it produces degeneration of the kidneys, and it threatens the life of the patient by its mechanical pressure. I will show you to-morrow a pathological specimen exactly analogous to this which caused the death of a patient—exactly as this may do at any time—by the exhaustion of suppuration, and finally by complete obstruction.

Since we cannot now cure the abscess, we will do what we can to render it harmless—that is, we will do a left inguinal colotomy—do away with the chronic intestinal obstruction and the irritation of the fæces to the rectum; try to get the patient into better condition; and, perhaps, subsequently attack the abscess directly through the rectum with some hope of success.

I will ask my associate, Dr. Gibbs, to operate, and while I assist I will call your attention to the points in the operation.

You observe that all the instruments we have thus far used about the rectum are now discarded, and that the most absolute antisepsis is used.

The incision crosses an imaginary line from the left anterior-superior spine to the umbilicus, at one inch and a half from the bony point; and is about two inches long. Step by step we work down on a director to the peritoneum, securing the bleeding points as we advance, and finally stopping all oozing by the steady pressure of a dry towel.

As the peritoneum is opened a coil of gut protrudes, and you see me at once close the opening with two fingers which have been carefully washed, and pass them deep into the pelvis for exploration.

I can feel the abscess wall distinctly. On its upper free peritoneal surface over a space the size of the palm it is much thinned and flaccid from being emptied of its contents. Deeper in the pelvis the walls where they press upon the rectum are dense and thick. Withdrawing my fingers the same coil of gut protrudes, and we see that there is a broad *longitudinal* band of muscular fibre and several *appendices epiploicæ*, showing us that we

unquestionably have, what we must always be certain of at this stage, a portion of the large gut in the wound. Were this not large gut, I should slip it back and bring up another loop from the pelvis.

You perceive that while I am talking we are having constant difficulty. The gut is much distended and thinned, it is the size of my fist; the patient is trying to vomit, and the gut is forced with great violence out of the wound. We cover it with a large flat sponge, both of us press it gently and firmly back into the abdomen, and the ether is pushed till the vomiting ceases.

Now, when all is quiet and the gut reduced, Dr. Gibbs passes a harelip pin first through the skin at one side of the wound, then through parietal peritoneum on the same side, then under the gut through its mesentery, then through parietal peritoneum on the other side, and finally through the skin. By this we have fastened the gut where we want it; we have secured a sharp fold or spur in the gut which will effectually occlude it at this point; and we have so passed the pin that the proximal end of the gut in the wound is much larger than the distal portion beyond the pin. In other words, when the gut is finally opened there will be two orifices. The proximal will be large, the distal small, and they will be separated from each other by a sharp bend in the wall of the gut where it passes over the pin.

The rest of the operation is simple. Eight sutures are introduced each passing through skin, parietal peritoneum, and the muscular wall of the gut. None perforate the calibre of the gut, and whenever possible, they are passed through the heavy longitudinal fibres for additional strength. I wish you to note that I do not draw the gut as far out of the wound as I often do in these cases, because should I deem it best subsequently to attack this abscess *per rectum* and should I succeed in closing it, I may want also to close this artificial anus, and I prefer to leave as much of the wall of the gut intact after my opening as possible.

The sutures being passed we cover the wound, without opening the bowel, first using protective, then wood-wool tissue, then cheese-cloth and bandage. The protective is necessary to prevent the adhesion of the gut to the dressing. After three days the dressings will be removed, the loop of gut will be opened by a longitudinal incision, and the edges will be trimmed with scissors down to the margin of the skin. This will not require ether, and, unless the patient sees what we are doing, she will be unconscious of the operation. The gut is not sensitive to pain.

The operation is completed. The patient will in all probability do well unless the kidneys give trouble. On the third day I will open the bowel and you shall know the result. My only regret is that you will not be able to see the benefits which almost invariably follow this operation in these cases, by having the patient under observation for the next six months. Still, the case is an unusually complicated and interesting one, and teaches many things. You heard my doubts as to the existence of a second stricture above the first, arising from the clinical history, and you saw them verified, the real cause of the obstruction being the abscess and not the old cicatricial contraction near the anus. You saw my error in mistaking an old abscess and pelvic inflammation for a fæcal impaction cleared up under ether. The mistake was a natural one, but none the less instructive.

You have seen us do a colotomy for a combination of diseases each one of which might possibly be handled by itself, but the combination was rapidly exhausting the patient. If she does well, gains strength and flesh, and seems in good condition for the effort a few months from now, I shall, in all probability, divide the stricture, open this abscess freely into the rectum, and try to induce it to close. If we succeed in this and the rectum is not occluded by the pressure of the pelvic exudation, which I fear will be the case, there is nothing to prevent our closing this artificial opening and restoring the fæces to their normal course; though the patient will by that time be so comfortable that she may not elect to undergo another operation.

Note.—There was no rise of temperature after the operation. The gut was opened on the third day. The pin was removed on the seventh; and the sutures allowed to work their way out.

ORIGINAL ARTICLES.

ESSENTIAL PAROXYSMAL TACHYCARDIA.[1]

By JOHN A. ROBISON, A.M., M.D.,
of Chicago, Ill.

The subject of tachycardia, or rapid heart action, has been of interest to me for some years, and I have been surprised to see how meagre is the literature bearing upon this important form of heart disease. An editorial on Essential Tachycardia in the *New York Medical Record*, November 30, 1889, gave a brief *résumé* of an exhaustive article on this subject by M. Bouveret, of Paris. I procured the September and October numbers of the *Revue de Médecine*, and have deemed the article of such importance that I give the following abstract:

Bouveret describes "essential paroxysmal tachycardia" as a peculiar affection of the heart characterized by paroxysms of cardiac palpitation, occurring in adults, in which the pulse increases to 150, 230, or even 300 beats per minute. He divides the paroxysms into two kinds, viz., short and long attacks. The short attacks last from a few minutes to four or five days. In these the principal symptom is rapid beating of the heart. If the attack lasts four or five days signs of passive congestion of the lungs appear, often followed by turgescence of the jugular veins, cyanosis of the face, visceral stases, and œdema of the extremities. The long attacks may last days, weeks, or even months. The symptoms are more grave; acceleration of the heart-beats remains the dominant symptom, but the secondary symptoms are more or less serious; there are disturbances of the respiration and general circulation,

[1] Abstract of paper by M. Bouveret in the Revue de Médecine and report of a case. Read before Chicago Pathological Society, March 10, 1890.

feebleness of the heart's action, dilatation and engorgement of the heart cavities; cough is frequently present, and the expectoration is mucous and viscid, like that in bronchial catarrh or pulmonary congestion. Often the sputum is bloody, and hæmoptysis frequently occurs. Dyspnœa is more or less marked, the respirations frequently being 40 per minute. Pulmonary resonance generally remains normal; sometimes, however, becomes exaggerated. Facial cyanosis and jugular turgescence are pronounced.

The cerebral symptoms are those of arterial anæmia and venous stasis of several days' duration. Restlessness, insomnia, and sometimes delirium are present, and, in some cases, anorexia, nausea, and vomiting. Bouveret noticed one case in which the attack ended in vomiting. Diminution of the urine does not occur in all cases. The skin remains pale and dry during the whole attack. The temperature is normal in the short attacks, but rises from one to three degrees during a long attack. This is probably due to the secondary pulmonary congestion.

Subjective symptoms. The vital forces seem prostrated. The patient experiences a heaviness, extreme weakness, and a general sensation of cold. Pain is seldom present, but there may be a sensation of constriction in the neck, thorax, abdomen, epigastrium, back, or præcordium. After the attack the pulse falls from 200 or 250 to 60 or 70 pulsations per minute. Frequently two or three slow, energetic contractions of the heart mark the transition to the normal pulse-rate. At that moment many patients experience particular sensations: one felt prostrated by an indefinable *malaise*, and it seemed to him that he would die; another patient, a woman, believed that there had been a rupture of some kind in the cervical region.

The secondary symptoms disappear slowly. It takes several days to efface all traces of the pulmonary congestion, venous stases, ascites, or peripheral œdema; but the secretion of urine is usually promptly established. Sometimes a transient polyuria ensues.

Course, Duration, and Termination.—The patient, like the epileptic, always remains liable to another attack. In the intervals his general health is good, and there exists no symptom indicative of trouble of the heart, nerves, or nerve-centres. This integrity of the heart and all the organs is another characteristic of essential paroxysmal tachycardia.

The duration of the malady is long and indeterminable. It may exist from one to fifteen years. The cases that survive long never indicate that they are cured, and they probably are always liable to recurring attacks. After the paroxysms, even those of long duration, there are never signs of organic heart disease. But in one case observed by Bouveret the acute dilatation merged into chronic dilatation. Though the affection seems functional, there is diminished power of the heart, the attacks become more frequent, the secondary symptoms disappear less rapidly, and the prostration of the vital forces persists longer after the cessation of the palpitations.

This form of tachycardia is certainly a grave malady. Bouveret's observations warrant the conclusion that it is almost always fatal. Of eleven patients, only one seemed to be actually cured, several years passing without a new paroxysm. Four patients died either from syncope or systolic paralysis. As many as six survive, but are subject to new attacks.

It is impossible to prognosticate concerning an attack, especially at the beginning. The long attacks are undoubtedly grave. Bristowe, of England, reports a case that terminated favorably after the paroxysm had lasted fifteen weeks, the pulse returning to normal, and the patient resuming his occupation.

Bouveret gives the following as signs of a fatal ending: A tendency to syncope, very extensive pulmonary congestion, great agony in the præcordial region resembling angina pectoris, and renewed acceleration of the heart-beats under the influence of bodily exercise or emotion.

Etiology.—Essential paroxysmal tachycardia has not been observed in infants. The ages of the patients observed varied from nineteen to fifty-two years. Sex, antecedent hereditary, hygienic, or pathological conditions seem to exert no causative effect, but the abuse of coffee and tobacco is apparently of influence.

Treatment.—Anæmia assuredly favors the development and persistence of the attacks, and if present it must be combated with ferruginous preparations and tonics and the proper hygienic and alimentary treatment. Bristowe has given iron to the larger number of his patients, and it seems to have diminished the frequency and intensity of the paroxysms in a number of cases. It is equally important to treat digestive difficulties, such as dyspepsias and diarrhœas, and disabilities of other portions of the organism. During the attacks complete rest must be enjoined. The dorsal decubitus is preferable, and the larger portion of the patients spontaneously seek this position, while others prefer to lie on the right side. Lying on the left side, quick movements, such as rising suddenly to the upright position, or emotional disturbance, aggravate the attacks. The greatest danger during the paroxysm is syncope and heart exhaustion, and during this time the patient should not be examined. Digitalis is certainly the remedy of first importance to reduce the acceleration of the pulsations of the heart. The doses which Bouveret employed were 7½ grains daily of the powdered leaves made into an infusion, four or

five days consecutively, until it moderated the action of the heart. Caffein, nitrite of amyl, and nitro-glycerin have not proven efficacious. Czermak has shown that compression in the cervical region over the course of the carotids, especially on the right side, slows the pulsations of the heart. Quincke has related his experience with this compression in a large number of cases, and has arrived at the conclusion that the lessening of the pulsations of the heart is due to pressure on the pneumogastric nerve. Deep inspirations, and suspending the respirations, are measures which have been used with a certain degree of success. Nothnagel believes that a deep, forced inspiration stretches the pulmonary peripheral twigs of the pneumogastric nerves and transmits an inhibitory influence to the nerve centres. Bristowe records one case in which the inhalation of small quantities of chloroform lessened the gravity of the attacks. Morphine has been given with good results. Venesection has been employed beneficially when there was dilatation of the right cavities of the heart and consequently an elevation of the venous tension and the rapid development of visceral stases. In one case observed by Bouveret the application of a blister over the præcordial region was beneficial. Bouveret believes at present that the only efficacious treatment for an attack of essential paroxysmal tachycardia is compression of the pneumogastric in the cervical region, as practised by Czermak and Quincke; but, as he has applied the treatment only three times, it must be admitted that we cannot as yet estimate the true value of this method.

W. A. R., aged sixty-two years, American born; an active worker, physically and mentally, all his life. For the past twenty years has been foreman of a large manufacturing establishment. His father died suddenly, presumably of heart disease. His mother died at an advanced age, of paralysis. The patient's general health has been excellent, with the exception of trivial attacks of dyspepsia, when he would experience palpitation of the heart in a mild form. He has been extremely moral and temperate, except in the use of tobacco and coffee. Has chewed tobacco *excessively* all his life until three or four years ago, when he almost ceased using it. He was in the habit of drinking from one to three cups of strong coffee with each meal until of late years. About one year and a half ago he was attacked with palpitation of the heart, his pulse rising to almost 150; there was a sensation of impending dissolution, extreme malaise and weakness, and cyanosis of the face and extremities. The physician who attended him said that he could pick up the skin and that it had lost its elasticity and color and resembled the skin of a corpse. The first attack lasted only a few minutes, but the patient was left in an exhausted state from which it took him two days to recover. After this attack he became extremely nervous, apprehensive of sudden death, and melancholic. At intervals of a few weeks he had several attacks, each recurrence lasting longer and leaving the patient more exhausted. But he would not give up his position in the factory until February, 1889. On one day in that month it was necessary that some work should be done on a "champering" machine, and, as the usual operator was absent, Mr. R. went to work at the machine himself, and worked very hard for two hours. Suddenly he was seen to stagger and fall, and when found he was almost in a state of collapse. His heart was beating so rapidly and feebly that its pulsations could not be counted, nor could a radial pulse be felt. He was cyanotic, the skin being cold and clammy. Notwithstanding the severity of the attack, after an hour's rest he arose and went one mile to his physician's office, and had a second attack there. Aromatic spirit of ammonium and whiskey revived him. But it was some days before he was able to be up and around again. He resigned his position, and at my suggestion was placed on cod-liver oil and whiskey. He improved very much during the summer, although he had slighter attacks at lengthening intervals. He noticed one fact, and that is, that a strong cathartic dose of calomel or blue mass cut short the attacks and sometimes prevented them.

The last attack occurred about three weeks ago, while in his office—the patient now being in the real estate business. He wrote as follows: "This morning I had a slight attack of palpitation while writing. It has passed away, but has left me with a sensation of fulness in the head. At the present time of writing my pulse is 130." By remaining away from business half a day all traces of this attack disappeared.

In this case digitalis seems to exert no beneficial influence. I have advised him to try compression over the cervical pneumogastric.

Aromatic spirit of ammonium and whiskey prove to be of the greatest service in shortening the attacks in his case. Nitroglycerin and nitrite of amyl have not been of any service. From the use of pepsin and cod-liver oil with whiskey the patient's weight has increased from 145 to 158 pounds.

Once or twice during the attacks a murmur could be heard with the first sound of the heart near the ensiform appendix. It was supposed to be a systolic tricuspid murmur. Dyspnœa has never been present, although cyanosis is sometimes extreme.

79 State Street.

SALICYLATE OF CINCHONIDINE.

By R. B. McCALL, M.D.,
of Georgetown, Ohio.

Attention has been recently directed to salicylate of cinchonidine, a drug which is probably but little known to the profession at large. From circulars issued by the manufacturing firm of John Wyeth & Co., of Philadelphia, I first learned of the high estimation in which it was held by them, it being considered almost a specific for cases in

which symptoms of both rheumatism and neuralgia are manifested. Like many others, I had long felt the need of a remedy that could be effectively used in such cases where the peculiar signs of the two diseases are blended together, and for that reason the more difficult of management. Salicylic acid, the salicylates combined with quinine and ferric salts and supplemented by anodynes, massage, and electricity have been employed with a measure of confidence and success, and yet there has been a very large percentage of unsatisfactory results.

It is useless to speculate as to whether two distinct pathological states exist in rheumatism and neuralgia. For the purposes of this article it will suffice to recognize the existence of two unrelated morbid conditions modifying and intensifying each other's effects—a condition we may call either rheumatic neuralgia or neuralgic rheumatism.

For symptoms, we may have impairment of the functions of a few or many joints—notably the shoulders, hips, ankles, and less frequently the smaller joints of the hands and feet. Tumefaction may be present in the larger articulations, but very generally is not appreciable; friction, soreness, and stiffness are always present.

To explain how salicylate of cinchonidine is more effective in these states than salicylic acid or the salicylate of sodium with sulphate of quinine would be difficult, and if accomplished would possibly have little practical value. Salicylate of cinchonidine probably owes none of its efficacy to its relationship to quinine, but solely to qualities engendered by the union of cinchonidine with salicylic acid. Given alone, its antiperiodic effect is very inferior to that of quinine, but exactly adequate to the demand in the present instance. The well-known value of salicylic acid in both rheumatism and neuralgia is increased by its intimate association with cinchonidine, and thus the two together, considered on theoretical grounds alone, must be acknowledged to possess those therapeutic qualities that are needed to meet the above described indications.

Before presenting the following cases, the writer may be allowed, in the way of a brief recapitulation, to state that with more or less strongly pronounced signs of rheumatism and neuralgia, such as pain or soreness and stiffness of the loins, with or without impairment of function of the smaller joints, with a history of previous similar attacks, and no permanent organic lesion, most satisfactory and in a great majority of cases, lasting relief will follow the faithful administration of salicylate of cinchonidine. The following are some of the cases treated by me during the year.

Case I.—Mrs. P., aged sixty-nine years, full habit, good appetite. She was nearly helpless, unable to change posture in bed without assistance, or to walk, on account of pain and stiffness of muscles of back. Temperature 99.5°, pulse 85 and intermittent. Strychnine restored the heart to its normal action but had no apparent effect on the condition of muscles. I therefore ordered the salicylate of cinchonidine in doses of two and a half grains four times daily, which after three days was increased to four grains. The patient's condition rapidly improved from the third day. On the twentieth day she was discharged and no relapse has been reported.

Since recovery she has been entirely free from discomfort, has a good appetite and sleeps well. The quantity of the drug taken in a single day never exceeded twenty grains, and averaged about fifteen grains. Not the slightest unpleasant effect could be attributed to its use. Patient gave a history of previous recurring attacks extending over many years from which she had been able to obtain only partial relief.

Case II.—Mrs. K., aged fifty years, plethoric. Her sleep was broken; temperature normal; pulse 80, not intermittent, though slightly irregular. She complained of palpitation and was frequently short of breath. Tenderness and rigidity of sterno-cleido-mastoid, pain in back of neck from occiput downward; muscles of abdomen tender; pain and stiffness of loins not so pronounced as in preceding case. Mrs. K. received the salicylate of cinchonidine in five-grain doses, three times daily, in capsules.

Improvement soon followed, the pain and stiffness disappearing, and the organs resuming their normal activity. Anorexia and insomnia, which had existed, were replaced by a natural appetite and sound sleep. No recurrence.

Case III.—Mrs. E., aged forty-two years, temperature 98.8°, pulse 85, irregular and occasionally intermittent; appetite capricious; sleep broken as a rule. Has had hæmorrhoids for eight years with fissure of anus. As in the other cases, there was a history of frequently recurring backache, sometimes so severe as to render the pursuit of her usual occupation impossible.

Notwithstanding complications, the remedy afforded considerable relief.

Case IV.—A colored woman, poorly sheltered, fed, and clothed. She was attacked with rheumatism and for three weeks was unattended. Temperature 99°, pulse 110, feeble and irregular; no appetite; unable to sleep from pain; urine scanty and high-colored; dull pain or soreness in most of the joints, pain and stiffness of lumbar muscles.

With strychnine, laxatives and diuretics, salicylate of cinchonidine was prescribed, and produced most gratifying results. Swelling subsided, soreness of joints and muscles disappeared, and activity was soon restored.

Case V.—An active, hard-working woman, with normal temperature and pulse. She was unable to sleep from persistent pain and discomfort located in small of back. The pain was relieved by the salicylate of cinchonidine in a very short time. This patient had suffered for years and assured me that she had never received such relief before, and ex-

pressed the desire to have capsules with her so that she could take them if needed.

CASE VI.—Was a woman aged fifty years, who for more than two months had been unable to attend to her household duties on account of pain and stiffness of muscles of back and abdomen. To her the salicylate was given in four-grain doses, three times daily, and rapidly caused complete and permanent relief.

These cases could be supplemented by others, but a sufficient number has been given to show conclusively that salicylate of cinchonidine has a positive therapeutic value in a certain class of diseases characterized by the presence of lumbar pain and immobility.

The leading symptom, therefore, and the one that should guide the physician in the use of the remedy is pain and stiffness located in the lumbar region.

The best forms in which to administer the drugs are tablets or capsules. For convenience the writer has been in the habit of employing capsules. I venture to prophesy that the drug will be found very useful in the treatment of the more simple forms of neuralgia and rheumatism and in the various neurasthenic states so frequently met.

SECONDARY CONSEQUENCES OF SURGICAL SHOCK.[1]

BY J. F. TODD, M.D.,
LATE COUNTY PHYSICIAN, CHICAGO, ILL.

THIS paper is submitted for consideration with special reference to the probable cause of the death of one Robert Burns, a native of Ireland, who, at the time of his death, was fifty-one years of age, and had been married twenty-five years. His history sheet at the county hospital is as follows:

Occupation, canvasser. Diagnosis, carbolic acid poisoning and ulcer of leg. Admitted March 27, 1889, discharged April 6, 1889. While on a spree attempted to poison himself by taking carbolic acid. Treatment: March 27th, whites of three eggs, milk and lime-water and sodium bicarbonate *ad libitum*. April 1st, potassium bromide, 15 grains, three times a day.

He was sent to the Detention Hospital on the night of April 9th, from there to the Insane Asylum at Dunning on the 11th, where death occurred on the 26th of the same month. His wife and brother-in-law testified that his general health had been good for twenty-five years, until a short time previous to his commitment to the Detention Hospital, but that he had the habit of occasional bouts of drinking, and that for some months he had shown symptoms of melancholia. They testified that on the 27th of March, and the 6th and 7th of April, they had seen him stripped naked while bathing and changing his clothes, and that there were no marks or discolorations on his body, except the ulcer on the left leg. Two male attendants at the Detention Hospital testified that they saw him naked in preparation for bathing on the night of the 10th of April, and that there were no marks or discolorations on the body, save the ulcer on the leg. Charles Beck, *alias* Hunter, testified to having witnessed a number of brutal attacks upon Burns by several of the attendants in the Insane Asylum at Dunning.

The autopsy was made about forty-eight hours after death. Present: Drs. Egbert, Hektoen, Perkins, and myself. The conditions found were as follows: Weight about 150 pounds, height 5 feet 9½ inches; *rigor mortis* absent, except in lower extremities, where it was slight. Full set of teeth. Hair dark gray and abundant. Post-mortem discolorations well marked on posterior surface. A slightly gaping linear scalp wound in the right parietal region near its centre. The wound was one inch long, and did not extend through scalp. On the outer surface of left arm, seven inches below the shoulder, was a contusion with extravasation of blood in the subcutaneous tissues one and three-quarters by two and one-half inches in area. On the outer surface of right arm just below the shoulder a contusion with extravasation two by two and one-half inches in area; two small contusions just below the right patella. A contusion with extravasation two by two and one-half inches in area, over the eleventh left rib anterior to a line from anterior margin of axilla downward. A contusion eight by twelve inches in area in the left inguinal region with numerous thrombi in the vessels of uninjured surrounding tissues. The tissues were filled with blood and pulpefied down to the fascia lata and abdominal muscles; the surfaces of all of these contusions were purplish-black, except that on the right arm, which had a yellowish-green margin. There was found a complete fracture of the sternum just above the cartilages of the fourth ribs with recent extravasation of blood above and beneath the line of fracture, and complete fracture of the eleventh left rib about three inches from its vertebral articulation. Subcutaneous fat abundant. Transverse colon filled with scybalæ; pleural and pericardial cavities normal; cavities of heart partially filled with liquid blood; valves found competent by water test; pericardium and endocardium and arterial tunics normal. Walls of right heart somewhat fatty, and right ventricle slightly dilated. Lungs normal, except that lower margins were somewhat œdematous; sections of both lungs crepitant under pressure and floated in water. Stomach contained a small amount of dark-colored liquid and in all respects normal; liver normal in size but slightly fatty; gall-bladder full of bile; spleen, pancreas and intestines normal. Kidneys showed a small amount of fat; normal in size. Capsules stripped off readily; cortical surface dark-red, one-quarter

[1] Read before the Chicago Medico-Legal Society, March 1, 1890.

inch in thickness, with normal markings. Dura mater adherent throughout and slightly thickened; otherwise the brain and meninges presented no abnormal appearances.

Based upon the foregoing facts, I gave the opinion to the coroner's jury that the death of Burns resulted from the injuries described, and that it was a consequence of shock and subsequent prostration. In support of the major proposition, Dr. J. K. Egbert, Assistant County Physician, and Dr. Charles F. Perkins, Assistant Demonstrator of Anatomy, in Rush Medical College, testified that in their opinion death resulted from shock produced by the injuries. Dr. Hektoen testified as follows: "In the absence of any other obvious cause it would seem that the contusions and fractures found upon the body would have a great deal to do with the death."

The coroner then asked: "Suppose that Burns was fairly healthy and had sustained the injuries from violent kicks or blows, what would be your opinion?" Dr. Hektoen answered: "I would have to say they might cause death." This *résumé* of facts and opinions has been given in order that the questions under discussion may be better understood. Dr. H. N. Moyer[1] submitted a paper to the Chicago Medico-Legal Society on the 9th of last October, in which he assumed that the facts disclosed failed to justify the opinion that the death of Robert Burns was caused by the injuries. The propositions upon which he based his argument were: 1. Fatal injuries must produce their effect, either by immediate shock or by remote and secondary consequences, such as hæmorrhage, inflammation, abscess, septicæmia, fat embolism, etc. 2. If death cannot be traced to one of these conditions, some other cause must be sought.

In a large proportion of deaths from shock the cause is so obvious that medical evidence is a mere formality to fulfil the demands of law; in such cases intelligent lay evidence would subserve all other requirements. A penetrating wound of the heart, extensive laceration of the lungs or liver, crushing of the bones of the skull or spinal column are properly recognized by the laity as mortal injuries; the character of such injuries is so rapidly fatal that the refinements of medical science and the subtleties of law fail to mystify even the average jury. In this class of cases the evidence is called positive.

In a certain proportion of cases the cause of death is not clearly recognizable. Evidence of serious injury may co-exist with pathological conditions tending to produce death from exhaustion. In this class of cases the evidence is called negative. It is the class that supplies the fees to criminal lawyers and professional experts, too often at the expense of the best interests of society. There are apparently no rules of evidence or degrees of professional skill that mitigate the discrepancies of expert testimony. Controversies as to the cause of death usually begin with the post-mortem examination of the subject, the statement of the facts discovered, and the inferences deduced from the facts. It is obvious that opinions may agree as to the fatal effects of an injury and vary as to the mode of death, and that opinions will vary upon all questions that are incapable of demonstration. It is admitted that the physician who makes a post-mortem examination should appreciate the importance of his duties, for the reason that they relate to the welfare of society. It is not essential, as alleged by Dr. Moyer, that "he should ever hold in mind the rules governing legal evidence," or even possess a knowledge of them; but it is essential that he should render a truthful statement of all the facts discovered and an honest opinion derived therefrom, uninfluenced by the raspings of cross-examination or the opposing influence or criticism of professional experts. He should formulate and express his opinions with due deliberation, estimating the tendencies to death from causes antecedent to alleged fatal injuries.

If the heart cavities are dilated he should seek for valvular incompetences or vascular degenerations, and evidences of organic disease of the lungs, liver, and kidneys; if the dura mater is thickened and adherent, he should conduct the examination with reference to organic disease of the brain, such as undue vascularity or morbid effusion. By this method of examination and exclusion an opinion as to the cause of death can alone develop an intelligent and well-founded belief. In the Burns case the nature of the injuries necessarily implied the application of great violence, granting a normal condition of the bony structure; no other opinion can be entertained. Hamilton[1] states that "fracture of the sternum, in itself, implies the application of great force," and that "the force requisite to fracture a rib is scarcely less." "The most common causes are direct blows of very great force." It may be assumed that such a force acting upon an enfeebled subject, as Burns was known to have been, was quite sufficient to produce shock. Dr. Kiernan certified to the board of health that death resulted from phthisis and the exhaustion of melancholia. He recognized that exhaustion was the chief factor in the case, but was unaware that the patient had sustained the fearful injuries that the autopsy alone could disclose. Granting that exhaustion due to lack of food and sleep and the nervous irritability of insanity existed, if they were supplemented with

[1] Fractures and Dislocations, p. 168.

the effects of a force sufficient to produce a complete fracture of the sternum, and a complete fracture of a rib, and add to that as a source of constitutional irritation numerous contusions, one of which caused the effusion of a pint of blood in the cellular tissues of the abdomen, with a breaking down of subcutaneous tissues to the muscular fascia over an area of eight by twelve inches, we are forced to the conclusion that shock of dangerous severity, if recovered from, must have been followed by profound exhaustion. It is no answer to such inevitable conclusions to say dogmatically that "insane subjects are not susceptible to the influences that produce shock in the sane, and that in many instances the effects are directly contrary."[1] My observations of this case and the weight of evidence relating to his symptoms are to the effect that Burns was morbidly apprehensive and hyperalgesic, conditions which Spitzka[2] mentions as sometimes coexisting. Savory states that "animals exhibit the characteristic phenomena of shock, and the insane surely do." It has developed in states of profound anæsthesia, and it is doubtful if any condition of animal life can preclude its occurrence on the application of certain stimuli. Forbes Winslow[3] says: "Much has been written on the subject of the insensibility of the insane with a view to establishing that it exists in a majority of cases of mental disease. Such an opinion could only have been expressed by writers practically unacquainted with the ordinary phenomena of insanity. The insane as a general rule are not reduced to a condition of anæsthesia. In many cases the sensibility, psychical as well as physical, is acutely and painfully present." Ross[4] says that all conditions which tend to impair the nutrition of the nervous system, as exhausting diseases, cerebral anæmia from whatever cause, dissipation, prolonged pain, and depressing passions, predispose to the production of shock. It is quite as difficult to fix a time-limit to the duration of shock, or a definite morbid anatomy for its secondary consequences, as it is to determine what physical or mental condition constitutes a bar to its occurrence. The fact is, that notwithstanding the advancement in neuro-pathology during recent years the essential nature of nerve force and the etiology and pathology of shock are but little better understood than they were fifty years ago. It is admitted that shock from sudden and violent mental impressions involves substantially the same pathological conditions that exist in shock, from physical injury; chorea, convulsions, hysteria, epilepsy, arrest of the lacteal and menstrual secretions are recognized as occasional secondary results.[1] Trousseau and Marshall Hall have given histories of paralysis, insanity, catalepsy, jaundice, and gout caused by sudden mental impressions.[2] Savory states that sudden fright has been known to produce deafness and that it is not uncommon to have various forms of local disease referred to some shock which the system has sustained. If the reflex effects of mental shock may so profoundly affect innervation that functional disturbance is continued in many cases for a series of months or years, and in exceptional instances during a lifetime, it is, to say the least, illogical to limit the effect of surgical shock to the period of suspension of nerve function that characterizes the condition of collapse, and still more illogical to insist that fatal secondary results must necessarily coincide with definite, recognizable pathological changes. The constitutional conditions, congenital and acquired, that predispose to shock, the widely varying degrees of tolerance to injury and pain, and the diversity of degrees and character of injuries sustained, render it exceedingly difficult to predict with certainty either the duration or final result of no small proportion of such cases. These considerations undoubtedly have deterred surgical authorities from fixing a time-limit to the duration of shock or the period of nervous exhaustion immediately succeeding it. *It is a problem involving an estimate of vital force present, supplemented by possible contributions dependent upon the functioning power of the sympathetic nervous system, every cell of which may suffer functional embarrassment, the degree and exact character of which we are profoundly ignorant.* Erichsen[3] states that. "On recovery from the immediate and depressing effects of shock secondary symptoms supervene. These are chiefly such as arise from lesions of the sympathetic system of nerves, and consequent disturbances of its vaso-motor action." Savory says that "A state of collapse may end neither in immediate death nor in direct recovery, the reaction may be imperfect and that condition which Travers has described as 'prostration with excitement' may supervene and this may lead indirectly to an unfavorable or fatal issue. In patients whose nervous systems have been shattered by intemperance or who have been exhausted by excessive mental strain or nervous excitement, the nervous symptoms that accompany the febrile disturbance may form so prominent a feature of the case as almost to justify the description of a third type, as has sometimes been done under the name of irritative fever. Often the fever is from the first of an asthenic type, espe-

cially in drunkards, in whom it resembles delirium tremens, ending in death from exhaustion." Agnew[1] says: "In some instances there exists an exciting struggle between reaction and depression, the system makes a gallant effort to recover from the influence of the violence. The symptoms in some measure abate, the recuperative effort is not sustained, and so the conflict is waged, now the one and then the other yielding, until the struggle closes either by recovery or fatal collapse." In illustration of this variety he gives the history of a fracture of a thigh and pelvis with sphygmographic tracings that terminated fatally on the evening of the fourth day after the receipt of the injury. Ross[2] says: "Reaction may gradually give place to health, but in some cases relapses are not infrequent, and convalescence is then protracted even when recovery takes place." Gay states that operations on neurotic subjects are often followed by great nervous excitement out of all proportion to the severity of treatment, and that convalescence is not only lengthened but the result is doubtful. Van Buren[3] states that "when an habitual drinker of spirits has been seriously injured reaction may gradually merge into the peculiar condition known as delirium tremens." Pilcher[4] says: "In the most favorable cases reaction is gradual and progressive, though it may occupy many hours or even days in its course."

Gross[5] writes that "the duration of the symptoms of shock is subject to no little diversity; at times they pass off in a few minutes or, at furthest, in a few hours; at other times they last for several days, and even then do not pass off completely. When very severe, death may occur instantly, or the case may linger on for some time in a state of doubt and uncertainty, with now and then an attempt at reaction, and at last prove fatal."

The foregoing quotations from standard authorities fully sustain my position that the primary and secondary effects of shock necessarily depend upon the constitutional condition of the subject, and justify the conservatism of the opinion that an exact time-limit to the phenomena of shock is impossible to determine. The question now arises as to the character of the secondary consequences. It will be conceded that the injuries that Burns sustained were adequate to produce shock of such severity as to provoke reactive fever. The large mass of broken-down tissues in the inguinal region, or either of the fractures, would produce traumatic fever in a typically healthy subject. Does traumatic fever necessarily depend upon septic causes, or an inflammatory condition? Erichsen says that simple traumatic fever is best studied in the class of injuries that this case presents, viz., in simple fractures and severe bruises of the soft parts, and that the exact cause of the fever has not yet been clearly settled. Lucas-Championnière is of opinion that we must look for its cause in the nervous system, and certainly in some cases it is difficult to conceive of any other mode of origin. Hamilton[1] says: "Irritation is the only invariable condition immediately precedent to inflammation; it is the direct and sole cause of many surgical accidents in which the interposition of inflammation cannot always be demonstrated, and of some few in which it plainly does not exist, *e. g.*, nervous shock, tetanus, traumatic fever, and traumatic delirium." We see, therefore, how important is the *rôle* played by irritation in its relations to surgical accidents and maladies. According to Erichsen, "In aseptic wounds and subcutaneous injuries we have three causes which may separately or conjointly produce the condition known as traumatic fever. First, a nervous disturbance, concerning the exact nature of which it is useless to speculate. Secondly, the absorption of the early exudation of a fresh wound. Thirdly, the ferment contained in the serum squeezed from a blood-clot during its contraction." It has been shown experimentally by Billroth and others that fresh aseptic serous discharge from a recent wound if injected into the subcutaneous tissues or vessels of an animal causes febrile disturbance. Gross says that "irritative fever bears the same relation to the nervous system that inflammatory fever, properly so termed, bears to the vascular; *i. e.*, that the fever is characterized in the one case by irritability or excess of sensibility, and in the other by plethora or redundancy of vascular action. Van Buren[2] writes that "reaction merging into fever *means that it is incomplete and halting*. It is important not to fall into the popular error that the reaction has passed beyond the limits of health into the region of 'inflammatory excitement,' and that it requires remedies of a lowering character. The excitement is in truth due to depression of the powers of life." Travers,[3] whose opinions are quoted affirmatively by nearly every writer on this subject, says "that the tumult of the system proceeding from the sympathy of the whole with an injured part, is a state in which reparative action is wholly incompatible. Some cases are followed by inflammation, and, incapable of sustaining it, die in collapse. The fever resulting from injury may be bold inflammatory or may be vacillating; but *irritation*, in my opinion of the term, is not fever under any modification. In irri-

tation we have no determinate or continued train of actions; it is everything by turns and nothing long: it may coexist with fever and not coincide with it, it may be a cause of fever or a symptom of it, or either may exist alone, as original conditions." These views coincide with Hunter's, who defined irritable habit as "an increased disposition to act without the power to act." The following quotation from Savory[1] on shock, admirably summarizes the essential and well-recognized physiological facts relating to this phase of our inquiry:

"There is no more important subject for inquiry than the relations of action to power in the living body. In the condition of health the balance is uniformly maintained, or at least the supply is equal to the demand. But if from any cause the power of an organ on the function of which life is immediately dependent be much impaired, this difficulty arises: its function must still be discharged to an extent at least sufficient for the purposes of life, and, therefore, deficiency of power may need to be redeemed by increase of action. But action involves exhaustion, and rest is needed for repair. The greater the effort, therefore, the greater the exhaustion; but, again, decreasing power must be met by increasing action. Thus cause and effect react each on the other. The relation between power and action becomes more and more reversed, until at length, the supply diminishing and the demand augmenting, the crisis with rapidly increasing pace is hurried on."

In this way collapse may indirectly terminate in death through excessive and exhausting reaction. Reaction may be for a long time, perhaps some days, only partial and defective, sufficient indeed to protract life, but rendering the prognosis extremely doubtful. Burns's history, as given by Dr. Kiernan, strongly suggests the effects of increasing exhaustion following shock from the undiscovered injuries. He says that Burns was put to bed on the 20th of April, began to fail rapidly on the 22d, rallied on the 25th, and died about noon on the 26th. The death was neither sudden or unexpected. It was not from sudden heart failure, and the conditions found, as described before the coroner's jury, suggest no theory that will sustain the opinion that death was caused by disease. The adhesion and slight thickening of the dura mater has no greater pathological significance than an adherent pleura. The dilatation and fatty degeneration of the right ventricle was not sufficient to involve either loss or embarassment of functional capacity: there was positive proof that there was no valvular incompetency. The slight fatty degeneration of the liver and kidneys was indicated by a slight change in the color of the tissues, and afforded no evidence of preëxisting disease; it was the condition found in a large proportion of the bodies of intemperate subjects. Paget says: "The whole history of fatty degenerations concur to prove that they are results of defect, not of disease of the nutritive processes, and they may be therefore classed with the atrophy which we recognize in merely diminished quantity of formation."

It has been alleged that the well-known tendency to degenerative changes justifies the opinion that the fractures were produced by muscular contraction. Spitzka, one of the most celebrated authorities on the pathology of insanity, refers these trophic disturbances to the conditions found in paretic dementia and chronic paralysis. The line of fracture in the sternum, in this instance, presents in color and cell structure a perfectly normal appearance, and the effusion of blood in the over- and underlying tissues indicated a recent ante-mortem fracture. All experience proves that fracture is very rarely caused by muscular contraction. Gürlt has been able to collect only 133 out of 13,000 cases, in which fracture was so produced. It has also been alleged that Burns was a syphilitic subject; that opinion is sustained only by the existence of a chronic ulcer of twenty years' standing over the left tibia, and the impressions said to have been derived from the appearance of copper-colored patches on the surface of his body. Reference has already been made to the discrepancy of testimony on this point, and as it involves a question of veracity, it will not be further discussed. Whatever view may be entertained, it is evident that syphilis sustained no causal relation to this death, other than possibly contributing with other causes to produce a condition of constitutional debility. The post-mortem findings closely correspond with the physical conditions existing previous to the infliction of the injuries, malnutrition, fatty degeneration, gradual failure of constitutional vigor.

Dr. Moyer makes allusion to the Hetzke case to illustrate the cause and morbid anatomy characteristic of fatal shock. In this case the injuries were "by no means severe, none of them extending through the subcutaneous tissues." The right cavities of the heart were enormously distended with blood, the body was that of a healthy boy absolutely free from organic disease; the opinion that death resulted from the injuries was based upon purely negative evidence, supported by the condition of heart cavities that indicated shock. In comparison with the injuries sustained by Burns, the boy's injuries were trivial. It is well known that youthful subjects are very susceptible to shock, and that they possess great power of resistance; the tendencies are reversed with advancing age, and the dangers are, as is well known, greatly augmented by whatever influence that tends to diminish vital power. Burns's case presents a variety of influences tending to develop susceptibility to shock, and

[1] Loc. cit., vol. i. p. 155.

all tending to reduce the power to withstand it. Chronic alcoholism, loss of sleep, morbid apprehension of violence, and melancholia combined to produce the degenerative changes described, and a condition of general debility. Chossab, who has made a special study of the progressive structural changes in starvation, says that animals placed on short rations are apt to die from trifling injuries. That has been the experience of surgeons under all circumstances, and it is upon such considerations that surgeons base their prognosis in surgical cases. The question arises as to the propriety of couching opinions in positive terms upon negative evidence as to the causes of death. All injuries of a severe character, not necessarily considered mortal, may prove fatal by reason of the existence of certain morbid tendencies, or constitutional peculiarities, which may be obvious or concealed, and may vary as widely in nature and degree as human character varies. Shall we qualify our opinions as to the cause of death in a case of alleged criminal assault, in which severe and numerous injuries are found to have been sustained, and no evidence found of other adequate causes? Or shall we, admonished by the fact that medical science is only a science of probabilities, permit our conservatism to develop doubts that grant immunity to crime? The answer and the responsibility are alike obvious.

No. 2447 Prairie Ave., Chicago, Ill.

ON THE DANGERS ARISING FROM SYPHILIS IN THE PRACTICE OF DENTISTRY.

By L. DUNCAN BULKLEY, A.M., M.D.,
ATTENDING PHYSICIAN TO THE NEW YORK SKIN AND CANCER HOSPITAL, ETC.

Happily the recorded instances of the communication of syphilis in connection with the practice of dentistry are relatively few in number, when compared with the very numerous cases on record where the disease has been acquired through other innocent channels; for, it must be remarked, the number and variety of modes by which this disease has been innocently spread from one person to another, entirely without sexual transgression, is many times greater than would be supposed or imagined by one who has not investigated or given some attention to the matter.

The subject of the innocent transmission of syphilis is a very large one, and one to which the public health officials might well direct their attention; but at the present time we can consider only a very small and limited subdivision of it, namely, as the disease may in any way bring danger through or to any one in the practice of a single branch or specialty in surgery, namely, in dentistry.

Although, as before stated, the reported instances where syphilis has been communicated in connection with or during the operations of dentistry are relatively few, nevertheless there are a sufficient number of cases on record not only to show clearly that this unfortunate accident has repeatedly occurred and may readily occur, but also to direct our attention to the methods or channels through which this may take place, and so to point out the means by which the danger may be escaped or avoided.

It would be quite out of place here to attempt a full consideration of syphilis as a disease, or even to give a description of its various manifestations and effects, which are more varied and manifold than those of any other known malady. But before entering upon our subject proper it may be well to recapitulate briefly the points which are well established in regard to the nature and pathology of syphilis, in order that the real dangers arising from the disease may be better understood.

Syphilis is no longer to be looked upon with the utter abhorrence with which it has been regarded in times past, when it was believed to be always the result of sexual transgression; it is not, indeed, to be always considered as a venereal disease, for advancing knowledge has revealed and science has recorded thousands of cases where it has been acquired in ways of which the unfortunate victim was as innocent as is one who catches smallpox, scarlatina, or measles; but, of course, the fact still remains that in the enormous majority of instances syphilis is acquired in sexual intercourse, because here is offered the greatest opportunity for abrasions to occur, through which the poison may gain entrance. But, on the other hand, hundreds or even thousands of physicians and midwives have contracted syphilis in the practice of their calling; in numbers of instances it has been conveyed by vaccination, tattooing, cupping, and breast-drawing, and, in fine, there is no end to the curious and previously unexpected methods by means of which this disease has been innocently communicated from one person to another.

This innocent transmission of syphilis has also occasionally happened in the practice of various departments of medicine and surgery. Not only have midwives acquired the disease in the practice of their calling, but several small epidemics are on record where a number of women, and from them their children and others, have acquired syphilis from a chancre on the finger of the woman who had delivered them; the disease has also been communicated in various surgical operations, and a striking illustration is found in the history of Eustachian catheterization, where as many as sixty cases were traced to the practice of one person. Instances will be given later where it has occurred in some of the operations of dentistry.

Syphilis is a well-defined disease, always depending upon the entrance of a definite, specific poison, which has never been perfectly isolated, and of whose exact nature we know nothing. It is most probably due to a microörganism, but although this has been thought to be discovered on several occasions, it has never been satisfactorily demonstrated, nor have inoculations been made with success by any pure culture of the same. It suffices for our purpose, however, to recognize that there is a poison capable of entering the system and thereby causing syphilis, reproducing itself there, and again under proper conditions communicating the disease to all who are properly and sufficiently exposed to its influence.

The poison always enters the system at some definite point, and at this place generally in from two to four weeks, a local sore, termed a chancre, which is the first sign of the syphilitic invasion, develops. This sore presents quite different appearances under different circumstances and in various localities. These appearances may be learned from many recent text-books and journal articles. The only exception to this mode of entrance of the disease is found in the case of hereditary syphilis, where the poison enters with the life, and possibly in some other rare conditions, which need not be entered upon here.

For the entrance of the syphilitic virus a broken epithelial or epidermal surface is necessary, although apparent exceptions to this rule have been occasionally met. But in some way the poison must come in contact with the absorbing elements of the body, either bloodvessels or lymphatics, and by them be taken into the circulation, where it multiplies and produces its lesions in various parts of the body; and when once the virus has gained entrance the individual is syphilitic, and unless the disease is checked by treatment, it will go on producing its manifestations, even for many years.

The period during which syphilis is actively inoculable has never been definitely determined, and will probably never be accurately known. It is certainly very contagious during the first year, and also for many months thereafter, and cases are on record where infection has occurred from cases many years advanced in syphilis; indeed, the period where danger ceases has never been determined. Although it is questionable if syphilis is often communicated by patients five years after their infection, no prudent man would take even a shadow of a chance of personal inoculation at this or even at a very much later period. Treatment, of course, greatly modifies the infective power of the disease, and the contagious character of syphilis, even in the earlier stages of the disease, is greatly lessened, if not entirely destroyed in some cases. But all these "ifs" and qualifying statements only show what a dangerous and treacherous affection we have to deal with, and how difficult it is always to be certain of immunity from danger.

The poison of syphilis may be received from three different sources: 1st. From the initial sore or chancre; 2d. From mucous patches; 3d. From syphilitic ulceration; and 4th. From the blood; these we will briefly consider in the above order.

The chancre, or initial sore of syphilis, is occasionally formed upon the lips, tongue, and other portions of the buccal cavity, but generally the lesion is so marked and painful that the patient avoids the dentist and there is relatively little danger of infection from this source. But infection does sometimes occur, as in an instance which fell under my own observation, about to be described, where the gentleman, supposing that the chancre was only a local sore due to sharp and rough teeth, went to his own dentist, and had them filed off, when the ulcer was very painful, and giving off an abundant virulently contagious secretion; so that his dentist must certainly have been exposed to the same. It is well, therefore, in the case of doubtful sores about the lips, tongue, or mouth, either to be assured of their harmless nature or to exercise such precautions as will insure perfect protection to self and others, which will be considered later.

The second source of the contagion, namely mucous patches, is far more fruitful of infection, and that against which special care must be exercised. It is to be remembered that at one time or another these lesions appear to a greater or less amount on the buccal mucous membrane of almost every case of syphilis, so that at some time almost every case is capable of communicating the disease from this source. Mucous patches are slightly raw surfaces of various sizes and shapes, which are at first slightly elevated, and then may become depressed by the loss of the epithelial covering. When newly developed they are of a redder color than the normal mucous membrane, but later may become grayish-white. They are always superficial and often do not cause much annoyance, so that the patient may readily attend to all the duties of life, and may go through considerable dental manipulation while having an abundant crop of mucous patches on the tongue, lips, or buccal cavity. The secretion from them is sticky, and intensely contagious. It is from these lesions that fresh chancres are most commonly contracted, and it is this secretion which adhering to instruments and articles such as cups, spoons, pipes, etc., gives rise to syphilis in most unexpected manners.

Certain deeper ulcerations of syphilis may sometimes give rise to contagion, especially when they occur in the earlier stages of the disease; but prac-

tically very few instances of contagion from this source are known, although this danger also should always be guarded against.

The fourth source of syphilitic infection, namely, the blood, is the least likely to present dangers in connection with dentistry; it is, however, quite possible for blood which is drawn during an operation, or by accident, to communicate syphilis, if by chance it finds an opportunity to enter another individual. It is just this uncertainty in regard to the possibilities of infection which gives to our subject such great practical interest; in few, if any, of the dozens of methods by which the disease has been innocently transmitted from one person to the other was the possibility of such an accident known or even suspected beforehand.

We will now consider some of the observed facts in regard to the communication of syphilis in dentistry, and afterward examine the modes of transmission and the means of prevention. Our clinical study will naturally divide itself into two lines of thought: 1st. In regard to the dangers from syphilis to *patients* undergoing dental operations; and 2d. In regard to dangers to the *operator*.

Inasmuch as it presents many points of interest, relating both to the patient and operator, I may be allowed first to relate the case alluded to which came under my own observation and treatment, and which first called my attention particularly to the subject.

Mr. X. W., a gentleman of intelligence and position, aged sixty years, came to me September 11, 1884, on account of a sore on the tongue which he feared was a cancer. The history was, that some ten weeks before his first visit, he had first noticed a little point of soreness, which had gradually increased in size, in spite of treatment, until latterly it had given him considerable annoyance, so that he was conscious of its presence at all times. The true nature of the sore had evidently not been recognized.

On examination there was found on the right side of the tongue, about an inch from its tip, a hard, inflamed mass, nearly half an inch in diameter, the centre ulcerating and the edges somewhat everted. It was not painful except when irritating food or drink touched it. The two upper molars were found to have sharp and rough edges, and he had been wearing a red rubber plate until recently. There was a small, enlarged, and painful gland beneath the jaw on that side.

Thinking that the ulcer might possibly be due to irritating local causes, he was given a soothing mouthwash, and an alkali internally. Five days later there was a marked improvement in the condition of the ulcer; it had a less angry look, but its edge was more clearly defined as the inflammatory element had somewhat subsided. He had been of his own accord to his regular dentist, and had had the roughened teeth made smooth, and had left out his set of artificial teeth.

From a careful second study of the case I then felt convinced that the sore was a chancre, a primary lesion of syphilis, and he was immediately put on antisyphilitic treatment; the general eruption and other symptoms which followed a few weeks later rendered the diagnosis certain, together with the remarkable manner in which the sore healed and symptoms vanished under proper treatment for syphilis.

In searching for the mode by which the syphilitic poison had gained entrance, it was learned that, during the month or so previous to the appearance of the sore upon the tongue, he had, through the persuasion of a friend, been under the care of a dentist of the cheap, advertising order, who, he had noticed, was not at all cleanly either in his person or with his instruments. He could not locate the exact date of the injury to the tongue by the dentist's instruments, but work had been done in that locality, and he remembered the instrument occasionally slipping, as will often happen, and inflicting injury to the soft parts. He was a married man with a family, and was very desirous of learning how he had become infected; he had certainly not been exposed in sexual intercourse, nor in any other manner which we could discover.

The interesting points in the case are: first, that while the proof is not absolute that he was infected in the dentist's chair, still the circumstantial evidence is so strong that little, if any, doubt can be entertained that the poison came through this channel.

The habits and methods of the particular dentist were such that poisonous material from the mouth of a previous syphilitic patient could readily have been transferred on instruments or otherwise to the wound made in the tongue, either by the sharp teeth or by a slip of an instrument. The second interesting point is that this patient, before the true nature of the disease was ascertained, had been to his own regular dentist for smoothing the teeth, and so had certainly exposed him, and others through him, to the poison which was secreted freely from the raw surface of the chancre.

The earliest recorded cases of the transmission of syphilis in dental operations are in connection with the transplantation of teeth, during the last quarter of the eighteenth century.

Sir William Watson[1] published a case of this description, and John Hunter[2] relates two similar cases, about which there can be no doubt. J. C. Lettsom[3] also recorded three cases: of these, one was personal, one was seen by a Dr. Hamilton, and the third occurred in America, having been observed by Kuhn in Philadelphia; these gentlemen furnished

notes of the cases to Dr. Lettsom. This mode of transmission does not occur again in literature, to the knowledge of the writer, although Gibier[1] says that "cases have been recently related." In view, however, of a recent revival of the operation of tooth transplantation, it is quite possible that the future may furnish fresh instances of this mode of the innocent acquiring of syphilis.

From this period no other cases of the transmission of syphilis through dental procedures are found recorded for nearly a century; indeed, not until the advent of modern operative dentistry and active medical observation.

The first case met with is one reported by Dr. C. W. Dulles,[2] of Philadelphia, and which was also seen by the late Dr. Maury. The patient, a female domestic, of excellent character, developed a chancre of the lip two weeks after a visit to a dentist, who on that occasion extracted a tooth, and later did some cleansing of the teeth. Although no confirmation was obtained, it seemed reasonable to suppose that the operation of extraction was in some way responsible for the inoculation.

Dr. F. N. Otis[3] also mentions a chancre of the lip which occurred in a gentleman, "about three weeks after a morning spent in a dentist's chair." Lancereaux[4] relates a similar case of chancre of the lower lip in a woman, after extraction of a tooth and other dental work; and Giovanni,[5] of Bologna, has reported a chancre of the lip, apparently from a dentist's instrument. Leloir[6] mentions having seen a man with chancre of the gum, in whom the infection seemed to have taken place in consequence of cleaning and filling a cavity in a tooth with soiled instruments. Lydston[7] has likewise reported the case of a woman with syphilis, in whom the chancre on the gum, below the lower middle incision, appeared to be the result of cleaning and repairing of the teeth, done three weeks previously. The glands beneath the jaw began enlarging a week or more after the appearance of the sore on the gum.

Roddick,[8] of Montreal, has recorded a case of more than usual interest, where the primary syphilitic sore on the gum was undoubtedly the result of inoculation by means of dental forceps used in extracting a tooth. This case is worth mentioning somewhat in detail. The patient, aged about thirty, was the wife of a physician, and the mother of healthy children. She had been in excellent health until about a year previous to her visit, when she had a tooth extracted, the operation being difficult and accompanied by considerable laceration of the gum. The wound showed no tendency to heal, but became sloughy and indurated. Within a few weeks the glands beneath the jaw were found enlarged, and shortly after, an erythematous rash covered the body and extremities, followed later by a papular and squamous eruption. Sore throat and alopecia were soon added, to complete the picture of constitutional syphilis. Careful investigation failed to reveal any other source of contagion than the dental operation; the husband was entirely free from disease, and Dr. Roddick, who is an exceptionally careful man and thoroughly qualified to judge, concluded that "in all probability the instrument used by the dentist was made the vehicle of contagion by being brought in contact with a mucous patch in the mouth of a syphilitic person previously operated upon."

In the second division of this portion of the subject, namely, the dangers from syphilis to the *operator* in dental procedures, the number of instances on record is fewer, but they are very striking and well authenticated.

The first instance discovered was that of a dentist, who reported his own case.[1] The inoculation took place on the middle finger of the left hand, above the nail, and was followed by constitutional syphilis. He could not trace the infection to any particular patient, but there could be no doubt that the poison came from mucous patches in some one's mouth, and lodged in one of the little cracks which are so common about the root of the nail. Bumstead,[2] when speaking of the digital inoculation of accoucheurs, says that he has "known dentists to suffer in the same manner." Neumann[3] knew of a dentist who tore his hand on a sharp tooth while operating on a syphilitic patient, which injury was followed by severe syphilis. Jonathan Hutchinson,[4] in his excellent little clinical work on syphilis, gives an illustration of a well-marked, circular, indurated chancre on the pulp of the finger of a dentist, which had been produced by a scratch on a patient's tooth.

Although the number of these recorded instances of syphilis communicated in dentistry which I have been able to find, after a very careful study of the subject during several years past, is relatively small, it is yet quite sufficient to establish the fact that such infection does occasionally take place, and to place us on our guard against such accidents in the future. Undoubtedly but few of the cases occurring have ever found their way into print, and it is possible

that when special attention has been called to the subject many more will be recognized and reported.

Having now considered the clinical basis on which rest the grounds for believing that there are dangers arising from syphilis in the practice of dentistry, we will examine the modes in which this accident can arise, and then consider the means for preventing the occurrence of this sad event. Two methods of the non-venereal transmission of syphilitic virus are recognized, namely: First, the direct, and second, the indirect. In the first instance the poison is transferred directly from one individual to another, either in already existing wounds or in those occasioned at the time. The number of recorded cases of the communication of syphilis by kissing is now very great; hundreds can be found in literature, and I myself have seen over thirty cases of chancre of the lips. Infants at the breast of syphilitic nurses frequently acquire the disease, and breast-drawing by adults has given rise to numberless cases. In several series of instances syphilis has been both acquired and given by the application of the tongue to the eye to remove foreign particles and to heal disease; the disease has also been acquired and given in the process of wound-sucking, and other more rare modes of transmission which have been reported could be enumerated did time permit.

The particular method which is, perhaps, of most interest to us in the present connection is that of tooth-wounds. The number of cases of this class which are on record is very great; nearly all of them are from bites, usually intentional, and details of these need not be presented here. There are also a number where the infection has taken place from a blow on the mouth, the knuckles being wounded by the teeth. The first of these tooth-wound cases was observed about the beginning of the present century, by Boyer,[1] but not reported until 1840, by his son. Since that time a number of observers have recorded cases, some of whom have each seen several. Thus, Gamberini[2] saw three cases; C. Pellizzare,[3] three cases; Van Harlingen,[4] five cases; Lavergne and Perin,[5] five cases; Lesage,[6] three cases; Finger,[7] four cases, and Jonathan Hutchinson,[8] three or four cases.

In connection with this may also be mentioned the fact that surgeons have repeatedly been inoculated in wounds acquired during operations on syphilitics, as also in other wounds when examining those with the disease. When we consider the relatively large number of physicians and surgeons who have become thus accidentally inoculated in the discharge of professional duties (and I myself have seen at least seven or eight cases), the only wonder is that the accident does not occur oftener to dentists, whose fingers are continually bathed in the buccal secretions, often from mouths with active and intensely contagious syphilitic lesions.

Syphilis is rarely communicated to the patient in dental operations by the direct or immediate method of contact, although the cases of the communication of syphilis by tooth transplantation, already referred to, were probably by the direct method, the poison being undoubtedly carried directly in the transplanted tooth from a syphilitic to a healthy person.

It would also be possible for a dentist with an unrecognized chancre on the finger, in an early stage, to communicate the poison directly to a patient's mouth, as in the case of midwives, already mentioned; but no such case has been found in literature.

The second, indirect or mediate, method of contagion is that which usually takes place in cases where the disease is transmitted during the operations of dentistry, and, indeed, in a large number of the cases of syphilis innocently acquired.

Time and space would fail to tell of even a few of the methods of mediate contagion of syphilis which are scattered throughout literature, but a brief statement of some of the principal modes by which it has been observed to be conveyed innocently from one person to another, may aid us in understanding how the accident can occur in connection with dental operations.

As is well known, various household utensils, such as cups and drinking vessels, spoons, tobacco pipes, etc., have been the means of spreading the disease to hundreds of cases. The glass-blower's pipe has also caused a number of small epidemics, and cases have been traced to the assayer's blowpipe, to whistles, musical instruments, toys, pencils, pins, tacks, nails, thread, paper money, coin held in the mouth, etc. Of instruments used about the mouth, laryngoscopes and tongue-depressors are peculiarly liable to transmit the disease, but the only instance found is a case reported by Jumon,[1] in which a paper-cutter used to depress the tongue gave rise to syphilis. The cases traced to the use of the Eustachian catheter have been already mentioned.

Syphilis has also been conveyed by means of various fabrics, and a number of striking cases are on record where towels and napkins have transmitted the disease. An interesting case is given by Leloir,[2]

where syphilis was communicated by means of a handkerchief.

Of peculiar interest are the cases, of which there are a number on record, where the venereal disease has been transmitted by means of a tooth-brush. This was first observed by Blumenbach,[1] where a lady received a chancre of the tonsil, apparently by means of tooth-powder, her syphilitic nephew dipping his brush into her box when cleaning his teeth.

It is understood, of course, in all these instances that the various objects served as media to convey the dried syphilitic secretion which adhered to them directly to the tissues of the individual who became infected, and it is readily seen how, unless precautions are exercised, the various implements and articles used in dentistry may likewise very easily become the bearers of syphilitic virus.

It is not always possible to determine exactly upon which instrument or in what manner the poison is conveyed, but the preceding instances show that the infection did take place in some way in connection with and in consequence of dental operations. The agents which may become the conveyers of the poison are as numerous as the implements and articles which may come in contact with the mouth in dental manipulations. For convenience, these may be grouped in four classes, as follow: First. Instruments proper. Second. Napkins. Third. Rubber dams, wedges, dental floss, etc. Fourth. Plaster, rubber, etc., used in the making of artificial teeth and sets.

Among instruments, the only one plainly shown to have communicated the disease is the forceps, in the case related by Dr. Roddick, in which the site of the extracted tooth, where the gum was torn by the forceps, became a syphilitic ulcer, the seat of the chancre or primary sore of syphilis. But it is readily seen that the instruments used in excavating and plugging may also become infected, while there is peculiar danger in such instruments as files, burrs, and drills, where there are many places difficult of cleansing which may receive and retain the virus. Napkins and towels may convey the poison, as has been shown; while rubber dams, if used a second time, would very easily convey infection from their prolonged contact with the soft parts. The same is true of wedges, portions of one being often used for different patients, as also thread, ribbon, or dental floss passed between the teeth. The different workmen in a furrier's shop were once infected[2] from a thread passed between them and bitten off. My scanty knowledge of the process of taking casts and preparing and fitting artificial teeth does not permit me to speak in regard to any dangers from this, but I should judge that possibly some danger might arise, perhaps, quite as unexpectedly as it has in other branches of dental practice.

We come, finally, to the most practical and important part of our subject, namely, the prophylaxsis, or prevention of the occurrence of this most unfortunate accident, the transmission of syphilis in the practice of dentistry. It may be somewhat out of place in the presence of a society composed of the best elements of the dental profession in New York to urge the simple matters of precaution about to be mentioned; but, as some may not heretofore have recognized the immense importance of the matter, it is best to err on the safe side, and to present briefly and clearly the precautions which seem to be indicated from what we know of the nature and virulence of the poison of syphilis.

As before mentioned, the virus or contagious element comes in liquid form from a chancre or a moist, exuding surface, or, more rarely, with the blood itself from a fresh wound. The secretion is very sticky and adherent, and when dried on an article forms a delicate coat which can hardly be perceived. Nothing is known in regard to the viability of the virus, or the length of time during which it may retain its actively contagious character, but from many instances in the various conditions of life and in medical experience, it would seem that under proper circumstances it retained its vitality and activity for some considerable period—longer than that possessed by the somewhat similar virus of vaccine. Days, weeks, or, perhaps, months, after an instrument or article has become infected it may again give off the poison and produce inoculation. Simple washing will not destroy the poison, although it may so dilute it that it becomes innocuous.

There are, however, several elements which are destructive to its life, and these are heat and cold, and the so-called disinfectants, antiseptics, or germicides. Cold can hardly be utilized practically, as a sufficiently low temperature for a sufficient length of time would be difficult to maintain. Heat, however, may readily be employed in a thoroughly efficient manner, and is undoubtedly the very best means for destroying contagious principles. Inasmuch as dry heat, as in a flame, would injure the temper of instruments, the desired results are best reached by means of moist heat, obtained in boiling water.

Instruments and other articles placed in a vessel and then subjected to vigorous boiling for half an hour or so may be considered absolutely free from any power of conveying contagious matter.

Various chemical substances are also capable of destroying the virus when efficiently used; prominent among these stand bichloride of mercury and carbolic acid. The mercurial salt has its disad-

[1] Bibliothek fur Aerzter, iii. p. 197.
[2] Archiv. f. Derm. et Syph., viii. 660.

vantages, both from its poisonous nature when in strong solution, and also from its corroding action on some metals. Carbolic acid, therefore, remains as the best of the two, and, indeed, when properly used, answers all the requirements of the case. But one must not be deceived by the odor, and be led to use a weak solution, for it is questionable how serviceable the high dilutions used in antiseptic surgery are in overcoming such a poison as syphilis. The strong acid certainly destroys it, and a safe method is to dip the instruments in a ninety-five per cent. solution, wiping or scrubbing them afterward. A much weaker strength, even a ten per cent. solution, would probably be effective if they were left in it a considerable time, and then thoroughly washed. I will not take the time to discuss other disinfectants, but I wish to impress the fact that, not only for ordinary cleanliness, but also and particularly to avoid the possible danger of infection, too great care can hardly be used in rendering instruments and everything pertaining to dental practice as absolutely clean as thought and labor can possibly make them.

Files and burrs are particularly liable to catch and hold the poison of syphilis in their fine serrations, and as they are also peculiarly liable to wound the soft parts, they may readily become means of contagion. Also, the various articles connected with polishing the teeth are dangerous if not properly cared for. I well remember more than one dentist, in times past, polishing my own teeth with a bit of wood dipped in pulverized pumice-stone, which wood had evidently been used for former patients. Rubber dams and wedges can of course be readily disinfected in strong carbolic solutions, and napkins by boiling.

In regard to the personal prophylaxis of the dentist against acquiring syphilis in dentistry little need be said. The careful guarding of fresh wounds, and thorough cleansing of the hands, and immediate sucking of any wound made during operations, will generally suffice to prevent the untoward event. "Forewarned, forearmed," applies well in regard to all the dangers from syphilis in dentistry; if the danger is thoroughly well known and appreciated half the battle is over.

The question here arises, how far the dentist should be able to recognize syphilis and avoid its dangers. Undoubtedly, it would be most desirable that this knowledge should be obtained; but unfortunately a practical acquaintance with syphilis is somewhat difficult, except after considerable clinical experience with the disease. But it is certainly extremely desirable that the mouth lesions should be known by dentists so as to be recognized, and this would be a fitting subject for the consideration of instructors in dental colleges.

In concluding our discussion of this topic, I would add that I by no means wish to excite unnecessary alarm, but only to present facts already well known and conclusions which must be accepted by all those acquainted with the subject. With the presence of such a disease among us, which often appears even in the best class of society, it is well to recognize and understand the dangers which may arise therefrom, and to do our utmost to avert them; this I trust will be the result of the presentation of the subject which has been considered.

MEDICAL PROGRESS.

Inhalation of Vaporized Calomel in Croup.—Rothe reports the case of a child (*Der Kinder-Arzt*, March, 1890) suffering from true croup, in which the symptoms were so severe that the necessity for tracheotomy was imminent. Before resorting to the operation, however, he decided to try the efficacy of inhalations of vaporized calomel, as described by Corbin. A tent over the bed was improvised by means of half-hoops and a blanket, and at the feet of the child a dish and spirit-lamp were placed, and in the dish 30 grains of calomel. The calomel was quickly vaporized, and in about eight minutes the noisy respiration of the patient became quieter and less labored. In ten minutes a profuse perspiration was induced and the child was quiet and comfortable, and without dyspnœa. On the next day the symptoms again increased, and the same treatment was resorted to with equal success. On the fourth day the child was convalescent.

In the second case, a child of seven years, the treatment was also successful. In both cases after the inhalations expectoration became free and less tenacious than previously, but in neither was the membrane discharged.

Early Symptoms of General Paralysis of the Insane.—In a paper read before the Harveian Society (*British Medical Journal*, April 5, 1890), Dr. George H. Savage described premonitory symptoms of general paralysis which are not usually noted in the text-books. Of particular interest are the following:

1. Fatigue after slight exertion is often the earliest symptom noticed by the patient, and is a valuable sign if noticed in connection with other suspicious symptoms.

2. Temporary aphasia is by no means uncommon as an early sign, but it must be understood that transient attacks of aphasia without apparent cause are not always followed by general paralysis. Closely related to this sign is a change in the handwriting; some patients alter their mode of holding the pen or cease writing altogether a year or more before the disease is distinct.

3. Sudden and slight attacks of loss of power or sensation, causing a man to drop whatever he may have in his hand are frequent.

4. Neuralgia, headache, and rheumatic pains almost invariably occur a year or more before the disease declares itself.

5. Changes of temper and character are probably the

most constant of all the changes which are noticed early in the disease.

The paper concludes with the advice that in a patient with a history of syphilis or of injury to the brain, do not neglect early fatigue, fainting or other fits, loss of smell, vague optic disk changes, unusual headaches, neuralgia and sciatica, and change of character.

General Treatment of Bright's Disease.—In the treatment of Bright's disease SENATOR advises the patient to seek a dry and equable climate, and to live almost exclusively upon a milk diet. Small amounts of white meats may be taken, but no red meats. Such vegetable food as herbs, cereals, and fruits are permissible, but it is important to avoid spices. Wines diluted one-half with water may occasionally be taken.

BAMBERGER insists on an exclusive milk diet, and uses the following ferruginous pills:

℞.—Chloride of iron . . . 3 grains.
Extract of taraxacum, sufficient quantity.—M.

One such pill to be taken three times daily.

Or,

℞.—Sulphate of iron
Bicarbonate of sodium } of each 75 grains.—M.
Extract of taraxacum

Make into sixty pills, of which three should be taken in the morning and three at night.

SEMMOLA also insists on a diet of milk, and gives the following mixture:

℞.—Iodide of potassium . . 15 grains.
Phosphate of sodium . . 30 "
Chloride of sodium . . 1 drachm.
Water . . . . 3 ounces.—M.

To be taken in twenty-four hours.—*L'Abeille Médicale*, March 31, 1890.

Sodium Salicylate for Biliary Colic.—PROFESSOR STILLER, of Buda-Pesth (*Wiener medizinische Blätter*), calls attention to the remarkable cholagogue effects of sodium salicylate and suggests that on this property its efficiency in rheumatism may depend. For five years Stiller has used the drug to assist in the expulsion of gall-stones and with most excellent results, not only in securing the primary object of treatment, but in quickly relieving the accompanying pain. He believes that the salicylate increases the quantity and decreases the consistence of the bile, the slowly increasing pressure dilating the ducts.—*Provincial Medical Journal*, April 1, 1890.

Dangers of Catheterization in Retention of Urine.—DR. ASSMUTH (*St. Petersburger medicinische Wochenschrift*) calls attention to the dangers of catheterization in certain forms of retention. The dictum that in old persons with overfilled bladders catheterization should not be resorted to, as a rule, is laid down, and still more imperatively should this be insisted upon where the tension upon the bladder has occurred gradually, perhaps occupying years in reaching this condition. The author's experience, as shown by cases occurring in his own practice, convinces him of the disadvantages of the use of the catheter under these circumstances. Suddenly produced changes of intra-vesical pressure bring about a disastrous issue through rapid urinary resorption. He advises that catheterization be employed only when acute retention supervenes; otherwise the interference should be restricted to the occasional introduction into the bladder of a full-sized metallic sound. This procedure proves useful in retention depending upon different causes, such as prostatic hypertrophy, paraplegia, etc. Patients learn, in the course of time, to urinate voluntarily, the urine approaches its normal condition, and the irritability of the viscus is markedly lessened. Only after a long persistence of the treatment by the sound, and further treatment being deemed necessary, should the catheter come into play; and even then the urine should not be fully evacuated until after many sittings, at the same time partially replacing the withdrawn urine by means of fluid.—*Annals of Surgery*, April, 1890.

Salol in the Treatment of Gonorrhœa.—For some time MR. J. ERNEST LANE (*Lancet*, March 22, 1890) has been testing the value of salol in all stages of gonorrhœa, in some cases relying solely upon its use, in others employing an astringent injection in addition. An analysis of the fifty cases treated shows that six were cured, twenty-four showed considerable improvement, in fifteen cases no change either for better or worse was noticed, while in five cases the symptoms were aggravated. The doses used were from five up to thirty grains, taken three times daily. The beneficial effects of salol manifest themselves in a very short time. When improvement takes place the symptoms show an abatement in from two to seven days; in acute cases the painful micturition is soon alleviated; in cases of a more chronic nature the discharge is materially lessened. In ten cases injections were employed in conjunction with salol; but he subsequently increased the dose of salol to ten, twenty, and in a few cases to thirty grains, and relied upon its internal administration without the assistance of injections. Out of forty cases so treated, an improvement was noticed in twenty within a week, while six were completely cured. Four hours after administration by the mouth of twenty grains of salol traces of carbolic and distinct evidence of salicylic acids, combined with other elements, were found in the urine. In one case the urine was blackened as in carboluria, the patient at that time taking thirty grains three times a day. It is said to be by the action of the pancreatic juice that salol is split up into carbolic and salicylic acids; of this change he was unable to procure any evidence, after having added pancreatin to a mixture of salol. In salol we have, in his opinion, a drug of considerable value in the treatment of gonorrhœa; its effect is apparently produced by the action of the urine upon the inflamed urethra, since that fluid contains salicylic and carbolic acids in combination, probably as salicylurates and sulphocarbolates. It may be given in doses of from ten to twenty grains three times daily at any stage of the disease, and in chronic cases an astringent injection will materially hasten the cure. The effect of the drug does not appear to be enhanced by larger doses than twenty grains; when the amount was increased to thirty grains, the urine became blackened and the symptoms did not show any proportionate improvement. He commenced by giving five-grain doses, but this was soon discovered to be too small a quantity.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to The Medical News will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author.

Address the Editor: H. A. HARE, M.D.,
1004 Walnut Street,
Philadelphia.

Subscription Price, including Postage.

Per Annum, in Advance . . . . . $4.00.
Single Copies . . . . . 10 cents.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 Sansom Street,
Philadelphia.

SATURDAY, APRIL 26, 1890.

THE TREATMENT OF DISEASES OF THE UTERINE APPENDAGES.

The universal law that action and reaction are equal finds frequent illustration in the swinging of the pendulum of medical opinion; active interference with and the removal of various organs of the human body are often followed by the establishment of some conservative method of treatment for the diseases of the organs in question. The zeal for laparotomy and extirpation of the uterine appendages has already passed its highest point, and is giving place to a less radical and more rational belief. The absurdity of invariably opening the abdomen has frequently been demonstrated by fruitless operations and by extraordinary mistakes in diagnosis.

Thus, a patient was very recently admitted to one of our hospitals with a history that while in early pregnancy the abdomen had been opened for the removal of a tumor; this tumor she now had with her, aged ten months, healthy and well developed, it being nothing less than the child which accompanied her. Fortunately, no harm was done by the laparotomy, and pregnancy was not interrupted; but certainly a more conservative method would in time have relieved the patient more safely and agreeably of her tumor.

A further illustration of excessive zeal resulting in imperfect and crude diagnosis is found in the case of a woman in whom double pyosalpinx was diagnosed by a laparotomist, and the fearful dangers to which the woman was exposed by reason of this condition were graphically portrayed. Falling into the hands of the hospital physicians to whom she was assigned, an examination of the patient revealed the fact that she was syphilitic, and that the pelvic tissues were infiltrated by syphilitic deposits; the patient was kept clean, put to bed, and treated by antisyphilitic medication, with the result of causing the alleged pyosalpinx to disappear. This case may represent some of the absurdities of the belief that laparotomy is the only reliable diagnostic means in disease of the uterine appendages.

An article by Tripier (*Bulletin Général de Thérapeutique*, March 30, 1890) describes a recent manual of gynecology by a French author, in which the anatomical description, the pathology, and operative procedures were most admirable, but in marked contrast with the therapeutics, which displayed a most lamentable paucity. After reviewing the various theories as to the origin of pelvic diseases in woman, Tripier describes his own success in the electrical treatment of congestions, inflammations, neuralgias, and defective development in the pelvic organs. His views represent those of a considerable number of gynecologists who are quite convinced that laparotomy and extirpation are not the panacea which they have been alleged to be, and that general and special therapeutics must be applied to the successful treatment of these cases, although it is true that electricians have undoubtedly been extravagant in their claims for success. It is an open question whether fibroid tumors of the uterus can be dissipated by electricity; that hæmorrhage from such tumors can be checked by the positive pole of an electric current is undoubted, and that pain can be relieved and the growth of such tumors often checked seem also true; but the danger of suppuration which not infrequently follows the attempt to dissipate uterine fibroids is so great as to throw doubt upon the value of this method. It does not seem rational to suppose for a moment that ovarian or tubal abscesses can be cured by electricity, especially when such abscesses follow specific infection, but that a simple salpingitis, or possibly hydrosalpinx, can be cured by this means there seems reason to believe, while chronic congestion about the uterus, defective uterine involution, pain referred to the pelvic organs, failure of proper development,

and exudates, the result of former inflammation, can undoubtedly be greatly benefited and in many cases cured by general therapeutics directed to the patient's general condition, and by electricity, douches, alterative applications, tampons, and the judicious employment of pessaries.

The somewhat remarkable statement that "the laparotomy craze is about over," was recently ascribed to a most radical laparotomist; but if such be the case, it is certainly a most hopeful condition of affairs. The fact that the statement was accompanied by the organization of a scheme for more extensive advertising to secure laparotomies from abroad gives credence to the belief that men of good judgment have ceased to be led away by the operative furor, and are recognizing the fact that it is the duty of every physician to give his patient the benefit of a careful study of her case, and the application of the science of therapeutics, with its potent resources, before recourse is had to the brilliant, but somewhat uncertain and often dangerous, methods of treatment by surgical interference.

"A WOLF IN SHEEP'S CLOTHING" AGAIN.

SOME months since we took occasion to criticise the business methods of a firm of opticians in this city who, for a number of years, have held an enviable position in regard to their relations to the medical profession.

Not content with having issued a circular in the early winter months, which was distinctly adverse to the welfare of the medical profession and themselves, they have but recently sent out "A Card to Physicians," in which they virtually offer to provide a thorough course of ophthalmology to any physician who may so distrust his fellows in the profession as not to be willing to receive their instruction, preferring that of the money-seeking optician.

While business push should always be coupled with business foresight, the medical profession of this city cannot but be amused at the methods to which certain persons are apparently forced to resort for the development of trade.

Perhaps before long they will provide hospital accommodations and courses in operative methods, unless they regard glasses as a universal panacea. If this same form of mental aberration extends to other trades connected with the medical profession, we may expect to have a truss-maker's school of herniotomy, or a gynecological clinic for teaching the proper fixation of pessaries or the employment of vaginal specula.

ELECTRICAL EXECUTION.

WE publish below an interesting letter from PROFESSOR J. WILLIAM WHITE on electrical executions. The fact that he has for so many years had ample opportunity to study the criminal classes renders his opinions worthy of careful attention. Execution of the death penalty by means of electricity is at present becoming more and more looked upon as the proper method of punishing the crime of murder, and this contribution will do much toward increasing the confidence in the propriety of the new method.

CORRESPONDENCE.

ELECTRICAL EXECUTION.

To the Editor of THE MEDICAL NEWS,

SIR: In reply to your polite request for my views in regard to the policy and method of the approaching execution under the present New York law governing capital punishment, substituting electricity for hanging, I send you a sketch of the line of argument which seems to me and to others who are for one reason or another interested in the criminal classes, to justify the present most important attempt to improve our methods.

In his essay on "Murder, Considered as One of the Fine Arts," De Quincey quotes the following sentence from Lactantius, named by St. Jerome "the Christian Cicero," famous at once for his piety and his polished eloquence: "If merely to be present at a murder fastens on a man the character of an accomplice; if barely to be a spectator involves us at once in one common guilt with the perpetrator, it follows of necessity that in these murders of the amphitheatre, the hand which inflicts the fatal blow is not more deeply imbued in blood than his who sits and looks on." Although he wrote of the gladiatorial contests of the courts of Diocletian and Constantine, and of the custom of giving criminals a mock chance for their lives while really dooming them to a barbarous and bloody death in the arena, his words apply with equal force to the highly civilized communities who have almost within the century witnessed the enforcement of inhuman and revolting death penalties with indifference or approbation. If those who sat idly on the benches at Rome or Byzantium were not guiltless of the crimes they saw enacted, were sharers in the guilt of unnecessary cruelty and barbarity, none the less are the intelligent and law-abiding peoples of the world to-day participants in whatever of injustice or inhumanity is enacted under the guise of law. The Anglo-Saxon race, in this country and the empire of Great Britain, is annually removing from its midst, extirpating, putting out of the world under the forms of law, several hundreds—possibly thousands—of its individual members. Admitting that it is justified in doing so by the necessity of establishing and upholding the public safety and welfare,

is the manner in which this public duty is performed all that could be desired from the standpoint of ordinary humanity? This question, which should be considered without sentimentalism, involves the determination of the most desirable (or least objectionable) form of execution, a subject which has of late years been of increasing interest to the intelligent public, and which, as time goes on, gains rather than loses in both practical importance and moral and humanitarian significance.

The rational discussion of the methods of capital punishment is, however, inseparable from a consideration of the objects of that punishment, as it is a case in which the end must justify the means. It is, perhaps, safe to say that from the time, not yet one hundred years ago, when, in such highly civilized countries as France and England, there were respectively one hundred and fifteen and one hundred and sixty offences punishable by death, down to the present day, the object of the death penalty in the eyes of legislators and lawgivers has been twofold: First, to protect society from the ravages of particular individuals, and, second, through them, to exercise a deterrent influence upon others of their class. Now, although the increased appreciation of the value and sanctity of human life prevents us from putting to death persons guilty of "heretical preaching" or of "carrying more gold or silver out of the country than is necessary for the voyage," or of "printing, selling, or circulating books without permission granted," offences still extant among us, the object of judicial executions remains the same and does not now, as it did not then, theoretically, include the idea of revenge. The most earnest advocate of capital punishment would probably be satisfied with the death of the individual in as speedy and painless a manner as possible if it were not for the thought of the second object aimed at—the deterrent influence upon the crime class.

The description which Sir Walter Scott gives in "The Heart of Midlothian" of the methods of execution in Edinburgh, recalls to the readers of *Waverley* the fact that until the beginning of the present century the criminals who were executed in Edinburgh were hanged in public at the eastern end of the Grass-market, to which place they were walked through public streets dressed in the shrouds in which they were to be buried, and were finally made to ascend a ladder to a considerable height to reach the platform on which the execution took place. Scott says, "This mode of execution is now (1830) exchanged for one similar to that in front of Newgate—with what beneficial effect is uncertain. The mental suffering of the convict is indeed shortened. He no longer stalks between the attendant clergymen, dressed in his grave-clothes, through a considerable part of the city, looking like a moving and walking corpse, while yet an inhabitant of this world; but as the ultimate purpose of punishment has in view the prevention of crimes, it may at least be doubted whether in abridging the melancholy ceremony, we have not in part diminished that appalling effect upon the spectators which is the useful end of all such inflictions, and in consideration of which alone, unless in very particular cases, capital sentences can be altogether justified."

It is probable, however, that this influence is more imaginary than real. In so far as it is supposed to affect the sensibilities of the habitual criminal, or arouse him to a realization of the enormity of his deeds, or awaken within him the feeling of remorse, I am convinced that it is a total failure. In 1875, when physician to the Eastern State Penitentiary of Pennsylvania, I endeavored to secure evidence in this direction by recording conversations which I held with some of the inmates convicted of the gravest crimes, in reference to their motives in committing those crimes and to their subsequent feelings.

Almost without exception the tone of their replies was unrepentant, or even jocular; so that, for example, a man who had knocked down his unoffending wife and kicked her in the stomach until she died, could laugh in talking about it, and say he "guessed she was better off." Within a few days I have repeated this experience in a number of instances. One example of many must suffice.

A man undergoing a heavy sentence for a murder of unexampled atrocity, surrounded by the most shocking circumstances, was asked if the thought of the crime never troubled him. I found that he never thinks of it at all, except when he takes his bath; then he sees the scar of a wound made by an accomplice, with whom he said he was determined to "get even" when he goes out, many years hence. An educated Englishman, who, for some commercial crime, served his time in Newgate, Millbank, and Dartmouth, and who has recorded his experience in an instructive work called *Five Years' Penal Servitude*, says of some of his fellow-convicts that they were "brutes in mind and demons in heart—irreclaimable, and not at all amenable to any ordinary moral influence. As a rule, they are as cowardly as they are brutal, their criminal instincts and propensities predominating to the almost total exclusion of any intellectual or human feeling." No one was more familiar with this fact and this class of criminals (found in larger proportions, it is said, among the roughs of London than elsewhere in the civilized world) than was Dickens, and in his last book—*Edwin Drood*—he calls attention to "the criminal intellect which its own professed students perpetually misread, because they persist in trying to reconcile it with the average intellect of average men, instead of identifying it as a horrible wonder apart."

Any one unfamiliar with the criminal character who doubts this frequent and truly remarkable absence of remorse, will probably be convinced by reading carefully the records of great prisons, or lives of great malefactors,[1] and will, I am sure, if they read understandingly, be convinced as to the absence of the moral sense in many criminals in whom, as Dr. Oliver Wendell Holmes has said in an article on "Crime and Automatism," "Nothing stands in the way of the selfish motive which leads to crime, except some stronger selfish motive."

[1] To those who may be inclined to take an interest in the general subject of the peculiarities of the crime class, I must recommend a perusal of the following works as introductory to the question, and as most interesting in themselves: Old Bailey Experience; Chronicles of Newgate; Lives of Celebrated Criminals; Crime, by Frederick Hill; Inspectors of Prisons. The Reports of the Eastern Penitentiary, written chiefly by my distinguished townsman, Hon. Richard Vaux, contain a mine of information upon the same subject. I should also include the work recently published by Inspector Byrnes, of New York, on the professional criminals of this country.

Julian Hawthorne has cleverly described the same peculiarity of habitual criminals (doubtless communicated to him by Mr. Byrnes) through the conversation of an imaginary journalist in one of his recent novels.

Col. Sir Edmund Du Cane, Inspector General of Prisons of Great Britain, records (*The Punishment and Prevention of Crime*) a quotation from an intercepted letter from a convict in Western Australia (where there is a law making a murderous assault on a warden a capital offence) to a friend at home: "They top [hang] a cove out here for slogging a bloke. That bit of rope, dear Jack, is a great check on a man's temper." That graphically indicates about the maximum deterrent influence of any form of execution.

The members of the crime class calculate shrewdly the chances of conviction and punishment; feeling little or no remorse, their only fear is of the law, and they are quite clever enough to know that in proportion to the horrible or revolting character of a death penalty the difficulty of a conviction under a jury system increases. Through my connection with the Eastern Penitentiary as physician, in 1874, 1875, 1876, and of late years as Inspector, I have known, or known of, many of the worst criminals of America, and I feel sure that if they and their associates could be polled they would vote for hanging in preference to any more humane method of execution, as they would for drawing, quartering, and disembowelling in preference to hanging. Punishment is effective with them as a deterrent influence in proportion to its certainty—not to its severity. Hazlitt, who for controversial purposes, questioned the truth of this maxim, practically admitted it later when he wrote: "When a moderate punishment is strictly and vigorously enforced, and a severe punishment is as generally and systematically evaded, the mind will undoubtedly be more affected by what it considers as a serious reality than by what it will regard as an idle threat." Unnecessary brutality as to the form of execution is in its effect upon juries or upon those entrusted with the exercise of the pardoning power precisely similar to unnecessary severity in the apportionment of the punishment to the crime. The Mikado's song expresses a principle of criminal jurisprudence which cannot be ignored without defeat of the very object of the law. The inherent sense of justice and right prevailing in all large communities will not permit them, when, as in modern times, they have power and freedom, to acquiesce in the workings of an inhuman statute. In the reign of Henry VIII. it is said 72,000 persons, or 2000 *per annum*, were executed. In England, from 1813 to 1833, 23,700 persons were convicted of capital crimes, of which number 933, or only about 1 in 25 were executed. Nothing could be more evil in its effect upon the crime class than the existence and practical nullification of such laws. Their glaring injustice doubtless led Dr. Benjamin Rush, in a memorial written in 1792, to protest against "the killing of one kind of murderer, while allowing the escape of quack doctors and a licentious press, who often destroy life and frequently with malice of a most prepense nature." A half century later Mr. Sharswood asserted that, on account of the death penalty and of its manner of execution, 'no crime was so likely to escape with impunity in Pennsylvania' as that of deliberate and wilful murder."

The New York Commission to Investigate and Report the Most Humane and Practical Method of Carrying into Effect the Sentence of Death in Capital Cases, in its report published some time since, expressed the following views on these points:

(1) That the effort to diminish the increase of crime by the indiscriminate application of capital punishment to various offences, involving different grades of moral turpitude, or, in other words, by the enlarging of the number of offences to which capital punishment is made applicable, has proved a failure.

(2) That any undue or peculiar severity in the mode of inflicting the death penalty neither operates to lessen the occurrence of the offence, nor to produce a deterrent effect.

If the above premises are sound, and if in addition those who believe in capital punishment recognize the policy of not needlessly furnishing arguments either to humanitarian agitators of the question or to the counsel for defendants in murder cases, the discussion of the preferable method of execution can be approached with the well-defined idea that the object aimed at is an instantaneous death without pain and without the possibility of shocking or repulsive circumstances of any description. The conclusions of the Commission quoted above will afford an excellent basis for the consideration of this part of the subject. They were as follows:

(1) That the present method of inflicting the death penalty be abolished, and, as a substitute, that a current of electricity, of sufficient intensity to destroy life instantaneously, be passed through the body of the convict.

(2) That every such execution take place in a State prison, to be designated by the court in its judgment and death warrant, and that the time of the execution be not fixed by the court, except by designating a period within which it must take place.

(3) That immediately after the execution a post-mortem examination of the body be made by the physicians present, and the remains be handed over to the medical profession for further dissection, or be buried without ceremony in the prison cemetery or graveyard, with sufficient quicklime to insure their immediate consumption.

(4) That the public accounts of the execution be limited as regards to details.

These admirable suggestions will appeal the more strongly to both reason and sentiment after a brief consideration of the physiology of hanging.

The principal modes of death by hanging as shown by autopsies are: 1st. Suffocation from pressure on the windpipe producing complete obstruction to respiration; 2d. Dislocation or fracture of the spinal column with consequent injury to the spinal cord. 3d. Congestion of the heart or apoplexy from the arrest of the return of blood from the head to the heart, the result of compression of the great bloodvessels of the neck. 4th. Injury inflicted by violent and prolonged pressure on the important nerves of the neck. The proportion in which these results follow hanging are variously estimated, but, as a rule, the conditions are more or less mixed. The amount of pain and distress excited by them must also vary considerably, but is probably inversely proportionate to the completeness and severity of the injury. Total obstruction of respiration, complete dislocations or fractures of the neck, extensive apoplexies doubtless cause painless and rapid death, but if the rope is above or upon

instead of below the larynx (as in suicidal hanging it was found to be in 140 out of 143 cases) suffocation is probably slow, and attended with the preliminary agony of a hopeless and helpless struggle for life. After asphyxia has begun the testimony is unvarying as to its painless character. Such testimony, of course, consists of the evidence of persons who have been resuscitated after apparent death from suffocation. The celebrated case of Hornshaw, who gave public exhibitions of so-called "hanging" in London, suspending himself by the neck, is in point. He became unconscious on three occasions, and was with difficulty resuscitated. On the last occasion, he says that, although he very soon lost his senses, he passed through a period during which he felt as if some great weight was attached to his feet, and he had the desire without the ability to take a breath—surely one of the most distressing sensations of which human beings are capable. Numerous similar descriptions are found in the records of unsuccessful hangings dating back as far as 1705, when one Smith, who was resuscitated, used almost the same expressions in recounting his experience. Captain Marryatt, the novelist, who was one resuscitated after apparent death from drowning, describes his feelings as rather pleasant, speaking of the sensation as similar to that of lying down in a green field, with the grass waving, the sun shining, etc.

It is usually assumed, I think, that if total and immediate obstruction to breathing could be assured in every case, hanging would be a reasonably humane method of execution. After all, however, this is mere conjecture. Our evidence upon the point is naturally limited, and when we further assert that the writhings and convulsions, which sometimes last for many minutes, during which time the heart continues to beat, and resuscitation is often possible, are merely reflex, and are not attended with sensation, our assertion, even if probably true, is not demonstrably so. The questions propounded by a writer in the *North American Review* are difficult to answer: "Who knows the last agony of the death struggle? Who knows its real duration in the opinion of him who is the last judge? Who can understand strangulation? Who knows through what a universe of misery flashes or struggles the soul of the sufferer?"

A further difficulty in approving this form of execution lies in the circumstances practically surrounding the operation as performed at this day in all parts of the United States and Great Britain; the clumsiness or nervousness of the officials, the occasional struggles of the condemned, the imperfections of the apparatus, etc. As the same writer has put it: "Some people are much better hanged than others. There must be as much difference between good and bad hanging as between entirely distinct ways of inflicting the death penalty." It is highly probable that in the majority of cases comparatively slow and painful suffocation occurs from a combination of these factors. As to the other causes of death the same remarks apply even more forcibly. Dislocation of the neck was found by Devergie only once in 52 cases, and Taylor says that to secure it the body must be heavy, the fall sudden and long, and considerable violence used by the executioner—*i. e.*, by giving the body of the criminal a violent twist or rotatory movement the moment it is turned off. Apoplexy occurred only 9 times in 85 cases, and death by injury to the nerves of the neck—a rare circumstance, fortunately—must be exceptionally painful. We probably hear the whole truth in relation to comparatively few of the bungled and mismanaged hangings, attended with the greatest agony, and most disgusting in their details, as the information would naturally be suppressed by those chiefly concerned, and who may have been actuated by a proper spirit, but ignorant of proper methods. Certainly, although we have improved upon the executions of our forefathers, when hanging was originally only a means of deadening sensation preparatory to drawing, quartering, burning with hot irons, etc., and when criminals on the way to the scaffold were exposed for hours to the hoots and peltings of a merciless mob, we still have much to hope for in the way of improvement. When guillotining was made the law of France in 1792 by the act of the Assembly, who, in adopting the celebrated law *Tout condamné a mort aura la tête tranchée*, provided that the cutting off should be by means of a "simple mechanism," it was regarded as a humanitarian step, and was indeed a vast improvement upon the decapitation by means of an axe in the hands of an ignorant, often a drunken or crazy, executioner.

The gallows of those days, both in France and England, a rude structure beneath which the condemned was driven in a cart, which, after the adjustment of the noose was driven away, was surely far behind the guillotine in effectiveness and neatness of action. The famous Louis, perpetual secretary of the Academy of Surgery, and one of the great scientists of the day, approved of the latter and suggested many of its details. It carries with it, however, the revolting element of dismemberment and deformity, and is further complicated by the doubt, as old as the century and originally suggested in 1793 by Sömmering the anatomist, as to whether the severed head may not for a short period retain consciousness and intelligence. The mere suggestion is enough! The question was thought to have been decided in the negative, but has been re-awakened by recent scientific experiments upon decapitated animals and upon criminals. Charcot presented, a few months ago, to the French Academy a record of observations upon the head of a criminal who had been decapitated. The criminal did not blanch (as is naturally usual) when placed in position, and the color of the face retained its life-like appearance for at least a minute. For five seconds a touch of the end of a finger to the globe of the eye brought about a quick closing of the lids. The jaws were firmly closed and could not be opened even by energetic efforts. Brown-Séquard had shown some time ago that by injecting fresh blood into the severed heads of dogs the muscles reacted, the eyes moved, and evidences of sensation were present. Last April similar experiments were made upon the head of the murderer Gamahut, a French criminal who suffered decapitation for his crime. Under the influence of transfused blood the face regained its color, the eyelids opened, and the lips quivered and seemed to be trying to speak. The account reminds one of the picture in the Musée Wiertz in Brussels—"*Pensées et visions d'une Tête coupée*," which, together with the other horrors of that curious collection, leaves an indelible remembrance.

In the face of the evidence as to continuance of sen-

sibility, though it is far from conclusive, and though the general probability points strongly in the other direction, and in view of the other objections which have been mentioned, guillotining hardly seems the most desirable method of capital punishment.

Garroting, as employed in Spain, is as uncertain as hanging, and even more unpleasant in its details. It is intended to consist of a combination of strangling and fracture or dislocation of the spine, but is clumsy and unreliable. The use of poison by the mouth would often involve a shocking struggle with the prisoner; by hypodermic injection would convert the executioner into a veritable Jack Ketch, who would doubtless feel himself almost as much a murderer as the condemned. Certainly the function would be revolting and almost impossible to a man of intelligence or refinement.[1] Shooting is open to the same objection, *i. e.*, the need of direct personal intervention.

The testimony as to the instantaneous character of deaths from lightning-stroke and, of recent years, from contact with the wires of powerful batteries used for industrial purposes, has led many to believe that in this direction we must look for a satisfactory solution of the problem.

At a meeting of the French Academy of Sciences held last spring a report was made upon some recent studies as to the mode of death by electricity, and it was shown that when the circumstances were favorable—*i. e.*, when the current was sufficiently strong and the resistance to its passage the greatest—death occurred through actual disintegration of the blood, as well as of the nerves and muscular tissue.

The details could most readily be suggested or arranged by electrical experts.[2]

The proceeding could be conducted with the minimum of uncertainty, and the person giving the final touch which completed the connection could do so from a considerable distance, and need not necessarily have seen the prisoner. I believe this is not unimportant, as I feel sure from a single experience that no one of ordinary sensibility can even look upon the most carefully conducted execution under our present laws without either great disturbance of feeling or positive brutalizing results. This must be vastly increased with those who have the unpleasant duty of actually carrying the method into effect.

If, in addition to a change in the mode of execution, there could be added modifications in the law, shortening the time after sentence to which by the efforts of ingenious counsel life could be prolonged, and if, during that time, the prisoner was absolutely sequestrated—was already dead to the external world—we might avoid the exhibitions of hysterical and irrational sympathy, and of mock or maudlin repentance, which are now so common. Then, too, it would be true mercy to the criminal to shorten that time, the horrible tediousness of which with the agonizing changes from hope to despair, and then to hope again, have been so vividly depicted by Victor Hugo in the *Dernier Jour d'un Condamné*, and which must be a thousandfold worse and more unendurable than the physical suffering of even the most inhuman execution.

It is earnestly to be hoped that the technical difficulties which surround the present effort to introduce an improved and scientific method of capital punishment may not be found insurmountable.

Very respectfully,

J. William White, M.D.

NEW ORLEANS.

To the Editor of The Medical News,

Sir: At the recent commencement exercises of Tulane University there were 93 graduates in the medical department; the class that attended the past session being the largest in the history of the medical college, numbering 373 students, principally from the Southern States.

It is a matter of surprise that this excellent institution, that for forty-six years has enjoyed deserved reputation in the South, and that still retains high lecture fees, has not yet instituted a three-years' graded course of medical instruction, and has not enlarged its faculty beyond the old-time number of seven professors. While the faculty recommend a three-years' course, and many students take it, the instruction is not graded. In 1889, a microscopical laboratory was opened, but it proved at once to be inadequate for the class in attendance. It is understood that the faculty have under consideration the importance of enlarging the present laboratory; of opening

[1] The New York Commission in the report above quoted makes the following just criticism of the method by poison: "Various suggestions have been made as to the means of accomplishing such a result. One has been the injection of a violent and sudden poison, such as prussic acid, by means of the hypodermic needle, into the body of the condemned, which is open to the very serious objection that the use of that instrument is so associated with the practice of medicine and as a legitimate means of alleviating human suffering, that it is hardly deemed advisable to urge its application for the purposes of legal executions against the almost unanimous protest of the medical profession."

[2] The Report of the New York Commission as to these points reads as follows: The most certain way to produce death would be to pass the current down the spinal cord from the crown of the head, as by the sudden application of wet surfaces or sponges. The result would be, with a sufficiently strong current of the proper character, a painless extinction of all the faculties; and the current being kept on for a little time, would result in such complete nervous exhaustion as to forbid any possibility of resuscitation by any means whatever. The best appliance in this direction is the one which will perform its work in the shortest space of time and inflict the least amount of suffering upon its victim. This can be accomplished by the use of electricity, and the most suitable apparatus for the purpose is that class of dynamo-electric machinery which employs intermittent currents.

The most effective of these are known as "alternating machines." The passage of the current from these machines through the human body, even by the slightest contact, produces instantaneous death.

That the ordinary electric light current used in these experiments is sufficient to cause instantaneous death of a human being is inferred from the many accidental deaths produced by such means. To witness the effect produced upon the heart in action is a demonstration which cannot be questioned, and offers a positive proof that death produced by a sufficiently powerful electric current is the most rapid and humane produced by any agent at our command; that resuscitation, after the passage of such a current through the body and functional centres of the brain is impossible; that the apparatus to be used should be arranged to permit the current to pass through the centres of function and intelligence in the brain.

a physiological and pharmacological laboratory; and, possibly, of making a three-year graded course compulsory and increasing the membership of the faculty. This would make the institution second to none. It has no competitor in this city, and the material at Charity Hospital is for its exclusive use.

This latter institution, supported largely in the past by the fees received from the notorious lottery company, treated, during the year 1889, 6445 patients; of whom about two-thirds were white. Notwithstanding the fact that all classes of diseases—those of the tropic as well as of temperate zones—were treated, the mortality was only fourteen per cent., and this would be reduced to eleven per cent. if cases that were fatal within the first twenty-four hours were not included. In the outdoor department, 13,938 patients were treated with an average of six visits each.

There are some peculiar features in the administration of the institution. The internes, instead of being graduates in medicine, are undergraduates; it being alleged that if graduates—that are disqualified for the position because they have the degree of M.D.—were employed, they might leave the hospital for outside practice in the event of an epidemic of yellow fever. The internes are called resident students, are appointed by competitive examination, and may, on passing another examination, be re-appointed for a second year's service.

While ostensibly the nursing is done by Sisters of Charity, actually it is largely performed by recovered patients, who often do this service for months with no remuneration save lodging and food. While, from an economical standpoint, such an arrangement may be satisfactory, it is hardly in the best interests of the patients, and is often a source of annoyance to the staff of visiting physicians and surgeons.

The Polyclinic has just opened its session, which will continue during April and May. It has an excellent faculty of thirteen lecturers, and the attendance is quite large.

The Louisiana State Medical Society will hold its annual meeting at Bâton Rouge on May 13th, but it is feared that the high water will seriously interfere with the attendance at the meeting.

The New Orleans Medical Society has just lost its president, Dr. Davidson, who died at the age of seventy-eight years; having been engaged in active practice for the past fifty-six years. His death was due to pneumonia following influenza.

While the influenza has not been as severe here as it seems to have been in the North, there have been a number of cases.

Dr. Joseph Jones, Surgeon-General of the Confederate Veterans, has addressed a circular to the survivors of the medical corps of the Confederate States Army, requesting data regarding the *personnel* of the corps; obituary notices of deceased members; and titles and copies of all published and unpublished reports relating to hospital work, military surgery, and diseases of armies, camps, hospitals, and prisons. It is his intention to publish the material collected.

The terms of several of the members of the Louisiana Board of Health having ended, the late president, Dr. C. P. Wilkinson, who has carried out Dr. Holt's quarantine policy, retires. He is succeeded by Dr. S. R. Olliphant, who is an able physician, and, as vice-president of the Board during Dr. Holt's administration, is familiar with the best quarantine policy for this State.

The Eye, Ear, Nose, and Throat Free Hospital having treated, during the first four months of its existence, 1542 persons, with 9203 consultations, has concluded that its resources are taxed by persons able to pay, and has called for a conference of the authorities of free dispensaries in the city to devise a means to remedy the abuse. In the future, it will charge a record fee of ten cents for each case.

PARIS.

The Treatment of Sprains. Uræmia. Fatigue as a Predisposing Cause of Infectious Diseases.

To the Editor of The Medical News,

Sir: At one of his recent clinics at the Hospital Broussais, Dr. Paul Reclus spoke on the treatment of sprains. After having reviewed the methods ordinarily employed, he described his method as applied to a sprained ankle. First, an elastic bandage is applied, extending from the toes up to the middle of the leg, with just sufficient pressure to keep it in place; and the patient is told that if the pressure is at all painful he must remove the bandage. If the sprain is not a severe one the patient may be allowed to move about. Morning and night the bandage is removed, and the joint is immersed in warm water the temperature of which is gradually raised to 122° F., or to as high a point as can be borne. In ten or fifteen minutes the foot is removed and dried, and massage is employed about the ankle for the same length of time, after which the bandage is reapplied. According to Dr. Reclus, this is by far the most rapid and satisfactory method that can be employed for the cure of sprains, and in some cases the result is quite remarkable.

Professor Renaut has communicated an interesting paper upon Bright's disease to the Academy of Medicine, in the course of which he gave his views upon the treatment of uræmia. In the prevention of this condition he follows the usual dietetic rules and, in addition, advises the use of dry cups twice daily, and the occasional application of leeches. During the attack efforts must be made to reduce the congestion of the kidneys. This can be best accomplished by venesection followed by the daily application of leeches until the secretion of urine is again properly established. Leeches, Dr. Renaut thinks, are better than scarification or wet cups. The next indication, according to this observer, is to increase the intra-vascular pressure by the administration of large quantities of fluids—milk or water. If the patient will not swallow water freely, eight ounces may be given by the rectum every two or three hours. Not only is the arterial pressure raised in this manner, but the more or less toxic substances which accumulate in the tissues are rendered more soluble. Finally, almost continuous inhalations of oxygen gas are to be used. The oxygen will act on the nervous system and on interstitial tissue changes which take great part in the destruction of the toxines which are retained in the tissues.

Drs. Charrin and Rogers have been studying the influence of fatigue as predisposing to microbic disease. Rats were used in the experiments, and were kept in

constant motion for about seven hours daily in a revolving cage. The microbes employed were the bacillus of anthrax and the bacillus of symptomatic carbuncle. The experiments proved beyond a doubt that the animals worn out by exertion were much more susceptible to these diseases than animals which had not been exerting themselves.

NEWS ITEMS.

Confederate States Army Medical Corps.—The following letter, addressed to the survivors of the Medical Corps of the Confederate Army, has been received:

"The surrender of the Army of Northern Virginia, on April 9th, twenty-five years ago, practically ended the struggle for the independence of the Southern States, and during this quarter of a century death has thinned our ranks, and our Corps can now oppose but a broken line in the great struggle against human suffering, disease, and death. S. B. Moore, Surgeon-General of the Confederate Army, is dead. Surgeons L. Guild, A. J. Foard, J. H. Berrien, J. T. Darby, W. A. Carrington, F. A. Ramsey, Samuel Choppin, R. J. Breckinridge, E. N. Covey, E. S. Gilliard, E. A. Llewellen, A. N. Tally, Paul F. Eve, D. F. Manson, Louis D. Ford, Habersham, James Bolton, and a host of other medical officers of the Confederate States Army are dead.

"The Association of the United Confederate Veterans was formed in New Orleans in 1888 with historical, social, and benevolent objects. Our illustrious Commanding General, John B. Gordon, Governor of Georgia, has ordered the United Confederate Veterans to assemble in Chattanooga, Tenn., on July 2, 1890. It is earnestly hoped that every surviving member of the Medical Corps of the Confederate Army will meet with the United Confederate Veterans on this important occasion, and promote, by his presence and his counsels, the sacred interests of the Association. It is of the greatest importance to the future historian, and also to the honor and welfare of the medical profession in the South, that careful records should be furnished the Surgeon-General of the United Confederate Veterans, embracing the following data:

"1. Name, age, nativity, date of commission in the Confederate States Army, nature and length of the service of each and every member of the Medical Corps of the Confederate States Army.

"2. Obituary notices and records of all deceased members.

"3. The titles and copies of all field and hospital reports.

"4. Titles and copies of all published and unpublished reports relating to military surgery and diseases of armies, camps, hospitals, and prisons.

"The object is the collection, classification, preservation, and final publication of all the documents and facts bearing upon the history and labors of the Medical Corps of the Confederate States Army during the Civil War. Everything which relates to this critical period of our national history which shall illustrate the patriotic, self-sacrificing, and scientific labors of the Medical Corps should be industriously collated, filed, and finally published.

"It is believed that invaluable documents are scattered over the land in the hands of survivors of the War which will form material for correct delineation of the Medical History of the Corps which played so important a part in the great historic drama. Death is daily thinning our ranks, while time is laying its heavy hands upon the heads of those whose hair is already whitening with the advance of years and the burden of care.

"No delay, fellow-comrades, should be suffered in the collection and preservation of these precious documents. This task of collection of all documents, cases, and facts relating to the Medical History of the Confederate Army invites the immediate attention and coöperation of his honored comrades and beloved compatriots throughout the South. Respectfully your obedient servant,

"JOSEPH JONES, M.D.,
"Surgeon-General United Confederate Veterans.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM APRIL 15 TO APRIL 21, 1890.

LA GARDE, LOUIS A., *Captain and Assistant Surgeon.*—Upon surgeon's certificate of disability, on account of sickness, leave of absence for twenty-three days is granted, in extension of leave of absence for seven days, granted him by Order No. 74, Fort Assiniboine, Montana, with permission to apply to the Adjutant-General of the Army for an extension of one month, on surgeon's certificate of disability.—Par. 4, *S. O. 43, Department of Dakota*, April 14, 1890.

By direction of the Secretary of War, PETER J. A. CLEARY, *Major and Surgeon*, is relieved from duty at Fort Wingate, New Mexico, and will report in person to the commanding officer Mount Vernon Barracks, Alabama, for duty at that station, and by letter to the commanding general Division of the Atlantic.—Par. 6, *S. O. 90, A. G. O., Washington*, April 17, 1890.

By direction of the Secretary of War, WASHINGTON MATTHEWS, *Major and Surgeon*, is relieved from duty in the Surgeon-General's Office, this city, and will report in person to the commanding officer Fort Wingate, New Mexico, for duty at that station.—Par. 6, *S. O. 90, A. G. O., Washington*, April 17, 1890.

By direction of the Acting Secretary of War, so much of Par. 2, S. O. 83, A. G. O., April 9, 1890, from this office, as directs the transfer of WILLIAM STEPHENSON, *Captain and Assistant Surgeon*, from Fort Verde, Arizona Territory, to David's Island, New York, is so amended as to substitute the words "Columbus Barracks, Ohio," in place of David's Island.—Par. 1, *S.O. 89, A. G. O., Washington, D. C.*, April 16, 1890.

MIDDLETON, PASSMORE, *Major and Surgeon* (St. Francis Barracks, Florida).—Is hereby granted leave of absence for two months, on surgeon's certificate of disability.—Par. 1, *S. O. 85, Headquarters Division of the Atlantic*, April 12, 1890.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING APRIL 19, 1890.

BEYER, H. G., *Passed Assistant Surgeon.*—Ordered to the U. S. S. "Yantic."

MCCARTY, RUFUS H., *Passed Assistant Surgeon.*—Died April 12, of pneumonia, on the U. S. S. "Yantic," at Key West, Florida.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1007 Walnut Street, Philadelphia.*

DERMOID CYST, COMPLICATED BY A TWISTED PEDICLE AND CONSEQUENT PERITONITIS. OÖPHORECTOMY DURING PREGNANCY FOR HYSTERO-EPILEPSY.

A Clinical Lecture.

BY DANIEL T. NELSON, A.M., M.D.,
PROFESSOR OF CLINICAL GYNECOLOGY IN RUSH MEDICAL COLLEGE, CHICAGO.

GENTLEMEN: I have a specimen to show you of considerable interest, a case of dermoid cyst, which I removed on the last day of November, 1889.

The history of the case is as follows: Mrs. R., puberty at fourteenth year, now fifty-seven years of age. She has carried this tumor for fifty-seven years, for dermoid cysts are born with the patients. She is the mother of two children, one thirty-three years of age, the other twenty-nine, both girls. The first child weighed nine pounds at birth, and the second six pounds. She remained in bed about ten days after each confinement, and nursed both children, which proves that there was no special disturbance during or after her confinements. She has had three attacks of pneumonia, the first attack having occurred before she was married, at which time she was ill five or six months. The second attack occurred in 1864, the patient being ill about a month; the third attack in 1880, when she was in bed ten days. During convalescence from the last attack, while sitting up, she suddenly expectorated three or four ounces of pus, which doubtless came from an abscess which had formed in the lungs as a result of the pneumonia. After this she rapidly recovered. Since these attacks of pneumonia she has had a continuous cough on rising from her bed in the morning and on lying down at night. Whether the cough had anything to do with the final development of this cyst, is a question.

Please notice that the last attack of pneumonia was in 1880. Eight years afterward, June, 1888, she had a slight attack of peritonitis, lasting about three days, and she suffered from soreness for some days after this attack. A second attack of peritonitis occurred in October, 1888. She was then confined to her bed for a week. The third and last attack of peritonitis, which was the most severe of the three, occurred in May, 1889, and was produced by stooping down. She went to bed that night and was obliged to remain there for a month, suffering greatly for some days, and, for a time, her life was despaired of. She was confined to her house two months. During these attacks of peritonitis the bowels were never as much constipated as is usual, and they were readily moved by laxatives.

The woman, I should have said in passing, was well developed, about five feet four inches in height, and weighed 180 pounds. After the last attack of peritonitis she lost in weight. The tumor had been noticed for two or three years, and increased in size very rapidly during the attacks of peritonitis, apparently both from its own enlargement and the enlargement of the abdomen as a result of peritoneal effusion. The effusion gradually subsided, so that when the operation was performed the cyst did not seem to be as large as it had been a month or two before; in other words, the tumor seemed to be decreasing in size. It was found necessary to make an incision (in the median line, of course) ten inches in length. After opening the peritoneum there was very little fluid found in the cavity. The tumor was everywhere completely adherent to the peritoneum, but the adhesions were not strong, and were comparatively easily broken down with the fingers. The intestines and omentum, and everything that was adherent, were broken away from the cyst. So intimately associated were the peritoneal adhesions that at first it seemed almost impossible to remove them, but after it was found that they could be broken down with no difficulty the cyst was easily enucleated from its bed. It had the appearance of an ovarian tumor, white, but, because of the adhesions, not glistening. But on tapping it no fluid passed through the trocar. The trocar was removed, when this greasy or sebaceous material which I now show you began to exude. On making a large enough opening, about a gallon of the material welled out, but no fluid. In ordinary dermoid cysts there is usually a considerable amount of fluid, but in this case, if it had been present, it was taken up by the absorbent vessels after the last attack of peritonitis.

After the tumor was freed from all adhesions, and the sac drawn out of the abdomen, the cause of the three attacks of peritonitis was readily seen. The pedicle was only about the size of an ordinary lead-pencil, and seemed to consist of vessels with a little areolar tissue. The Fallopian tube upon the left side was found, but no ovary. The tube and ovary on the right side were atrophied as after the menopause. I confess that I did not search for the ovary on the left side with extreme carefulness, but I believe that the tumor represented all there was of the left ovary. The pedicle, as you see, was exceedingly small, and an interesting point is that it had been twisted through three complete revolutions. Remember that there were three separate attacks of peritonitis. During each attack there must have been a twist which did not completely obstruct the circulation, but which was sufficient to congest the tumor and set up peritoneal inflammation which, except in the last attack, was of short duration. The third twist seems to have obstructed the circulation to a greater extent. I am not sure that there was any circulation left. You will say, if there was no circulation through the tumor why did it not slough? My answer, and the only explanation I can offer, is, that the inflammatory adhesions had been so intimate through the thousands of minute

vessels connecting the wall of the cyst with all the surrounding viscera, that nourishment was kept up in that way. You know malignant tumors may gather new sources of vascular supply in this way, and fibroid tumors as they grow take on new life from the adhesions. In such cases the ovaries may be removed, but the tumor will not stop growing, receiving its nourishment from the adhesions which have been formed.

Now, I believe, though I cannot demonstrate it, that the last twist was sufficient to obstruct the circulation completely; and that the tumor did not die simply because it received nourishment from the adhesions. If the tumor had died the woman would have died also.

After the removal of the cyst the abdominal cavity was washed out with pure boiled water, and a glass drainage-tube inserted, and the patient made an uninterrupted recovery. Her highest temperature was 100.2°. Unfortunately she had a very troublesome cystitis on account of the frequent use of the catheter. The cystitis, however, passed away, after a short time, under antiseptic treatment.

I should have said that one of the attacks of peritonitis came on after stepping out of a carriage. Perhaps that was the exciting cause. In one other case it was certainly an exciting cause of the twist. When you have a tumor which seems somewhat movable in the abdomen with a sudden attack of peritonitis coming on after some exertion, as stooping, lifting, getting in or out of a carriage, especially if the patient be corpulent, you should suspect a twist of the pedicle, and if the patient's life is not endangered by the peritonitis, there may be no need of an operation in the midst of it. On the other hand, suppose the patient's life is endangered and you expect that she is not likely to live through the peritonitis, do not wait for her to die and make a post-mortem removal of the tumor, but operate in the midst of the attack of peritonitis, and in such cases the sooner you operate the better. Possibly the patient will recover from three attacks, but do not risk another. After the three attacks in this case there was no possibility of the tumor twisting any more, because it was so firmly adherent. This lesson was taught me some years ago by watching a patient in a hospital with an attack of peritonitis and a large abdominal tumor, upon whom we hoped to operate, but we wanted to get rid of the peritonitis before operating. She never rallied. We allowed her to die.

Post-mortem examination showed a sarcoma of the ovary about eight or ten inches in diameter, entirely movable in the abdomen, and with a twisted pedicle. I believe the tumor might have been removed and the patient's life saved if we had dared to operate.

HYSTERO-EPILEPSY—OÖPHORECTOMY DURING PREGNANCY.

The next patient I present to you has a history which has been most remarkable and is extremely interesting. She is apparently in perfect health to day. She first came to the clinic in October, 1888, and her history as given then was as follows: She was twelve years old at puberty, is now twenty-five, and was born in this country. She has been married six years; has had no children and probably no miscarriages. She has received treatment for five out of the six years of her married life, wearing pessaries, and using tampons, wet and dry, all of which seemed to give her but little relief. She has been in the habit of losing consciousness for five to thirty minutes at a time, and is worse toward night. I might say, before reading her further history, that she is suffering from hystero-epilepsy. The epileptic seizures are more frequent and worse just before the menstrual period and last from five to thirty minutes. She does not froth at the mouth. She feels more comfortable after a sleep. Epileptic patients usually tell the same story. She feels better if left alone, and this is also true of most epileptic patients. The various attempts to bring them to consciousness by rubbing them, dashing water on their faces, pouring various remedies down their throats, is not agreeable to them; it makes them feel worse, they say, than if they were allowed to recover consciousness in their own way.

As a result of these epileptic seizures many patients begin to lose their memory after a time, and this was the case with the patient before you. Her bowels were constipated, appetite variable, she took cold easily, she had difficult breathing on exertion, and suffered from cold hands and feet, and she was exceedingly nervous. Menses were irregular before October, 1888. Sometimes three months would pass without menstruation; in one instance a year. She had a leucorrhœal discharge, usually white, but at times yellow in color, constantly for five years. She could not walk easily, and it gave her great pain to be on her feet.

Local examination found this state of affairs in the pelvis: The left ovary was resting upon the broad ligament, and adherent in that position, prolapsed and tender; the right ovary, also tender, was behind the uterus, where it was being irritated by the latter organ. Uterus sensitive. Pressure upon the uterus, and more particularly on the ovaries, made her feel as though she would have a convulsion, consequently the examination was not as thorough as it otherwise would have been. She had been married six years and had never been pregnant so far as she knew, and I supposed was not likely to be. She suffered from attacks of nausea at the time of the first appearance of the menses, and from shooting pains in both thighs, which were worse in stormy weather. This leads us to suppose that she was a victim of rheumatism also. Abdomen, hands, and feet were swollen; micturition was sometimes free, sometimes difficult, and attended with more or less pain. She had had spasms for two years before coming here. During these spasms her limbs were drawn up and she felt a sense of suffocation. They occurred either at night or early in the morning. This was in October, 1888. She had received a variety of treatment during five years without any apparent benefit, and as her memory was gradually failing and the ovaries were tender, adherent, and so much displaced, it seemed to me to be a case in which the removal of the ovaries was the only treatment that was likely to promise any satisfactory results. The operation was therefore done on November 20, 1888. The menses, you remember, had been irregular for some years, occurring, as stated, sometimes at intervals of six weeks, two months, and at other times even longer intervals, the last period having been September 28, 1888. She recovered from the operation satisfactorily and presented herself at the clinic after the opera-

tion very considerably improved. I saw her frequently during the winter of 1888-'89. She occasionally suffered from rheumatism. Of course she did not menstruate.

In the summer of 1889, while I was away, she began to feel very uncomfortable, with nausea and other symptoms. The abdomen gradually enlarged, and it soon became probable that she was pregnant, and as time went on there was no question whatever that she *was* pregnant. On July 31, 1889, she was delivered of a fine baby, which was presented in the clinic, and which she tells me is still alive and doing well.

The ovaries were removed November 20, 1888, and she has had no menstrual period since. I have the specimens of the ovaries and tubes in my possession, and I hope to be able to show them to you at some future time. I think I can prove to you that the ovaries were thoroughly removed, which is corroborated by the subsequent history of the patient. The patient must have been pregnant about a month at the time they were removed. I believe I should do the operation under the same circumstances if a case presented itself to-morrow, though perhaps I should be a little more careful in determining whether pregnancy was present at the time or not The urgent necessity of doing something to prevent the menstrual returns, which were accompanied by the hystero-epileptic seizures, certainly must be acknowledged. I do not think any one will say that other treatment would have been better. If such a case presents itself to you, and the patient has been under skilful treatment for five or six years, as in this case, without any material benefit, it will become your duty to operate. This patient had received treatment of different kinds for five years, and we not unnaturally supposed that she would have been benefited by it in that length of time if it were possible. She would not, I believe, have gone through her pregnancy had the ovaries not been removed and the epileptic seizures stopped. She tells me to-day that since the operation she has had no return of the epileptic seizures. She has, however, about once a month, slight fainting spells, but which are not serious, and she is in far better health, as her appearance shows.

She suffers now from neuralgic or rheumatic pains in the ovarian region, and thinks there is still a tumor, but none can be found. This disturbance will continue for quite a time, but will gradually fade away as the organs atrophy. Undoubtedly there are permanent pathological conditions where the ovaries were, caused by the breaking up of the adhesions, and the cicatricial condition of the parts will give rise to neuralgic pains. Men who have had their limbs broken or dislocated suffer from rheumatic pains in the injured limbs. In other words, the cicatricial or abnormal tissues are the ones most likely to suffer.

While it is an interesting case and one upon which criticism might be made for removing the ovaries, yet when we consider the fact that she was under treatment for five years and was gradually growing worse, I feel that we were justified in removing the ovaries at that time.

I believe the ovaries and tubes were thoroughly removed or she would have menstruated again, and I am satisfied that there is no third ovary left from which she can subsequently become pregnant, or from which she is likely to have trouble. Her future will be a decided gain upon her past. She has been relieved of the hystero-epileptic seizures, but she will be nervous, perhaps for years, because she has a weak and shattered nervous system from which it will take a long time to recover.

The right ovary was five or six times its normal size; the walls of the right tube were thickened, and its fimbriated extremity was closed and had developed into a cyst the size of the diseased ovary and was filled with a serous fluid. The right ovary and diseased tube lay behind the uterus and were constantly teased by the pressure of that organ. The left ovary and tube rested upon and were adherent to the broad ligament. This ovary was two or three times the normal size, and the tube was shortened and thickened and partially adherent to the ovary at its fimbriated extremity.

2400 Indiana Avenue.

NEPHRECTOMY. SARCOMA OF THE JAW. TUBERCULAR ABSCESS. ALVEOLAR SARCOMA.

A Clinical Lecture
delivered at the Hospital of the Jefferson Medical College, February 8, 1890.

By WILLIAM W. KEEN, M.D.,
PROFESSOR OF SURGERY IN THE JEFFERSON MEDICAL COLLEGE.

NEPHRECTOMY.

Gentlemen: I shall, in the first place, occupy a few minutes in showing you a specimen which I removed yesterday. The patient is a young woman, aged twenty-four years, who had undoubtedly for some years a floating kidney. As a result there developed first an intermittent and later a permanent hydronephrosis. This formed a large cystic tumor in the abdomen which was tapped and drained by my friend Dr. Joseph Price. The operation was followed by a urinary fistula. Dr. Price informs me he would have removed the kidney had the condition of the patient warranted it. My attention was recently called to the case by Dr. James C. Wilson, her attending physician. I found a considerable quantity of pus as well as urine discharging through the fistula. In addition there were only from nine to twelve ounces of urine secreted by the healthy kidney (the left), and I decided not to operate until this kidney should be whipped into greater activity. In order to determine whether the ureter of the right kidney was patulous and therefore whether the urine from the bladder all came from the left kidney, I injected milk through the fistula on the right side of the abdomen and a little later drew the urine. I found the urine free from milk and concluded that the right ureter was impervious. As ascertained by Dr. Charles M. Wilson, the urine of the left kidney was free from albumin and sugar, though its percentage of urea was normal, while the discharge from the fistula contained albumin and pus and its percentage of urea was much diminished.

Under suitable treatment the left kidney became more active and her condition improved so much that I operated yesterday. The difficulty, as you can readily understand, was to secure an aseptic operation, in view of the constant discharge of urine and pus from the fistula. Dr. Charles M. Wilson first closed the fistula by his finger. Then the abdominal wall was quickly

cleansed by a 1:500 sublimate solution. Next, I made a vertical incision into the peritoneal cavity very close to the fistulous opening, and as quickly as possible got my thumb and finger in so as to seize the neck of the sac that I might prevent any contamination of the peritoneal cavity by the urine and pus. I then made a short transverse incision and dissected loose the mouth of the sac. As soon as this was ascertained to be free from any adherent intestine it was clamped by a large pair of forceps. Then I readily drew out and removed the kidney and sac which I now show you. The temperature this morning is 99.8° and she has secreted eleven ounces of urine in less than twenty-four hours. Her prospect of recovery is therefore good.

[NOTE.—In one week the stitches were all out. She made an excellent recovery, the other kidney secreting from thirty to forty ounces of urine a day.]

RESULT OF OPERATION FOR TUMOR OF THE BREAST.

I have next to show you the case of amputation of the breast for cancer on which I operated one week ago. I have seen this wound twice. The first time was twenty-four hours after the operation. You will remember that the breast was amputated, but as the tumor was pretty clearly a fibroma and as the axillary glands were not involved, I did not open the axilla. But I did not hesitate to remove the entire breast and tumor, for at her age, forty-two years, I am fearful that any tumor of the breast may undergo malignant degeneration. On Sunday morning I removed the dressing, which was saturated with blood, and took out the rubber drainage-tube. The dressing was again removed on Wednesday and there was scarcely a stain upon it. At that time I removed one-half of the stitches and the horse-hair drain which had been left to favor the escape of the slight serous oozing. The wound is now, as you see, practically healed in one week, and the patient will probably leave the hospital to-day. The temperature has not been over 99° and most of the time it has been normal.

This is the result that I always expect, and if I do not obtain it, I am sure that there has been, on my part, some mistake, either of omission or commission.

SARCOMA OF THE CHEEK AND JAW.

The next case which I bring before you is one which I approach with a great deal of hesitation. The growth involves the whole of the left side of the lower jaw, the cheek, and a large portion of the floor of the mouth. It is growing rapidly, and although it began only some ten weeks ago, has reached a large size. The question in my mind was whether or not any operation should be done. I have put the matter frankly before the patient and he decides in favor of operation. Professor Brinton and Dr. Hearn saw the case with me a few days ago, when all the possibilities were laid before the man and he decided to accept operation. If it were not for his positive decision, I should prefer not to operate.

The dangers of the operation are twofold. The first is hæmorrhage. The tumor goes rather deeply under the jaw and almost certainly involves all of the branches of the carotid artery with the exception of the posterior ones, and we shall, therefore, have abundant hæmorrhage. The jugular vein as well as the carotid artery is probably involved in the growth. And this causes two unfavorable complications. As the operation involves the mouth, the blood will pass into the trachea, obstruct the breathing and so interfere with the operation, and it will also favor the development of pneumonia. In order to avoid this danger, I propose to perform a preliminary tracheotomy and then use the canula of Trendelenburg. This, as you see, is a tracheal tube having around it a little bag of rubber which can be distended by compressing the bulb connected with it. When inflated the rubber bag completely fills the trachea so that no fluid can enter from above. By means of a flexible tube connected with the tracheotomy tube proper the chloroform enters the lungs. The use of such apparatus is a necessity in certain operations about the mouth where much bleeding is inevitable. Some of you saw Professor Annandale, of Edinburgh, operate in this amphitheatre eighteen months ago, using this apparatus in a case of naso-pharyngeal polyp.

Another and greater danger is that the hæmorrhage may prove directly fatal. In a large professional experience it has been my good fortune so far never to lose a patient on the table. The nearest I have come to it was in a case of lumbar nephrectomy for cancer where it was impossible to complete the operation on account of adhesions. The hæmorrhage was abundant and the patient died three hours after the operation. It is not impossible that this patient may die upon the table. Even if the hæmorrhage is not quickly fatal it will be a severe shock to him and be a source of great danger at a later period.

As it will probably be necessary to tie all the branches of the carotid artery—the thyroid, the lingual, the facial, the temporal, the internal maxillary and smaller muscular branches—I propose, in order to avoid the primary hæmorrhage, which not only impedes the operation but also causes immense shock to the patient, to ligate the carotid artery prior to the operation upon the tumor itself.

I have told the man definitely that the chances are that the tumor cannot be removed, that he has a fair chance of dying from the immediate operation as a result of shock and loss of blood, that there is a chance of his dying later from septic trouble, for it is impossible where we have to remove the jaw, a part of the cheek and a part of the mouth, to have an aseptic wound. It cannot be kept so on account of the exposure to the air, the saliva and the food. I have also told the man that after I have removed this as well as I can, it will probably recur and destroy his life. All these possibilities, I have frankly laid before him and still he elects operation. Is it my duty absolutely to decline to operate? This is a grave question, one of those questions which affect a man's moral as well as his professional sense. The conclusion which I reached long ago after a careful consideration of this question is, that if after all the dangers of an operation are faithfully and honestly laid before the patient he elects operation, the surgeon should be willing to give him the one small chance that he has, provided there is a reasonable possibility of his recovery. Suppose even that this case is fatal in an hour, or twenty-four or forty-eight hours, how will that compare with doing nothing? He will have a painless or practically almost painless exit. It will be speedy, and I confess that, so far as I am concerned, had

I such a growth, I should pray for the speediest death that could come to me. I do not expect to do much toward prolonging this patient's life; I may even terminate it more quickly than it would otherwise would be, but I am giving him, at his own positive choice, the only possible chance that he has. I may be unable to complete the operation, but I shall take away all that I can.

While the patient is being brought in I will give you briefly his history.

George B., aged thirty-six years, born in Philadelphia, was admitted to the hospital February 3, 1890. His occupation is that of a boiler-maker. He states that one year ago he had the roots of two decayed teeth extracted leaving a sound one between them. This was on the same side of the jaw (the left) that the growth now occupies. He also noticed a small kernel the size of a Lima bean just beneath the body of the left inferior maxilla, but paid no particular attention to it. Three months ago he was struck with considerable violence just above this kernel by a flying rivet-head. The bruised spot became slightly swollen and red. Two weeks after the injury he consulted a physician and tincture of iodine was applied for a fortnight without improvement. Then the sound tooth above mentioned was extracted with the hope that this would permit the escape of pus. The cheek, however, continued to swell and the gum also became enlarged. Poultices were then applied, and two months after the bruise the swelling was lanced and a small amount of pus and blood discharged. The tumor then somewhat diminished in size, but still remained hard. When admitted five days ago there was a discharge of bloody serum, and when pressed upon pus and blood-clots escaped. The tumor has doubled in size in the past four weeks.

Now that the patient is before us, you see the tumor, which is as large as a fist. I employ chloroform as the anæsthetic in this case, because if we use the Paquelin cautery there will be no danger of fire as would be the case if ether were used.

The man, you will observe, takes chloroform very badly; his pulse is feeble and his color bad, and in face of these new conditions the question again arises whether I should proceed with the operation, which, as I have explained to you, is of a threefold character: tracheotomy, ligation of the carotid, and removal of the growth. I will ask Professor Brinton to examine his condition.

After consultation with Dr. Brinton I am decidedly of the opinion that I should do nothing. I might tie the carotid, which would probably diminish for a time, at least, the rapid growth of the tumor, but his condition is such that I think it unwise to undertake even this part of the operation. Death would be inevitable in a very few minutes.

You can now easily understand, gentlemen, how the judgment of the surgeon must instantly vary with changing conditions, and this case is much more profitable to you as a lesson than if you had seen the operation. I should be very foolish—not only foolish, but I should do wrong if I attempted to do an operation which would absolutely give no chance, but kill the patient on the spot. We never have a right to do that. While I might pray for a speedy death if I had such a disease myself, yet I have no moral right to give this man an euthanasia either by chloroform or by operation. This question arose a few years ago and was widely discussed in the medical and popular magazines for a long time. The almost universal conclusion, in fact so near universal as to make the exceptions prove the rule, was that we have no right in a case of cancer or other at present incurable diseases to set the limits and say "thus far shalt thou live and no farther," and to give one what has been properly called an euthanasia, a happy, easy death. We have no right to destroy life, though we may risk life. We may run great risks to save or to lengthen life, just as a general will run great risks for victory, but we are not justified in going into absolute and certain defeat.

TUBERCULAR ABSCESS.

The next patient that I bring before you is a colored woman, twenty-three years of age. Six months ago, after lifting a heavy weight, she felt pain just above the right breast. The pain continued for one month. She then consulted a physician and topical applications of iodine were advised. Later a hard lump appeared, the pain leaving on its appearance. The lump has gradually increased in size and is now half as large as the fist.

The family history is that the parents and grandparents are healthy, but a sister of the patient died one year ago at the age of twenty-one, of phthisis. This is the only case of consumption in the family so far as we have been able to ascertain.

You see here a soft, fluctuating tumor over the manubrium and under the inner end of the right clavicle. It is painless and is growing slowly. The skin is perfectly natural and there is no sign of an acute abscess. But the tumor evidently contains fluid. My judgment is that it is a so-called "cold abscess," which is really no abscess at all, for the matter present is not pus. It has been proven beyond cavil that such matter is the result of tubercular degeneration and not a purulent product. There is no fever in this case. If this were a phlegmonous abscess it would have ruptured long ago.

The question comes up, What shall we do for it? What I like best is the introduction of ether and iodoform. Originally glycerin and iodoform were employed. The advantage of ether is that it vaporizes the moment it enters the sac and carries the iodoform into every crevice. The modus operandi is very simple. I shall employ this aspirator, which is provided with a two-way stop-cock. It can, therefore, be used either to remove or inject fluids. I employ the largest sized canula that goes with the instrument. The stop-cock being shut off the piston is withdrawn, making a vacuum in the barrel of the syringe. The needle is then introduced through the skin and when the eye has disappeared the stop-cock is turned so that the vacuum is continuous to the end of the needle. The needle is then forced onward, and as soon as fluid is reached it will be seen as it passes through the little glass tube inserted in the rubber tube which connects the needle to the syringe. When the syringe is full the stop-cock is turned so that the fluid can be thrown out into a basin. Another syringeful is withdrawn in the same way and this process is continued until the sac is emptied. All the broken-down matter being removed the cavity is washed out with warm boiled water. Having washed out the sac, I am

ready to introduce the ether and iodoform. The strength of this is one to twenty, and the quantity injected should not contain over one drachm or a drachm and a half of iodoform.

There are two things to be considered in connection with this patient. One is: Are the sternum and the ribs involved? I think it probable that this "cold abscess" has arisen from some disease of these bones, the result of her violent effort. It may possibly prove necessary at a later date to lay open the swelling and remove the carious bones. The second point, which is of considerable importance, is: Does this cyst communicate with the cavity of the chest? How can we tell? By continued compression. I have tried this, and there is no evidence that there is any communication with the chest. If there were, I should hesitate to inject a large quantity of this solution.

The diagnosis here is tubercular abscess, and I see no reason to doubt its correctness; but we must remember one thing, and that is that we all make mistakes. I am more charitable than I used to be, for I have made a good many mistakes in my day. You remember in the case we had a week ago to-day how the diagnosis wavered—first a cyst, the character of which was uncertain, then it was thought possibly to be a growth connected with the submaxillary gland, and finally, after dissecting out the submaxillary we reached a sebaceous cyst near the floor of the mouth, undoubtedly resulting from invagination of the skin in fœtal life. There is always a possibility of mistake in these cases. I bring them before you, and if I am wrong you will see it. I shall never forget a mistake that I saw made by the distinguished Langenbeck, of Berlin, a most skilful operator and accurate diagnostician. While I was at his clinic in the winter of 1865 and 1866, he diagnosed a tumor as a mammary scirrhus and at once removed the breast. After taking it out he turned to the class and cut it in half, and was a good deal surprised when he opened an abscess of the breast. Looking at it for a moment, he naïvely remarked: "Well, gentlemen, I never made that mistake but once before." Those of us from America remarked that that was a new way of opening an abscess of the breast—first to remove the breast and then open the abscess.

Before I inject the ether and iodoform, I shall take advantage of the flaccid condition of the sac to explore the condition of the bones beneath it. I find a deep cavity over the sternum, so that this is probably a cold abscess arising from traction by the pectoral muscle on the sternum and possibly also the ribs. I now introduce the ether and iodoform, proceeding slowly so as to determine the effect of the vaporization of the ether. This is at first a little painful, but the solution soon exerts its anæsthetic effect. As you see, the sac at once becomes distended and is larger than before it was emptied. One trouble resulting from this is that the pressure is so great that when the finger is removed from the opening a quantity of the fluid is apt to be forced out. In order to avoid this as much as possible, I apply a large piece of rubber plaster over the opening and secure it by a bandage.

A lumbar or psoas abscess can be subjected to this treatment, and sometimes in twenty-four hours the patient can go about, although I prefer to keep him quiet for at least two or three days. Two or three injections may sometimes effect a cure. Occasionally even one is sufficient—as in a little girl of fourteen years, now in the wards, cured of such a tubercular "abscess" a short time since by a single injection.

RARE FORM OF ALVEOLAR SARCOMA, SURROUNDED BY A LAYER OF VARICOSE VEINS.

The case that I shall now show you is, I think, an example of a very common form of tumor, but as I have told you before, there is nothing so uncertain as the character of a tumor. You can say that it is a soft or a hard tumor, but to say positively what is its nature is very difficult. Your patients, however, expect you to know all about it, and you will be constantly asked whether a certain growth is a "cancer" or a "tumor." In other words, whether it is malignant or benign. You are generally pretty safe in pronouncing it a "tumor," and in your opinion to the patient you need not go any further. You may say to yourself that it is a fatty or a sebaceous or other form of tumor, but do not be too sure in telling the patient, for you may find that it is not the kind of tumor that you first thought.

This tumor has been present for three years. It occupies the posterior part of the left thigh. It is not painful. It is movable. While it does not fluctuate, it is just on the verge of it. It is soft and resilient. You must remember that at the temperature of the body the fatty and sebaceous matter that we have in the tissues is not solid, as you see the fat about a sheep's kidneys in the shambles, but almost fluid. This tumor has no pulsation. Taking these facts into consideration, my decided conviction is that this is a fatty tumor. As I have told you on another occasion, there are two kinds of fatty tumors. One is a pure fatty tumor which is lobulated. Such a tumor can be enucleated without difficulty. There is a second form, a fibro-fatty tumor, in which there is a considerable amount of fibrous tissue. These fibrous trabeculæ stretch out in all directions and are attached to the skin, making it much more difficult to remove, as they have to be cut through.

Is it possible to tell which variety of fatty tumor you have? Generally you can. If you grasp the skin over the tumor and pinch it up, if the tumor is of the fibrous variety, each little fibre will draw down the skin and produce pitting. This would be absent in a pure fatty tumor. The proper thing to do with a fatty tumor is to take it out. I have never seen such a growth undergo malignant change. They, however, never get any better. They frequently become so large as mechanically to cause great inconvenience and annoyance. I have seen the skin over them ulcerate and the greatest discomfort produced.

While the patient is being etherized, let me say a few words in regard to the organization of an operation. Before you begin any operation you must decide what instruments, what special appliances, and what dressings will be needed. Give a written list of them to the nurse the day before the operation, so that everything shall be ready before operating. Many years ago I had a printed formula made out showing what preparations should be made in the room, the bed, the patient's person, and what instruments, dressings, etc., would be needed. I have found this a most useful plan, saving me a deal of time and annoyance. You must not forget the dry bichloride of mercury towels. I have seen more than one patient suffer decidedly from cold, shock, and rheuma-

tism in consequence of the wet antiseptic towels spread over the field of operation. I never use the wet towels except in an emergency. In ordinary cases, I direct that the night before operation one or two dozen towels be wrung out of a 1 : 1000 bichloride solution, hung up and dried. They are then folded and an antiseptic towel wrapped around them. These are spread around the site of operation. In the hospital sheets are prepared in the same way. In operations about the head and neck, where the patient is liable to throw his hands about, it is well to pin a prepared towel around his arm. The operator can then grasp the arm without danger.

We shall now proceed with the operation. The tumor, as you see, occupies the posterior part of the left thigh. You observe that there are numerous varicose veins in this region and we must avoid them. I make an incision in the axis of the limb and immediately come down on the tumor, which now does not present the appearance of a fatty tumor. When I saw these varicose veins, the idea of a blood tumor suggested itself, but the fluctuation did not seem distinct enough for that. Making a small incision into the tumor, there is at once a free discharge of venous blood. I close the opening with hæmostatic forceps. It will be necessary to enucleate this mass very carefully, for these varicose veins always have very thin walls. Underneath these veins is a more resistant mass, much harder than the veins, but yet approaching to fluctuation. You see now how deceptive a tumor may be. All the physical signs here were those of a very common form of tumor—a lipoma. Dissection reveals a very rare form of tumor, for Professor Brinton tells me that he recalls only one instance at all like this, and I cannot myself remember ever to have seen even one similar case.

[NOTE.—The operation was prolonged by the numerous fibrous trabeculæ, which had to be cut one by one with care so as not to injure the large varicose veins on the surface. Eventually the entire mass was dissected out and removed, no pedicle, vascular or otherwise, being found. When removed a large opening in the fascia lata was found immediately under it. Dr. Coplin examined it and found it a soft alveolar sarcoma covered with a layer of varicose veins. It had probably originated in the connective tissue under the fascia, later forced its way through this dense fascia, the fibres of which produced the trabeculæ above described. The patient was shown to the class a week later entirely well, his highest temperature having been below 100° F.]

ORIGINAL ARTICLES.

THE TREATMENT OF MEMBRANOUS DYSMENORRHŒA.

BY J. N. MARTIN, M.D.,

ACTING PROFESSOR OF OBSTETRICS AND DISEASES OF WOMEN IN THE UNIVERSITY OF MICHIGAN, ANN ARBOR.

WHILE we are not able to speak positively concerning the etiology of membranous dysmenorrhœa, the microscope has made a correct differential diagnosis possible. Without the use of this instrument it is impossible to ascertain whether the mass expelled from the uterus is dysmenorrhœal membrane, a product of conception, or a blood-clot which has been retained in the uterus and with the fluid portion squeezed out. Experience in treatment has taught us to be guarded in our prognosis. While most cases of true membranous dysmenorrhœa cannot be entirely cured, yet I believe it is equally true that almost every patient suffering from the disease can be materially benefited by careful and systematic treatment.

There is a mass of membrane to be forced through a canal of given size which perhaps is sufficiently large for the fluid menstrual secretions to pass without causing pain, but not large enough to permit the abnormal formation to pass without much expulsive effort and consequent pain. Again, if the disease has existed a long time, there is more or less inflammation of the uterus which adds inflammatory to membranous dysmenorrhœa. And again, this extreme suffering accompanying the condition produces a marked effect upon the nervous system; and so great is this result in some patients that they become nervous or mental wrecks. Then by treatment we should strive to prevent the formation of the membrane or to favor disintegration at the time of the menstrual period, and also to get rid of the results. Not understanding the cause of the formation, we are working in the dark in endeavoring to get rid of it.

While there are many forms of treatment, I have had satisfactory results with the following plan:

First. To relieve the inflammation of the uterus as much as possible between the periods with prolonged hot-water douches once or twice daily; applications to the interior of the uterus two or three times per week of equal parts of 5 per cent. solution of carbolic acid and Churchill's tincture of iodine; and also the use of tampons saturated with glycerin, hydrastis, or boro-glyceride (10 to 20 per cent. solution).

Second. To correct constitutional disturbances and give nerve and general tonics. Bromides and similar agents generally make patients worse in the end, and I never resort to opiates except in the most extreme cases.

Third. To divulse the cervical canal from five to seven days before the time for the period; repeating for two or three months: thus making the canal so large that the membrane may be passed with but little expulsive force. Sometimes after divulsing, inflammatory pains are slightly worse for one or two periods, but in the end it benefits in a majority of cases.

Fourth. To prevent the formation or to favor disintegration, I scrape the uterus thoroughly with a dull curette in the middle of the inter-menstrual period, and afterward apply 1 : 300 or 1 : 400 solution of bichloride of mercury to the interior of the

uterus once in three or four days, and repeat for from two to five months, as may be indicated.

I have followed this plan for about four years, and can say with truth that I have considerably benefited every case excepting one. Two cases were entirely cured; at least it has been more than a year since one of them passed any membrane, and nearly a year since the other did so.

The one patient not relieved does not pass a membrane every month: about every third month there is no membrane expelled, but at each period following the omission, she passes two membranes one within the other. On January 15, 1889, I presented this patient in clinic, with a double membrane expelled, and also another patient with membranous dysmenorrhœa who happened to be in the University of Michigan Hospital for treatment. Five patients with well-defined membranous dysmenorrhœa were presented to the class last year, and I saw two others in private practice.

PHTHISICAL PATIENTS AT CLIMATIC RESORTS.

By CARL von RUCK, B.S., M.D.,
of Asheville, N. C.,
Member American Climatological Association, Member American Medical Association, Director Winyah Sanitarium for Diseases of the Lungs and Throat, etc.

It would be most instructive if accurate data could be obtained of the benefit derived from the climatic treatment of phthisis, and particularly so if we could get at the number of real cures which result therefrom. But, as with any other method of treatment which we carry out in our daily practice, it will ever be more or less difficult to ascribe to the means employed their proper value, and after the result is known it may always be conjectured that if this or that had been done the outcome would have been different.

Much of our therapeutical knowledge is empirical, and this is particularly true of our resources in the treatment of consumption. Climate has stood the test of experience for centuries, and is to-day still recognized as, perhaps, the most valuable of all the means available in our battle with this disease, not only by the profession, but by the laity as well, and what everyone believes must contain at least some truth. I am far from underestimating the value of climate, the beneficial influence of which I daily see convincing evidence. Do we not see, almost at once, improvement in one or several directions, with the arrival of many such patients—a steadily falling pulse-rate, diminution of cough, expectoration, and fever, increase of the appetite and assimilation, and gain in body-weight, especially if the patient is at once put upon a proper regimen? Besides, there are many undoubted cures on record at such climatic resorts, and, although not accessible to statistical demonstration, the proportion, as compared with most painstaking management at less favorable localities, is such as to remove all doubt from the mind of the unbiassed observer in favor of the climatic treatment of phthisis.

I have, however, also observed that the disease is curable in less favorable localities, even where it is very prevalent, and that under proper management much better results than the usual can be obtained, comparing, indeed, most favorably with climatic treatment as usually carried out, or, at least, with the results which I have been able to observe, when climate was chiefly relied upon for a cure.

If, then, climate has any value at all, the results must improve in proportion as we carry out, in addition, the management which is found valuable in the absence of a favorable climate, and this, too, my experience has verified. In gaining such experience I have guarded myself as well as possible against erroneous conclusions, and have based them, in the first place, upon a comparison with my results obtained at what must be considered an unfavorable locality, and again, upon results in cases which I considered under proper management in addition to climate, and still others, under the same climatic advantages, but treated under conditions where it was impossible to enforce the essential regimen.

Anything which, in view of the great mortality, can contribute ever so little to better results, or which may be honestly believed by a careful observer to have so contributed, deserves the careful attention and consideration of the profession, and obviates the necessity for an excuse in bringing up a subject so much debated and written upon as is the one under consideration.

Believing as I do, that the conduct of the patient while undergoing climatic or any other mode of treatment, other things being equal, is responsible for success or failure in almost all cases where there is still reasonable ground for hope, and that such conduct, either through ignorance or wilful disregard of advice, is faulty in the great majority of cases which I have observed; and believing, also, that I have had unusual opportunity for observing, it is my object to point out the things that such patients do, or do not do, to their detriment, so that a more watchful care, more pointed advice, and stronger reprimands will be administered by those who assume the duties of medical adviser to these unfortunate sufferers.

This watchful care, this continuous exhortation to the path of duty, these frequent reprimands for commission or neglect, or the words of approval for painstaking compliance with our orders and advice, make up much or all that is essentially proper management, providing, of course, that the advice itself is sound and proven by experience to be the best.

Many patients have little will-power to begin with, and as disease has still further reduced it, they flounder on the slightest occasion; many others have become wise in their own conceit, have borrowed medical books and read up their case, know a great deal, and like to play their own doctor, or argue the case with their physician; others listen to the advice of every quack medical advertisement, or any advice backed by a story of wonderful recovery; others still, expect miraculous results in the course of a few weeks or months, and are most easily discouraged. All these to be benefited at all require strict supervision and management in a well-conducted institution. Most difficult they are to manage, even there; and, if the whole *clientèle* in an institution should be made up of such material, may the Lord have mercy upon the managing physician!

There are, fortunately, a goodly number of sensible and reasonable patients who are willing and anxious to profit by our advice, whom we can trust in all ways, and who, if they err, do so only from ignorance. Such patients do well outside of institutions, also, and with the exception of the advantage of prompt aid, should any complications arise, they are as well off in private practice, provided the physician can see his patient frequently, and the conditions of hygiene, proper diet, rest, etc., are equally good.

But to come to the faulty conduct of phthisical patients at climatic resorts: First, most of them do not wish to admit that they are sick—they have come for a change only, and endeavor to play the *rôle* of a well person; they say that their physician has told them that there is "nothing really the matter with their lungs," being only "weak," or that they have only bronchitis or throat trouble. All this leads them to a feeling of security or to expect that the climate "will fix everything" in a short time.

I contend that the physician who sends away a phthisical patient for climatic treatment sends a sick person, no matter how early the stage of the disease, and that this patient needs competent care, supervision, and advice from the day he reaches the climatic resort until he is cured: unless this is the case he will, in all probability, derive little or no benefit. A patient who is to recover should be made to understand by his physician that it takes a considerable length of time, even in the early stages, to effect a cure; that it will cost not a little money, and that a few weeks or months are entirely inadequate. All this can be done without depriving the patient of hope for his restoration.

Second. The patients who are at all able to undergo climatic treatment come from a class who have comfortable homes, good beds and food, and live in houses well heated, with inside water-closets and baths; and, finding prices higher than they anticipated on leaving home, frequently go to cheap boarding-houses, where they forego many comforts and conditions absolutely essential to their favorable progress. If anything, better conditions than those to which the patient has been accustomed should be secured, and to get them at health resorts, which are far distant from centres of supplies, means increased expenditures over what would be required for the same accommodations at home. Patients who are sent away should be made to understand this, and that a few dollars expended to get the necessary accommodations are well invested.

Third. Upon arrival at climatic resorts the amount of out-of-door life and exercise requires careful regulation, and it must depend entirely upon the conditions existing in the individual case. But many come only with the idea that the more exercise they take the better, and instead of judicious rest after their journey we find them out bright and early after their arrival, on a hunt for boarding-houses, often on foot, the fatigue which should be avoided frequently amounting to actual exhaustion, and there are cases where the first day spent in the manner described leaves effects never to be recovered from. After being settled they continue to exercise far beyond their strength and endurance, taking unaccustomed horseback rides, with parties of well-trained riders, ascending mountains when exercise on level ground should be limited, and all this regardless of fever or other complications. At night they visit clubs, play cards, dance, and follow their inclinations for amusement, which, perhaps, permissible within reason for some, can only bring disaster to others; they then find that the looked-for improvement in appetite, etc., has either not been realized at all or been very transient, and they begin to doubt the judgment of their home physician who recommended the climate.

Fourth. No case should endeavor to work out his improvement or cure at a climatic resort without professional oversight. This is a delicate point for physicians to urge who practise at such resorts, and I content myself by quoting at length Dr. Clifford Allbutt,[1] from Dobell's monograph on the initial stages of consumption:

"Let us, then, bring the friends always and the patient generally to realize that recovery from phthisis, however incipient, probably means a very costly and prolonged system of treatment, and, what is more, a steady, clear-eyed persevering walk on the part of patients and friends, if success is to be obtained. Now, when a man has had it put straight before him what phthisis means, even in its small beginnings, he will learn that a serious, an unflinching and vigilant attitude is his only way of safety; and a little homesickness, some sense of tedium, and some love of change must not be allowed to turn him from his long and arduous course. Once more I would

[1] Lancet, October 13, 1888.

urge on all phthisical patients the importance of incessant medical supervision. Apart as I am from practice in Alpine health resorts, I may brush aside all scruples, all suspicion of self- or class-service, in saying this and repeating it. For those medical men who do practise in these health resorts there must be a fear of misconstruction of their motives when constant supervision seems to them more necessary than it may seem to the patient or his friends. But scruples of this kind, honorable as they are to the physician, must give way to a clear view of the need of such supervision. The patient must be kept at his best—at the best of his digestion as well as at the best of his pulmonary disorder. His temperature should be again scheduled whenever any sense of lassitude is felt, and the catarrhal or other varying conditions of the lungs should be systematically recorded. Not only so, but the regular visits of his doctor keep up the patient's serious resolve, strengthen his will, inform his judgment, and discipline his habits. And in all this lies most of the battle."

These, Dr. Dobell says, are the wise and considerate words of an unusually wise, experienced, and independent practical physician. Dr. Allbutt has applied them to cases of phthisis, even in its early stages:

"They apply to it more and more strongly as we go further and further back in its small beginnings to what I wish to be emphatically recognized as the smallest of all beginnings, its true first stage, its pre-tubercular stage, its stage of comparative simplicity and of comparatively easy cure."

But if this is all true, as it no doubt is, what is to be said of the needs of the cases who are well advanced in the early stage, who are upon the confines of the second stage, and in whom still a fair percentage of recoveries or rather permanent arrest of the disease is possible?

As a rule, medical men who practise at resorts are not consulted by patients sent there unless some complication arises, or when the patient himself fully realizes that he is getting worse instead of better, as he had expected. The complications passed, the regular attendance ceases until the next relapse again requires professional aid or advice.

Under such conditions no painstaking physical examinations are made matters of record for future comparison, and the regimen and advice are adopted only for the exigencies of the time being. Under such conditions not much progress is possible, but, if any is made, it is, as a rule, undone by some indiscretion.

Take, however, the cases of patients exercising little control over their inclinations, who suffer so frequently from gastric and intestinal derangements due to errors of diet; take those who, in the state of advancing disease or softening processes, suffer from more or less continuous fever; the cases with repeated slight or more severe hæmoptysis, or cases with frequently recurring pleuritis; take cases with tubercular laryngitis, with nasal catarrh, and stenosis—how are all these to get on under self-management?

Fifth. Phthisical patients, as a rule, give up climatic treatment and professional management at a period when arrest of the disease is but temporary, and when, if possible, the efforts should be doubly rigid and vigilant to make such arrest a permanent one and an actual cure. They mistake the attending improvement in general health, the returning strength, for evidence of cure, and propose to let the little remaining cough wear itself out at home. Ninety-nine out of one hundred of such cases relapse sooner or later, and regret bitterly enough when it is too late that they abandoned perhaps their last or only chance. Such patients, if under medical care at all, do not consult us often as to the propriety of their course, unless with the expectation of following it even if we should dissent. As a rule, they tell us that they think they are well enough to go home, or they have come for so many weeks or months only and the time is up. Many times our remonstrances are less strong for fear that our motives may be misunderstood; and for better results in all these matters nothing can have a greater influence than the home physician's support and advice.

Some climatic resorts have the disadvantage of being available only for certain periods of the year, and, of course, changes from such to others are necessary with change of season. But Asheville, although possessing a most favorable all-year climate, has, nevertheless, much the same seasons of exodus and arrivals as do the strictly winter or summer resorts. The class who come here in the fall and winter pack up for home in the spring; those who come in the spring and summer (until recently, as a rule, from Southern States) make room for the winter guests. I consider this most detrimental. It takes, usually, several months, or even more, to make any decided gain, and just as the prospects become the best and the chances for a cure have greatly improved, the patient interrupts the favorable progress to go home, or somewhere else, for a season. I strongly contend that a patient who has made real improvement at a climatic resort, and if the conditions of climate are favorable throughout the year, should, under no consideration, attempt a change until a permanent result is obtained.

Finally, it is deplorable that so many far advanced cases are allowed to leave the comforts of home and friends in search of what they can never find. I suspect that many medical men permit these straw-grasping efforts because, in the kindness of their hearts, they are unwilling to deprive the sufferer of this last hope. I doubt if they really do him a kindness. Far better to urge on the early cases—those "in the small beginnings"—so that the necessity will occur less and less frequently of sending them home almost exhausted or dead.

It is chiefly the home physician who is to decide

what the percentage of recoveries shall be from climatic treatment. Early diagnosed, early sent, properly instructed, and the physician at the climatic station supported in his efforts to enforce a discipline which will result beneficially, are the essentials if we wish to take advantage of every means in the interest of the phthisical patient, who, otherwise, is almost sure to go astray, and whose recovery becomes thus more and more a matter of chance and accident.

ŒSOPHAGOTOMY FOR IMPACTION OF ARTIFICIAL TEETH.

BY JOHN B. DEAVER, M.D.,
DEMONSTRATOR OF ANATOMY AND LECTURER UPON SURGICAL ANATOMY IN THE UNIVERSITY OF PENNSYLVANIA; ATTENDING SURGEON TO THE PHILADELPHIA, GERMAN, ST. MARY'S AND ST. AGNES'S HOSPITALS, PHILADELPHIA.

THE patient, a white man, aged twenty-seven years, was admitted to the insane department of the Philadelphia Hospital in the early part of July, 1889, with the following history: After an alcoholic debauch, lasting three weeks, he became so unmanageable as to require removal to a police station, where he was placed in a cell. While there he fancied that demons were preparing to kill him, which led him to attempt suicide by striking his head against the wall. A few days later he was taken by the police authorities to the hospital.

On admission examination of his face and scalp showed many contusions. He complained of sore throat, was unable to swallow solid food, and could with difficulty swallow a small quantity of liquid. There was profuse, purulent, and offensive expectoration. Examination of the mouth showed an acute pharyngitis, also the absence of a number of teeth from the upper jaw. In the centre of the hard palate was a prominence of mucous membrane like that made by the plate of false teeth. He casually remarked that he had lost his teeth. Local treatment was given for the pharyngeal trouble, with no effect. A probang passed into the œsophagus demonstrated the presence of a foreign body at a distance of about two inches from the commencement of the tube. Having recovered from the effects of the alcohol he was apprised of his condition and advised to have whatever interference might be necessary for the removal of the foreign body, which was most probably the missing plate of teeth. To this he consented, and accordingly I made an attempt to remove the foreign body with a pair of long, well-curved forceps. With them I could reach the body, but was unable to grasp it, and before adopting any other procedure I had the patient etherized. Under complete anæsthesia a second attempt with the forceps was made, but with the same result as before. I now tried to dislodge it with the œsophageal probang, but it was so thoroughly fixed that I was not able to accomplish anything. There was then left but one course for me to pursue, that of opening the œsophagus at the side of the neck. The patient was placed with the head inclined to the right side, the left side of the neck being selected through which to make the incision, and the shoulders raised upon a pillow. An incision, commencing at the sterno-clavicular articulation, was carried through the skin to near the angle of the jaw, when the anterior jugular vein very much distended was seen in the superficial fascia. The vein was ligated at two points and, with the fascia, severed between. The deep fascia was now incised, lifted upon a grooved director and divided to the length of the superficial wound, when the sterno-mastoid muscle with the bloodvessels was displaced backward, the anterior belly of the omo-hyoid muscle downward, and the sterno-hyoid and sterno-thyroid muscles forward. The œsophagus, made prominent by the distention occasioned by the foreign body within, was clearly exposed. Above and below the distended portion of the œsophagus were seen the superior and inferior thyroid vessels. The œsophagus was opened in the line of its longitudinal muscular fibres, when the knife came directly upon a tooth. The wound was then enlarged upward and downward to the extent of two inches, when the plate of a partial set of teeth was exposed lying upside down and crosswise, the front of the plate, containing two teeth, presenting at the bottom of the wound. After a great deal of difficulty I succeeded in removing the plate, and upon removal it was found that a tooth was missing. This was expectorated during the night following the operation, and I have no doubt that it was detached during the extraction of the plate. The wound in the œsophagus was closed with catgut sutures, a rubber drainage-tube placed external to it, and the superficial wound closed with silver wire. The patient reacted well and was nourished for three days entirely by enemata of dextrine, eggs, beef tea, and peptonized milk. From this on he was given, in addition to enemata, milk and whiskey, introduced into the stomach by a pliable passed through the anterior nares. The expectoration continued to have the same character as before the operation.

The wound was dressed the third day after the operation, when it presented a perfectly satisfactory appearance. Two days later, the dressing being much soiled, the wound was exposed and a purulent and offensive discharge was seen escaping from and around the tube. The apparent line of union was much inflamed, showing some signs of breaking down. The following day the discharge having soaked through the dressings, they were removed and the wound was found broken down throughout, the tissues presenting a gangrenous surface. Liquids

now introduced in the mouth escaped through the wound. Wound packed with iodoform gauze. On the evening of the sixth day after the operation the patient had a chill, followed by high temperature, rapid pulse, and increased frequency of respiration. Examination of the chest demonstrated the presence of pneumonia of both lungs. On the following day, the seventh after the operation, he died.

Autopsy, made forty hours after death. Examination of abdominal cavity showed the kidneys to be large and intensely congested. Spleen enlarged, soft, and pulpy. Other abdominal viscera showed no gross lesions. Heart and pericardium normal. Both lungs contained innumerable dark-red solid areas, varying in diameter from one-eighth to three-eighths of an inch, which appeared to be peri-bronchial. Examination of wound showed the condition as described at the third dressing. The larynx, trachea, œsophagus, and lower portion of the pharynx were removed in a single mass. On the left side of the œsophagus immediately below the cricoid cartilage, was seen the incision through which the teeth were extracted. The edges of the opening were dark in color and gangrenous; it measured one and one-half inches in length and one inch in width On the same side of the lower portion of the pharynx was an opening about the size of that in the œsophagus, and presenting the same appearance. Through this opening was seen exposed the left superior cornu of the thyroid cartilage, also the upper border of the cricoid cartilage. Immediately above the cricoid cartilage, a little to the left of the median line posteriorly, was a small opening leading into the larynx. In the extreme lower portion of the pharynx, posteriorly and a little to the left of the median line, was an ulcer one-fourth of an inch in diameter which had perforated the walls. The mucous lining of the pharynx immediately surrounding the openings was gangrenous. On the laryngeal surface of the epiglottis was a small superficial gangrenous ulcer. There were evidences of an active laryngitis, tracheitis, and bronchitis.

I believe the teeth were first arrested in the lower portion of the pharynx, remaining there long enough to set up the destructive inflammation which resulted in the formation of the openings found, and which, coupled with the efforts of swallowing, caused them to be dislodged; they becoming fixed the second time and permanently in the upper part of the œsophagus from which they were extracted.

In the light of the autopsy it is quite evident that the patient could not have lived with any treatment, but the points for discussion in the case of foreign body in the œsophagus calling for operative interference are the following: First. When it is impossible to extract the foreign body through the mouth, but possible to push it down into the stomach, is it not better to do this, providing its character is such as not to lacerate the walls of the œsophagus, and perform gastrotomy, than to remove it by the operation of œsophagotomy, as the former operation offers a better chance for success than the latter? Secondly. Having done an œsophagotomy is it better to close both wounds, or simply close the œsophageal wound, packing the wound in the neck, or to allow both wounds to remain open? In another case such as I have reported, I would not close either the wound in the œsophagus or the wound in the neck, but would trust to healing by granulation, as I believe in this case drainage was an essential factor which was by no means thoroughly obtained.

THE EMPYREUMATIC OIL OF COFFEE, OR CAFFEONE.

By EDWARD T. REICHERT, M.D.,
Professor of Physiology in the University of Pennsylvania.

When coffee is roasted an empyreumatic oil is developed which is supposed to impart to it new physiological properties. The actions of this substance have been studied chiefly by means of a distillate obtained from a strong infusion of coffee; by a comparison of the effects produced by the use of preparations of raw and roasted coffee; or by the administration of the pure oil.

In experiments on three individuals Lehman[1] found that the distillate from roasted coffee caused nervousness and slight sweating, and acted on the brain, affecting the mental faculties rather than the imagination. The solid constituents of the urine, such as urea, were diminished to a greater extent than by caffeine. After large doses there occurred congestion, profuse sweating, and sleeplessness. In two instances diarrhœa was noted. Nasse,[2] in experiments on animals, states that when he injected a few drops of a strong infusion of freshly roasted coffee into the jugular vein of a rabbit, peristaltic movements of a decided character occurred in the intestines which he was unable to produce with caffeine. Méplain[3] obtained from a litre of strong infusion of coffee 200 grammes of a liquid which possessed the aromatic odor of roasted coffee and a slight bitter taste. After the ingestion of this the pulse was increased from 64 to 74 per minute, arterial tension was diminished, and the face congested. Marvaud (*ibid.*) obtained similar results. Rabuteau[4] states that he has "recognized in caffeone the exciting properties attributed to coffee. Everybody knows that an infusion of coffee hinders sleep, but that this effect is not invariably present. We have wrongly attributed this difference in action to idiosyncrasy, but it is due to a difference in the composition of the coffee, for while an infusion of coffee

[4] Compt. rend., lxxi. p. 733.

containing caffeone prevents sleep, the same effect is not produced by the ingestion of an infusion which has been freed from caffeone by prolonged boiling, or by that which has been prepared from coffee too much roasted, or from green coffee, or which contains a small quantity of the particular substance which gives coffee its peculiar odor." He also found that caffeone possesses decided toxic properties, and prevents the development of low organisms in organic fluids. Binz,[1] in experiments on three dogs with a distillate, obtained results in some respects opposed to those already recorded. The distillate, he states, was of a light golden color, of a very aromatic odor and taste, and cloudy when cold. In one experiment a dog, weighing 720 grammes, was given by the stomach 25 c.c., representing the one-half of the distillate from 22 grammes of coffee, in 150 c.c. of hot water. No phenomena were observed, except a quickening of the heart-beats from 110 to 145 per minute. In another experiment with a dog, weighing 1790 grammes, and drunk with alcohol, 12 c.c. of a distillate from 16 grammes of coffee in 1 litre of water were injected subcutaneously in two places. In six minutes the respiration rate was doubled in depth and frequency. In the last experiment the dog weighed 1840 grammes, and was completely narcotized with alcohol. Before giving the caffeone the arterial pressure was 76 mm. of mercury and the pulse 39 in fifteen seconds. Twenty c.c. of a distillate of 85 c.c., which was obtained from 20 grammes of roasted coffee in 100 c.c. of water, were injected subcutaneously, and 50 c.c. given by the stomach. In ten minutes the pressure fell to 68 mm.; in fifteen minutes, to 66 mm., and in forty minutes, to 56 mm. The force of the pulse was doubly strong, and the heart-beats increased in frequency. The diminution of blood-pressure he consequently attributes to vascular dilatation.

It is obvious that in the investigations above referred to, the actual quantities ingested of the so-called caffeone were not known; it therefore occurred to Hare and Marshall[2] to isolate this substance and study the effects of definite doses. They extracted the oil with pure petroleum ether, and allowed the latter to evaporate spontaneously. The product thus obtained was of the consistency of dilute syrup, varying in color from a light to a dark brown, according to the color of the seeds, and possessing to a great degree the peculiar aroma of roasted coffee. When injected into the jugular vein of a dog the pulse was for a short time increased and then diminished, and the arterial pressure was lowered. If the dose was sufficient to kill, the heart-beats became slower and slower, arterial pressure gradually fell, and the heart was arrested in diastole. The asserted antisoporific properties attributed to caffeone led them to make one experiment on a dog and three on men, in each of which single doses of from 50 to 60 minims were given by the stomach. In the dog and in two men sleep occurred and in one case sleeplessness.

The investigations of Hare and Marshall I have recently supplemented and extended during the progress of a study with caffeine. The oil was prepared in the same manner, and the results obtained from its intravenous injection in dogs were identical. It seemed to me, however, that an oil of such consistency, and which is practically insoluble in the blood, would, when thrown directly into the circulation, mechanically clog up the capillaries in the nerve-centres and elsewhere and thus give rise to serious disturbances. Therefore, in another series of experiments, I substituted for the oil of coffee pure olive oil and obtained similar results. In a third series, in order also to obviate these mechanical effects, the oil of coffee was given subcutaneously in amounts varying from 1 c.c. to 3 c.c. per kilo of body-weight, but without any effect on the heart-beat, arterial pressure, cerebral functions, respiration, or heat phenomena. It is, therefore, conclusive that the empyreumatic oil of coffee, as obtained by Hare and Marshall, is inert.

The positive results recorded by various observers following the ingestion of a distillate from roasted coffee, the evident differences in the activities of infusions prepared from raw and roasted coffee, the change in the properties of the infusion of roasted coffee which occurs from continued boiling or in the seeds by excessive roasting, certainly lead to an inevitable conclusion that some volatile principle is developed during the roasting which is dissipated by prolonged heating and which possesses definite physiological properties. It would, therefore, naturally be inferred that such a substance would pass over in the early distillate from a strong infusion of coffee. I consequently prepared a distillate by placing 500 grammes of freshly roasted coffee in a Florence flask, adding sufficient water to cover it, and collecting the first 200 c.c. distilled. This was of a pale yellow color, slightly turbid, bitter, and had the strong aromatic odor of roasted coffee. A small dog, weighing 6 kilos, whose carotid was connected with the kymographion, was given, by means of the external jugular vein, within ten minutes, 105 c.c. of this distillate in doses of 10 c.c., but without any definite effect on arterial pressure, pulse, respiration, bodily temperature, or otherwise. A similar distillate was prepared from other samples of coffee, but all were inert, although appropriate tests demonstrated the presence of organic matter. The opposite results obtained by different observers

[1] Archiv f. Exper. Path. u. Phar., ix. S. 45.

[2] THE MEDICAL NEWS, 1888, vol. liii. p. 337.

and myself, lead to the belief that this hypothetical principle is more volatile in some samples of coffee than in others. Whatever may be its nature, it is clearly not identical with the empyreumatic oil which is so abundant in roasted coffee.

Physiological Laboratory, University of Pennsylvania.

CLINICAL MEMORANDA.

TOXICOLOGICAL.

A Case of Cannabis Indica Poisoning.—On February 15th, at seven o'clock, I was called in haste to see Mr. B., a single man, aged thirty years, and found him almost in collapse, with moist, pale, cold skin, fingers and lips blue, pulse very weak and rapid, respiration slow, mind clear, though excited by the dread of death. He complained of shocks like electricity passing through the body, beginning at the neck. These spasms were so marked that they could be felt by those rubbing his hands and feet. He complained also of burning flashes of heat proceeding from the thorax. He felt them coming, and showed a great dread of death at such times. He also had great difficulty of breathing, with a weak and very rapid pulse, which was scarcely perceptible.

I at once administered carbonate of ammonium and whiskey (no digitalis being at hand), to which he responded very promptly for a short time. His extremities were rubbed with whiskey, and hot-water bottles were applied to his feet.

I then inquired for the history. No similar attack had ever occurred. He had taken a teaspoonful of medicine three-quarters of an hour before, but what it contained he did not know. While at the supper-table the symptoms suddenly came on, and he called to some one to catch him, as he was falling. He had just recovered from influenza, and this medicine was given as a tonic. I excluded fainting, as the mind was clear, then thought of strychnine, owing to the twitching of the muscles, but the heart symptoms did not correspond. I did not give an emetic owing to his weak condition, and because three-quarters of an hour had elapsed since the medicine was taken. After repeating the ammonia and whiskey several times and giving digitalis, which had now come to hand, the symptoms in the course of an hour grew better, and the family physician with another doctor now arrived. On inquiry the doctor said he had ordered 2½ minims each of tincture of nux vomica and tincture of cannabis indica, and 20 minims of dilute phosphoric acid in tincture of cinchona.

We then concluded the druggist must have made a mistake. I withdrew shortly after; the family physician remained during the night, and stated that the patient talked in a rambling way until midnight, with short intervals of sleep, after which he dozed lightly till morning. On going to the pharmacy we found the prescription to be as follows: "Acid phosphoric. dil., tr. nux vomica āā ℥j, tr. cannabis indica ℥vj, elix. calisaya ℥vj, syr. prun. Virg. ad ℥iij. S. one teaspoonful three times daily." The druggist had made no mistake. The cannabis indica was the cause of the symptoms. The doctor ordered the drug on the basis of the American Pharmacopœia, which directs the tincture to be made from the powder, while the prescription was put up on the basis of the English Pharmacopœia, in which the tincture is made from the extract and is much stronger. The English drug is more stable than the American, and here, where the drug comes directly from India, it is still better. The teaspoon used held more than a drachm, so that the patient must have taken at least the equivalent of one grain of the extract. It probably would not have produced such dangerous effects had the patient not been of a nervous disposition and much weakened by the influenza.

The heart failure shown in this case is not mentioned in the text-books as a symptom of hemp poisoning. It is curious that the drug did not act as a hypnotic, and that it did not produce that apparent prolongation of time that is ordinarily spoken of. Great weakness remained, especially of the lower extremities, so that he was a week regaining the condition that he was in before the poisoning.

The above proves that it is important:

1st. To follow the repeated warning given in the text-books that such a drug should be first used in minimum doses and increased as indicated.

2d. That toxic drugs should not be prescribed in a foreign country unless one is familiar with the strength of the preparation according to the Pharmacopœia of that country.

3d. That we should not prescribe a dangerous drug when there is no indication for it.

S. P. Glover, M.D.

Beyrout, Syria.

MEDICAL.

Salicylate of Sodium in Typhoid Fever.—In The Medical News of December 14, 1889, Professor George L. Peabody, writing on typhoid fever, says: "It would seem that any one possessed of facts bearing upon the subject, need offer no apology for presenting them to his brethren," and as my mode of treatment is altogether different from any other method that I have seen described, and is gratifying in the extreme, I here present it for acceptance or criticism.

Living in a small town, and doing an extensive country practice, it is impossible to take the temperatures of my patients at stated hours, for they are frequently ten miles apart.

During the past year I have treated about twenty cases of typhoid fever, with but one death. This patient, a lady, of thirty-five years, had taken large and repeated doses of podophyllum for ten days before sending for me. She died of intestinal hæmorrhage soon after I saw her. Four cases were children, between five and ten years old, the remainder adults. To the latter I gave daily twelve grains of the salicylate of sodium every two hours until four doses were taken; this amount (forty-eight grains) reduced the temperature promptly in every case save one with hepatic symptoms, who received ten grains of calomel in two doses. After the function of the liver was reëstablished in this case the salicylate was, for a few days, efficient in controlling the fever. Afterward it seemed advisable to assist its action with spirit of nitrous ether. If the skin is hot and dry, the sodium salicylate produces free diaphoresis in from one-half to one hour after the first or second dose. The pulse becomes softer

and diminished in frequency. It is occasionally necessary to give a few doses of fifteen grains each, but this amount should not be continued, as such large doses cause symptoms of depression. To some patients I gave four drops of the tincture of digitalis every four hours, to prevent cardiac depression. Turpentine was applied to the abdomen of each patient, and was rubbed upon the legs, soles of feet, arms, shoulders, or lumbar region when aching in the limbs or back was complained of. In a few cases, where tympany was marked, ten drops of turpentine were given every five or six hours. When diarrhœa was excessive I gave the following mixture:

Tincture of myrrh	. . .	1½ ounces.
Tincture of capsicum	. . .	½ ounce.
Tincture of catechu Tincture of opium	of each .	1 " —M.

One teaspoonful every two or three hours.

Calomel, in my opinion, is not indicated unless so-called bilious symptoms are present In such cases it is useful, but if given *late* it is potent for harm, and I should hesitate to give it after the tenth day. Cold or tepid water should be applied to the hands and arms if fever be high, and the back may be sponged and fanned if the patient experiences no discomfort from it.

The diet should be restricted to milk, or meat broths containing a small amount of farinaceous substance. An enema of warm water, or a suppository of soap, is sufficient to move the bowels if they become constipated, but they should not be used oftener than every fourth or fifth day.

With the above treatment I have never seen the fever continue longer than eighteen days, and have often limited it to less, and even aborted it entirely. If quinine be a specific for intermittent fever, I believe that salicylate of sodium is for typhoid fever. A child of one year can take two grains; of five years, five grains; and of seven years, ten grains.

Given as above it will control fevers, and why it has not been used before cannot better be explained than in the language of Professor William Goodell, who says: "Truth evolves slowly, and does not, like Aaron's rod, bud and blossom in a night."

HOSPITAL NOTES.

TREPHINING THE SKULL FOR EPILEPSY. EXCISION OF A SPINA BIFIDA. EXCISION OF AN EXOSTOSIS OF THE FEMUR. DOUBLE CASTRATION.

Abstract of a Clinical Lecture delivered at the Roosevelt Hospital, New York.

By CHARLES McBURNEY, M.D.,
ATTENDING SURGEON.

Case I.—The first case for operation was one which had been sent by Dr. M. Allen Starr. The patient, a man thirty-one years of age, fell from a moderate height when nine years old, and received a scalp wound on the left side of the head near the junction of the parietal and occipital bones, two inches to the left of the vertex. No more serious injury was discovered at that time and the wound healed without the development of any cerebral symptoms. For the next fifteen years his health was excellent, when he was suddenly seized on awakening from a nap with a violent epileptiform convulsion. This was the first convulsion he had ever had, and it came without premonition. Convulsions then recurred at intervals of about a week, but they rapidly increased both in frequency and severity so that recently he has had as many as thirty or forty every month. The attacks begin by an uncomfortable sensation in the epigastrium which is quickly followed by entire loss of consciousness, twisting of the head and shoulders toward the left, and then a general convulsion of the muscles of the whole body. The attacks usually last fifteen or twenty minutes and are sometimes followed by very violent delirium. He has received for a long time the usual medicinal treatment for epilepsy, but without any benefit. Examination showed a slight scar on the left side at the site already mentioned, and some inequality of the bone underneath. Pressure on the scar caused a muscular tremor all over the body.

His case seemed to be a favorable one for operation: (1) Because the frequency and severity of the seizures were like those often seen in traumatic epilepsy; (2) the treatment for ordinary epilepsy had proved ineffectual; (3) the increasing frequency of the attacks indicated a direct source of irritation; and (4) on account of the peculiar effect of pressure upon the scar.

A curved incision was made so as to expose a large area of bone. The bone anteriorly showed only a slight groove, and posteriorly a very superficial circular depression. A button of bone was removed by trephining from both of these situations, and the bone cut away so as to unite these two openings. There was no evidence of injury upon the inner surface of the bone, but the dura bulged markedly into the opening. After incising the dura palpation of the brain showed it to be much softened over an area about one and one-half inches in diameter. The softened portion was removed with a sharp spoon and by sponging, and beyond this on all sides the brain appeared normal. Two small rubber drainage-tubes were inserted and a portion of the wound sutured with catgut. The remainder of the wound was packed with iodoform gauze and a large antiseptic dressing was applied.

Case II.—A woman with a rather puzzling cystic tumor of the buttock was next presented for operation. According to her statement the tumor made its appearance about seven years ago, and, she thought, was the result of a blow. It grew rapidly to about the size of a lemon, when it was removed by operation; but within a year returned. The tumor was at present the size of an orange and was situated just over the base of the sacrum. Its size varied greatly with the position of the patient, so that Dr. McBurney suspected that it might be found to arise from the pelvis.

An incision was made over the tumor and a little dissection showed that the cyst passed into the sacrum through a foramen in the median line measuring about one and a half inches long by one inch broad. Finding it to be a spina bifida the dissection was carried down until a pedicle about the size of a goose-quill was reached. It was then ligated at this point with catgut and excised. Though the patient was positive that there had been no tumor in this region before her twenty-

fourth year, Dr. McBurney thought that a small spina bifida had probably always existed, and that its growth had been more rapid after the injury. A rubber drainage-tube was inserted and the greater part of the cavity closed by buried catgut sutures. The antiseptic dressing was applied and retained by a double spica bandage.

CASE III.—The next patient was a girl twelve years of age, who had an exostosis on the inner anterior aspect of the femur, projecting about one and one-half inches from the bone, just above the junction of the epiphysis and the shaft. These exostoses occur almost invariably in young people, and very commonly in the locality indicated, probably on account of the great activity of bone growth at that point. It had given her only slight inconvenience, but any traumatism of the part would readily lead to troublesome inflammation of the bursa situated in front of the bony projection.

The base of the exostosis was exposed by an incision, and was then removed, together with the surface of the shaft on which it was implanted, by means of a chisel. If a part of the shaft had not been removed recurrence would be probable. Drainage for the first two days was thought necessary, and the limb was bandaged to a straight posterior splint provided with a foot-board.

CASE IV.—Dr. McBurney then presented a man with tubercular degeneration of each epididymis, which was rapidly advancing, although the spermatic cord on each was still free from disease. There were no evidences of tubercular deposits in the lungs or elsewhere. Dr. McBurney proposed to perform double castration with the object of preventing the advance of the disease along the cord and vas deferens to the bladder, prostate, and surrounding parts. He has never seen any ill-effects from removing organs so diseased, although some operators claim that disease in other parts of the body would be produced by such surgical interference. On the contrary, it has been his experience that where the disease has not advanced too far, the removal of such suppurating foci, whether in this locality or elsewhere in the body, is invariably followed by improvement.

MEDICAL PROGRESS.

Technique of the Porro-Cæsarean Operation.—In an address before the Southampton Medical Society, MR. LAWSON TAIT gave the following clear description of the various steps of the Porro-Cæsarean operation: The instruments required are two or three pairs of catch forceps for arresting bleeding points, a small sharp scalpel, two or three bayonet-pointed suture-needles, some silk, a piece of India-rubber drainage-tube, and two needles of steel wire, and none better than the ordinary stocking-knitting needle can be found. A *serre-nœud* may be added, but it is not in the least degree necessary.

The first step in the operation is the abdominal incision, four inches in length, involving the skin and muscles down to the sheath of the rectus, all of which ought to be divided by a sharp knife at one stroke; then the tendon of the one or other of the recti is opened, the muscular tendons fall aside, and the posterior layer of the tendon is nipped by two pairs of forceps and divided between them. The extraperitoneal fat is treated similarly, then the peritoneum is raised by two pairs of forceps, a slight notch being made between them. The moment this is effected air enters, and all behind falls away. No director is required, nothing but an observant pair of eyes, lightly applied forceps, and a sharp knife delicately applied. The finger is then introduced into the peritoneal cavity, and the relations of the uterus and bladder exactly ascertained. The peritoneum is then opened to the full extent of the four-inch incision, and the cut edges are seized on each side by a pair of forceps and pulled to their respective sides. No better retractors can be employed.

The piece of India-rubber drainage-tube, about eighteen inches or two feet long, is now held as a loop between the fore- and middle-finger of the left hand, slipped up over the uterus and pulled down over the cervix, passing the fingers behind the cervix to see that coils of intestine are not included. One hitch is then made on the tubing when it has been placed as far down as possible, and it is pulled as tight as is consistent with safety. The second hitch may be made in it, but what is far better, an assistant keeps the tube on the strain, so that the one hitch will be quite enough.

A hole just large enough to admit the finger is then made in the uterus; if it is possible, the position of the placenta may then be ascertained; if not, the right fore-finger is inserted, and between the two, by gentle rending, a larger aperture is made in the uterus, and the leg of the child is seized. The fœtus is then carefully delivered feet first, which, despite all authorities to the contrary, is by far the best proceeding; less blood is lost, and it requires but very gentle manipulation to relieve the head.

As soon as the fœtus is removed, the placenta is sought for, and removed in a similar manner. The uterus itself, being then completely contracted by this time, is pulled out of the wound, and the elastic ligature is tightened once more, and the second hitch is applied. The main details of the operation are now completed; all that is required is to pass the needles through the flattened tube and the uterus, and out at the other side, forming a St. Anthony cross, or two parallel bars, to support the weight of the uterus and the stump, and to keep it outside the wound. A complete toilet of the peritoneum is then made, not forgetting the anterior vesical *cul-de-sac*, and stitches are passed in the ordinary way to close the wound accurately round the uterine stump.

The uterus is now removed close down to the needles and strangulating rubber tube, leaving a little tissue above. A little perchloride of iron is then rubbed gently over the surface of the stump; it is dressed with dry lint and some cotton gauze, an ordinary obstetric wrapper is put on, and the operation is at an end.—*British Medical Journal*, March 22, 1890.

The Treatment of Typhoid Fever by Prolonged Immersion.—At the close of a lecture upon the above subject (*Lancet*, March 29, 1890), DR. JAMES BARR drew the following conclusions: 1. So long as the fever is mild there is no necessity for interfering with the temperature, and there is more to be lost than gained by attempting to produce continuous apyrexia. In continued fevers with a persistent high temperature and no marked intermissions, there is no period for building up tissue, and hence it is important to moderate the intensity of the pyrexia,

and, if possible, produce a prolonged daily remission, with a reduction of temperature to at least 100° or 99°. The reduction should be obtained not only by abstracting heat but by limiting its production, and this is the action of baths.

2. Immersion causes a marked improvement in the vaso-motor tone; the bloodvessels become smaller, the pulse slower, fuller, and of improved tension. The heart maintains its vigor, and the only cases in which the sounds have become weaker were those which were not put in the water until a late stage of the fever.

3. The respirations lessen in frequency; the bronchitis and congestion of the lungs improve, and soon disappear.

4. The improvement is, perhaps, more marked in the digestive tract than anywhere else. The tongue becomes moist and clean, salivary secretion increases, appetite and digestion improve, and the diarrhœa not only lessens, but the character of the motions changes for the better.

5. The effects on the nervous system are excellent, delirium disappearing, and the general well-being of the patient improving.

The Treatment of Laryngeal Tuberculosis.—Dr. J. Neumann has communicated to the Royal Society of Physicians of Buda-Pesth an account of his experience in the treatment of laryngeal tuberculosis. A solution of one-half per cent. of sulphate of zinc, mixed with one to two per cent. of cocaine, was useful in catarrh of the larynx and trachea in tuberculous patients. Sixty cases of extensive tuberculous ulcers of the larynx were treated with insufflations of iodoform, with the result that the ulcers became clean and partly covered with epithelium. No cure, however, was obtained. The anodyne effect of the iodoform on tuberculous ulcers was often surprising. A rather large quantity of the powder should be insufflated. Iodol, mixed with equal parts of boric acid, was a milder application, which had proved serviceable in 300 cases. A twenty per cent. oily solution of menthol was not well borne, and had no great effect. In the final stages of the disease the application of from five to fifteen per cent. of cocaine was useful, especially as enabling the patient to swallow with comfort. Eight minutes after the third brushing, he began with antiseptic insufflations in order to make the effect more complete. Morphine mixed with pulverized acacia, or iodol-boric acid, was used more rarely. Ice poultices and ice pills also effectually relieved pain. Of fifty patients treated with lactic acid, three remained well for a long time, while about thirty were relieved to a certain extent, but relapsed and died. The lactic acid was never hurtful, but was only useful in ulcers. Circumscribed infiltrations must be scraped away with the sharp spoon, if the patient is strong enough to bear it. In advanced ulceration, severe treatment should not be employed. With regard to tracheotomy, Dr. Neumann shared the opinion of Schmidt, that the favorable effect of the operation is due to the increased inhalation of oxygen and the rest given to the diseased organ. Of eleven patients operated upon, six died, four of whom were *in extremis* when admitted; five remained alive. One of these patients had now been under observation for two years, and another for one year.—*British Medical Journal*, March 29, 1890.

Camphoric Acid in the Night-sweats of Phthisis.—Camphoric acid, which is produced by the oxidation of camphor by an acid, has been given by Dr. Leu (*Wiener medicinische Blätter*) to thirteen patients suffering from night-sweats—fifty-five doses in all. Perfect success was obtained in sixty per cent. of the cases; partial success in eighteen per cent. The average dose was thirty grains, although in some cases this dose was increased to forty-five or even seventy-five grains, thirty-five to forty-five grains being given in the evening, and about thirty grains in the middle of the day. A remarkable fact was that sometimes the favorable influence of the camphoric acid was not noted until the evening after its administration, while, further, the good effects persisted for several successive evenings. In order to make a comparison with a remedy which possesses great repute in the treatment of night-sweats, the author administered atropine to six different cases in twenty-four instances, alternating each evening with camphoric acid. It appears from these experiments that perfect success was obtained in but forty-two per cent. of the cases treated, atropine thus falling below camphoric acid in efficacy; while, further, even in the cases which were favorably influenced by the atropine, the duration of the effect was not to be compared with that of camphoric acid. Moreover, the after-effects of camphoric acid are quite insignificant, which cannot be said of atropine. In some cases the patients attributed a certain amount of soporific effect to the action of camphoric acid, although this, perhaps, was attributable to the fact that the suppression of the sweat removed a cause which ordinarily would tend to disturb sleep. The author has also made a number of experiments upon the effects produced by the external application of alcoholic solutions of camphoric acid. In one patient, who suffered from marked local sweatings, the substance was locally applied, and seemed to be extremely efficacious.

Though the drug has not a very unpleasant taste it was given by Dr. Leu in capsules.—*Therapeutic Gazette*, April 15, 1890.

The Significance of Albuminuria.—Dr. Goodhart, in a paper read before the Harveian Society of London, detailed his observations upon 272 cases of albuminuria which had come under his notice in the past ten years. He called special attention to a form of congestive albuminuria, in which the patient complains of a certain amount of ill-health, whilst on inquiry it is found that he eats and drinks too much, takes no exercise, and probably has gouty antecedents. The urine in some cases is of high specific gravity, and contains only a small amount of albumin. The treatment of such cases consists in the periodical administration of a purge, and in making the patient live according to the ordinary laws of health. Such cases are clearly not due to nephritis. A temporary albuminuria in females may sometimes be explained by the fact that the urine has become mixed with leucorrhœal discharge, whilst in the male the seminal and prostatic secretions may produce a similar result. In cases where albuminuria follows scarlatina, and is therefore presumably due to nephritis, and the patient continues in good health, Dr. Goodhart thinks the phenomenon is to be explained by supposing that each organ has a margin of working power which can be

temporarily encroached upon without bad results. Dr. Goodhart considers that slight and transient albuminuria in a young person is of very little importance, but if the quantity of albumin is large, if it is persistent, or if it frequently reappears, it must be regarded as a danger signal, and is, in some cases at least, due to patches of inflammation in the kidneys.—*Practitioner*, April, 1890.

Menstruation after Oophorectomy.—The question of the cause of menstruation continuing after removal of the ovaries is still an open one. DR. ENGELMANN (*Annals of Gynæcology and Pædiatry*, April, 1890), after a study of the subject, concludes:

1. That the continuance of menstruation after removal of both ovaries is due to remnants of ovarian stroma left *in situ*.

2. That particles of ovarian tissue, however small, which remain after the removal of the greater portion of the organ, whether or not the Fallopian tube be preserved, *may* retain their activity and continue the functions of the entire organ, and from this we infer that menstruation is more or less intimately associated with ovulation, and that the menstrual condition indicates the ovarian status, provided the uterine tissues be normal in character.

3. That even elongated pedicles may contain ovarian stroma in which the functional activity of the organ may be continued.

4. That remnants of ovarian stroma do not *necessarily* preserve their vitality and functional activity.

5. That the ovary is an essential factor in the functional life of woman, and that menstruation is inseparable from ovarian activity, if not from ovulation.

The deductions of practical value to the operator are as follows:

1st. If menstruation is to be checked and the change of life produced, it is requisite that every particle of ovarian stroma shall be removed, if the result desired is to be expected with certainty.

2d. If shrinkage of fibroids, limitation of hæmorrhage, or cessation of annoying symptoms is to be accomplished with the greatest possible certainty, both ovaries must be *completely* removed.

3d. In the performance of double ovariotomy in women not beyond the climacteric, and not suffering from uterine reflexes, such healthy ovarian tissue as may exist should be spared in order that functional activity may not be impaired.

The Therapeutics of Codeine.—DR. LOWENMEYER, of Berlin, reports his results with the use of codeine (*Internationale klinische Rundschau*, April 6, 1890) in 400 patients, in some instances the drug being given for a considerable period. The effect in many painful conditions, such as gastralgia and colic, was most satisfactory, pain being subdued and the patient falling into a sleep. It was difficult to determine what kinds of pain were most favorably influenced by codeine, but it was apparently of least benefit in cases of very severe paroxysmal pain, such as gall-stone and nephritic colic.

In such affections of the respiratory organs as phthisis, pleuritic pain, bronchitis, and pneumonia, good results were obtained from codeine. It also rendered excellent service in asthma. The author's experience shows that it may be given without fear where there is cardiac disease. The doses employed by Lowenmeyer varied from ½ to ¾ grain.

Fluorescein in the Diagnosis of Corneal Lesions.—DR. R. L. RANDOLPH, in the *Johns Hopkins Hospital Bulletin*, April, 1890, details his results in the diagnosis of corneal diseases with fluoresceïn, as described by Dr. Straub, who states that corneal abrasions are temporarily stained a deep green by solutions of this compound.

Fluoresceïn is a red powder, soluble in water, and is one of the products of coal-tar distillation. Dr. Randolph employs a solution of 10 grains of the powder to the ounce of water, to which are added 15 grains of the bicarbonate of sodium.

He has never known the solution to have an irritating effect, and has used it in the most intense forms of corneal inflammation. The portions of the cornea stained retain the color from half an hour to several hours. The solution produces not the slightest impression upon the healthy cornea. He always found that when positive defects in the corneal epithelium existed—in other words, where there was actual loss of substance—the coloration was more apparent. So long, then, as it is possible to color any portion of the cornea, we may be certain that some lesion still exists. In excoriations of the cornea positive results were the rule. In ulcers of the cornea positive results were always obtained and in simple superficial keratitis the coloration was much less distinct than when this disease was associated with an ulcer. In parenchymatous keratitis the results were invariably negative. In foreign bodies in the cornea, no matter how small the foreign substance was, its position and size were located to a nicety. Here the coloration was immediate and distinct, showing itself by a green ring just around the foreign body. He thinks that when one is accustomed to the use of the solution—in other words, understands that where the coloration is produced the anterior epithelium is involved—the agent is of value in detecting, with accuracy, lesions of this part of the cornea. Ulcers so small that it is impossible to see them by diffuse daylight are brought out with perfect distinctness, quite as clearly indeed as under oblique illumination, and small points, which it is possible to overlook even with the oblique illumination, are invariably revealed by a drop of the solution; and, moreover, in half the time that it takes us to subject a patient to the former method. In minute ulcers of the cornea in very young children, where the blepharospasm and photophobia are frequently so intense that the lids have to be forced apart in order to get a view of the eyeball, and then the latter is rolled about so continuously, and the cornea flits so rapidly before our eyes that we are obliged simply to infer from the attendant symptoms the nature of the trouble without actually seeing the lesion itself, a drop of the solution will locate the disease and its extent, and bring it out distinctly so that it can be seen, no matter how fast the eyeball moves about.

Test for the Purity of Woollen Garments.—According to the *Sanitarian*, the genuineness of woollen clothing may be tested by placing a small fragment in caustic soda, which quickly destroys animal fibres, but has no effect upon those of vegetable origin. If the article is all wool it will be completely dissolved; if it has a groundwork of cotton the latter will remain.

The Medical News.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author.

THE REVISION OF THE PHARMACOPŒIA.

ON the 7th of next month the Convention for the Revision of the United States Pharmacopœia will be convened in Washington, and, while we have already called the attention of the profession to the importance of a full delegation of medical men being present, we wish to reiterate the facts which have been already presented, and to offer additional reasons why everyone should go who has received the proper qualifications.

In the first place, the United States Pharmacopœia when arising from the intellect of but a few persons coming from a very limited territory, many of them having peculiar ideas, can in no way represent the opinion of the professions of medicine and pharmacy throughout the United States. Anyone who will glance at the Pharmacopœia of 1880 will notice that it contains some drugs which are exceedingly local in their use, and which perhaps are not employed anywhere out of the county, or at least the State, in which they are grown. It will also be found that remedies which have a much wider use do not appear; and more than all, that the measures for the manufacture of many of the pharmaceutical preparations are impracticable in the hands of the ordinary pharmacist.

We have also called attention to the immense variation which occurs in the strengths of tinctures and fluid extracts, and we have but recently seen a case in which belladonna was given, obtained from one store, without any effect, while that obtained from another store was too powerful in its influence, and occasioned decidedly unfavorable symptoms. It is evident that if the practice of medicine and pharmacy is to be based on scientific ground, better directions than the use of so many ounces or parts of a crude drug and so many parts of alcohol must be resorted to; since plants of the same species, growing under different circumstances in regard to heat, moisture, and soil vary, as everyone knows, very considerably in their external appearance, but even more so in the quantity of their active principles.

Unfortunately for the cause of standardization of drugs, a number of the members of the medical and pharmaceutical professions have obtained the idea that the movement is for the benefit of a well-known firm of manufacturers of medicines, and that this measure is calculated to be solely beneficial, from a commercial standpoint, to the members of this firm. Nothing can be more unjust or absurd, since the opponents of standardization virtually acknowledge by this outcry that their preparations are not standardized, for if they were, no objection would be made on their part to the movement. By the bitter opposition which some journals exhibit, the fable of the dog and the bone is exemplified; for, in their endeavor to prevent standardization by denouncing the only firm using standard methods, they give their opponents an advertisement and indorsement than which nothing could be further from their wishes, and which has already caused a number of physicians in this city to order only those drugs made by the one firm in dispute. We cannot help feeling, however, that the adoption of the term used at present by any single house to designate standardized drugs is entirely out of place, and we think that the word "standard" or "assayed" is the word to be employed.

CHRONIC PLEURISY AND EMPYEMA.

INFLAMMATION of the pleura is an important subject, both by reason of its frequency and of the serious complications, or sequelæ, that may attend it. That "busy practitioner," for whom so much compressed and sugar-coated literature is nowadays manufactured, is too apt to pass by unread, contributions on so old and familiar a theme, unless, perchance, his eye be taken by the formula of a never-

failing prescription. Yet, as LIEBERMEISTER, in his recent valuable series of articles (*Deutsche medicinische Wochenschrift*, 1890, Nos. 10, 11, 12, 13), observes, "physicians whose resort to percussion is infrequent, may for many weeks together treat a patient for gastric catarrh, while in reality he suffers with an extensive pleural effusion;" for the symptoms of chronic pleuritis are indefinite and often misleading. Fever is slight, or, indeed, absent. Cough may be wanting. The phenomena, and especially those of pain and discomfort, due to pressure upon, and displacement of, neighboring organs by the distended pleural sac, are open to complete misinterpretation. Only by careful physical examination is the true nature of the case made evident; nor are the results of physical examination, while usually conclusive, absolutely beyond possibility of mistake in all cases. The diagnosis, then, is not a matter of such plain sailing that everyone may assume to know perfectly all the ins and outs of the channel, so soon as he has received his pilot's certificate. In those cases where the intrapleural effusion persists or recurs after subsidence of the more prominent symptoms of an acute attack, mistake is less likely to occur than in the not uncommon cases where the affection is, from the outset, sluggish and ill-defined. The patient, in this latter class of cases, most frequently comes under observation late in the progress of the disease, and has no history of acute distress in the thorax to direct attention to that region. In our own dispensary experience, moreover, even when cough and dyspnœa are so marked in cases of chronic pleurisy that superficial examination of the chest cannot be omitted, it is not rare to find that such diagnoses as asthma and consumption have been made. Especially is the case liable to be mistaken for pulmonary tuberculosis, when the effusion is purulent and irregular chills and fever form part of the clinical picture. Hydrothorax from passive transudation, as in cardiac and renal disease, may sometimes be difficult to discriminate from effusion the result of chronic inflammation of the pleura. In the former, however, the effusion more readily shifts its place with change of body-posture, being thinner and unhindered by adhesions. Hence, too, the line of the upper level of dulness is horizontal, while the corresponding line in cases of pleuritic effusion is more usually curved. Further, hydrothorax is almost invariably bilateral, while pleurisy is more frequently unilateral. Hydrothorax is rarely the only manifestation of a systemic process, but is associated with ascites or general anasarca. Nevertheless, as Liebermeister points out, the two conditions may coexist as complications, or there may be transition from one to the other. For example, effusion due to neoplasm may be called chronic pleurisy with as much propriety as inflammatory hydrops. Or if, after the disappearance of a general hydrops, some obstinate residue be left in the pleural cavity, it may be considered as certain that we have been dealing not merely with a simple transudation, but with an inflammatory process as well. If the fluid be drawn off, it may be considered non-inflammatory when it contains no fibrin, is of low specific gravity (1014 or less), and is feebly albuminous (2½ per cent. or less of albumin). If, however, it contains 4 per cent. or more of albumin, or the specific gravity reaches 1018, it is of inflammatory origin.

Empyema may follow acute or chronic pleurisy with sero-fibrinous exudation, in which a constantly increasing number of round cells is developed, gradually converting the whole into a purulent exudation. In particular, this result may quickly follow when through any means—for example, a paracentesis not made aseptically, or during the performance of which, air is allowed to enter the chest—pyogenic microbes are introduced. Suppuration often occurs, however, without ascertainable extraneous infection, and in many cases the pleuritis assumes from the first a purulent form. The latter condition, according to Liebermeister, is by no means so uncommon as recent writers assert. It occurs in traumatic disease, when the thorax is penetrated and air or foreign bodies enter the pleural sac; in inflammation following suppurative processes in neighboring structures, whether through perforation or extension by continuity of tissue; in the pleuritis of pyæmia or puerperal fever, whether as a sequel to metastatic abscesses in the lung or without the development of such abscesses; in variola and scarlatina, and, less often, in other similar infections. Finally, in the form which accompanies pneumonia, the exudation is so frequently purulent from the first, that ground is given for the opinion that the same microbe which excites the pulmonary inflammation is the direct cause of the accompanying pleurisy. In children, as is a matter of everyday observation, purulent pleural exudations are more common than in older persons.

Concerning physical diagnosis, Liebermeister can give us no means of discriminating between

purulent and non-purulent effusions. Auscultatory signs, he believes, depend less on the qualities of the exudate than upon the condition of the bronchioles in the compressed lung. This accords with our own experience. In the absence of external evidence of abscess, or the formation of a fistula, the hectic fever, emaciation, and rational signs of suppuration suggest the diagnosis, and finally exploratory puncture confirms it. When the presence of purulent effusion is not detected, and the collection of pus is allowed to remain undisturbed in the pleural cavity, the consequences are serious, and, in the majority of cases, fatal. Penetration of pus into a bronchus with evacuation by cough, is said to be the least unfavorable route for spontaneous discharge. Penetration externally, with formation of subcutaneous abscess, however (*Empyema necessitatis*), is by no means an unmixed evil, for it has, in instances which have come under our own observation, led to incision of the fluctuating swelling in the back or side, and thus to the recognition and proper treatment of the previously unrecognized condition. Nevertheless, the practitioner who is not too busy to examine his patients, will not willingly trust the unassisted efforts of nature to secure evacuation of the pus, but will proceed to remove it as soon as he has made himself aware of its presence.

The questions as to the best method of operation, whether by puncture or free incision, and the details of the procedure; as well as those bearing upon the indications for removal of non-purulent effusions, demand consideration in another article.

LIKENESS AND UNLIKENESS.

The shades of resemblance between the denizens of the various natural kingdoms are infinite, and it is this pleasing variety which stimulates the devotee of science to new research and prevents his work from being rendered stale by custom. It is this, also, which, in common with the "personal equation," leads to the greatest differences of opinion in every field of research and more particularly if the field is microscopic.

A recent number of The Medical News contained an editorial on the effect of heat upon the red blood-corpuscles, and warned against the possible mistake of confounding the changes thus induced with those caused by the hæmatozoon malariæ. The article elicited a reply from a learned and distinguished *confrère*, who states that these effects of heat are well known to the expert, and are not likely to be misunderstood by anyone not a tyro.

When, however, it is recalled, first, that the number of experts in such matters is very small; secondly, that it took them a long time to confirm the observations of Laveran, and, thirdly, that one of the best known among them at first pronounced the malarial changes in the red corpuscles to be nothing more than vacuoles, it becomes evident that our warning, which was given for the benefit of all, and not for the few, was well timed.

REVIEWS.

A Treatise on Materia Medica, Pharmacology, and Therapeutics. By John V. Shoemaker, A.M., M.D., and John Aulde, M.D. 8vo., pp. 353. Philadelphia and London: F. A. Davis, 1889.

The authors of this treatise have evidently struggled for originality, with a result which, to say the least, is somewhat peculiar. Their classification of drugs is exceedingly confusing, and in some instances misleading. For example, "alkaline or antacid medicines" are divided into (1) "direct alkaline remedies," including solution of potash and bicarbonate of sodium; (2) "direct, but not remote," including solution of ammonia, and, for some inexplicable reason, charcoal; and (3) "remote alkaline remedies," including salts of potassium and sodium with a vegetable base. Alum, sulphate of iron, perchloride of iron, oxide of zinc, oil of turpentine, creasote, and carbolic acid are placed in a list of the mineral acids, an innovation which we think demands an explanation. Digitalis is considered as a vascular sedative and grouped with aconite, hydrocyanic acid, tobacco, etc. On the next page we find a list of so-called "vascular tonics" (not vascular stimulants, which are elsewhere considered, with no mention of digitalis), among them acids, astringents, alcohol, iron preparations, ammonia, and digitalis *again*. Such a system, or rather want of system, cannot be other than confusing and discouraging to medical students.

Inaccurate statements show that the book has been either hastily or carelessly prepared. For instance, in discussing asthma it is stated that "Dr. Bosworth gives a tabulated account of eighty cases treated mainly by the insufflation of cocaine, and with marked success." Bosworth's eighty cases were *not* treated mainly by cocaine, but by cauterization, septum operations, removal of polypi, adenoid growths, etc. The authors probably had in mind a previous paper of Bosworth in which he said that intra-nasal applications of cocaine *relieved* the asthmatic paroxysms.

Another unfortunate feature of the treatise is the frequency with which the authors state their own beliefs dogmatically as facts, without qualification or supporting evidence.

The most useful sections are those upon alimentation and electricity, which are fairly complete and instructive. There are also interesting descriptions of hypnotism,

earth dressings, climatology, and several other therapeutic agents not usually considered in text-books.

The book could have been greatly improved by judicious pruning, by closer attention to the rules of composition, which are sadly neglected, and by the avoidance of unnecessary digressions; and it is to be hoped that the authors will make these changes should the volume ever reach a second edition.

A Text-book of Human Anatomy: Systematic and Topographical, including the Embryology, Histology, and Morphology of Man, with Special Reference to the Requirements of Practical Surgery and Medicine. By Alexander Macalister, M.A., M.D., F.R.S., F.S.A. Philadelphia: P. Blakiston, Son & Co., 1889.

This is, in many respects, a remarkable book, comprising as it does the outcome of modern scientific methods as applied to human anatomy. To the student interested in morphology and embryology it will be most valuable, as it embraces in all their essential details the facts pertaining to these departments of study in their relation to the various regions of the body considered topographically.

The thoroughness and perspicuity with which the whole subject is treated are impressed upon every page, and testify to the well-earned reputation of the author.

As a book of reference for the advanced student or practitioner, it will prove very useful; but to the beginner or ordinary student of medicine, it cannot be recommended as a text-book.

The endeavor to conform to the exact technicality of modern scientific expression and the substitution of new descriptive terms for older and less accurate ones, while it may be a satisfaction to the mind of the author, will not render the difficult study of anatomy any easier, unless it has been preceded by a more careful scientific training than most of our colleges afford.

The ordinary names of parts and distinctive terms, which long usage have rendered characteristic, are hard enough to comprehend and acquire, but have, by their very individuality, a power of arresting the attention of the learner, besides possessing the historic value to which Professor Macalister refers.

We would especially call attention to the chapter on *cranio-cerebral topography*, where, besides referring to the divergence of the angle between the Rolando-auricular and ecto-cantho-Rolandian lines, and similar typical expressions for determining the relations of brain surface and bone surface, the author makes the really important statements that "the relations of the convolutions to the surface markings are variable within many wide limits," and "that all systems of definite measurements must be taken with limitations." This is well worthy the emphasis put upon it, in refutation of the assertions not uncommonly met with in the medical writings of the day, by which the uninitiated would be induced to believe that any clever surgeon can put his finger over the exact spot where a cerebral lesion exists.

The illustrations are numerous, and—with the exceptions of those showing the bones and muscles—well chosen. The original diagrams are excellent.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Section on Pædiatrics.

Stated Meeting, April 10, 1890.

L. Emmett Holt, M.D., in the Chair.

Dr. F. M. Crandall presented a urethral calculus which he had removed from a child three years old. Although the child had passed very little urine for seventy-two hours previous to the removal of the obstruction, the chief symptom for which the mother had sought advice was a continuous forcing down of the rectum. The calculus was situated one-fourth of an inch from the meatus.

Dr. I. H. Hance presented a renal calculus which had been removed post-mortem from a baby of twenty months, who had presented no symptoms of such trouble. There were no signs of pyelitis found. The question arose as to whether it was congenital, which the size of the stone seemed to indicate.

The Chairman reported two cases of

ACUTE PRIMARY PNEUMONIA IN INFANTS, WITHOUT FEVER.

In neither case were any of the usual symptoms of pneumonia present, and yet the post-mortem examination, both macroscopical and microscopical, showed the characteristic lesions of pneumonia.

Dr. A. Jacobi said that the description of the microscopical appearances in these cases indicated that the pneumonia was not a secondary process. Pneumonia, with but little rise of temperature, was noticed in very young and in very old subjects, in young infants whose vitality had been impaired by previous disease, and in the cases with brain symptoms at the beginning of the disease.

The discussion on

THE USE OF SPIRITS AND MALTED DRINKS IN NURSING WOMEN

was opened by Dr. A. Jacobi. He said that a proper understanding of the subject necessitates a consideration of the nature of the mammary secretion, and the circumstances under which it might become mixed with drugs or other substances found in the circulation. It is well known that various substances of this nature have been found at times in human milk; but the results of such observations have often been conflicting. These discrepancies, however, can be reconciled by an application of our knowledge of the physiology of lactation. Milk, so far as its chief solid ingredients are concerned, consists of the transformed cells of the mammary glands. It contains a considerable quantity of potassium, phosphate of lime, a very little chloride of sodium with casein, milk sugar, and more fat than is found in the blood. If the change in the mammary epithelium is incomplete, the resulting secretion is not milk, but colostrum; and the condition of the gland itself influences the quality of the milk much more than any single article of diet. But the general health, emotional condition, and the period of lactation all profoundly influence the quality of the secretion, and may, by causing its deterioration, lead to an ad-

mixture of the milk with transuded blood serum. This "transudation milk" often contains medicinal substances found in the circulation; and hence, a dose of opium which in the later months of lactation would have no effect upon the child, might, if administered immediately after confinement, while the colostrum is still being secreted, exert a dangerous influence upon the nursling. A similar state is induced by sudden and violent emotions. Applying this knowledge to the topic under discussion, it is seen that while the mammary secretion is of proper quality, alcohol might be taken without affecting the child in any way; but a deterioration of the milk might be accompanied in some cases by unpleasant symptoms referable to the alcohol which had been taken by the nurse. The literature of this subject is very scanty, and many of the modern observations lack scientific precision. In 1853 Becquerel announced as the result of a series of observations, that children of nurses who took alcohol freely exhibited somnolence, restlessness, and occasionally convulsions. Stumpf concluded, as the result of his researches, that the quantity of milk was not influenced by the presence of alcohol, and he added that he knew of only one remedy which would increase its quantity, and that was salicylate of sodium. This is in accordance with Dr. Jacobi's own experience with the effect of salicylate of sodium upon other secretions, notably that of the liver. He considers it the most reliable remedy in our possession for preventing the formation of gall-stones. He thought the use of alcohol by nursing women should be forbidden, except where there is a definite indication for its use as a medicine. Ordinarily, women require about 90 grammes of albumin daily, but when nursing, this amount increases to about 150 grammes; and the additional quantity is to be supplied by a liberal diet of meat and milk.

Dr. E. L. Partridge was of the opinion that the quantity of milk could be decidedly increased by the use of malted drinks; and he thought this was brought about partly by the larger quantity of fluid ingested, and partly by its beneficial effect upon the maternal nutrition. He did not, however, approve of this "high-pressure nursing" any more than he approved of a broker sustaining his strength, amid excitement, by the use of tobacco and alcohol. Such nursing is likely to bring on functional disorders of the heart and pelvic organs, and it is entirely unnecessary in these days of improved artificial infant foods. Many women with deficient milk are improved by anything which they firmly believe is capable of rendering the desired assistance; and this knowledge can often be turned to good account to tide a nervous, apprehensive patient over a critical period. It is on this principle that he explained the good effect which he had observed to follow the use of a much-vaunted preparation. He believed its therapeutic virtues were to be found in the positive assurances of its efficacy, as stated on the label. There is no good reason for depriving those long accustomed to the use of malted drinks of their accustomed beverage, and there is no advantage in beginning the use of alcoholic drinks during lactation, except for medicinal purposes.

Dr. A. Seibert said that in the discussion, so far, the *rôle* played by the bacteria found in alcoholic beverages had been entirely ignored. Many of the poorer classes drink large quantities of stale beer, which he had often seen affect the child very unpleasantly. It was his custom, therefore, whenever a child was taken sick with a gastro-intestinal disorder, to forbid the use of beer by the mother.

Dr. E. H. Grandin has always been in the habit of allowing malt liquors to such nursing women as seemed to need a stimulant; and although he has had excellent opportunities for observing the effects of beer-drinking, he has never been able to trace any injury to the child from the moderate use of such liquors. He thought that both the quantity and the quality of the milk had been improved by such treatment.

Dr. Jacobi, in closing the discussion, remarked that there seemed to be a pretty general agreement upon the statement that liquors were unnecessary, and for the most part injurious when used by nursing women; although they might be required as medicinal agents to aid in some cases in the digestion of the large quantities of carbo-hydrates necessary for the proper nutrition of the nurse.

CORRESPONDENCE.

SHORT-WEIGHT QUININE CAPSULES.

To the Editor of The Medical News,

Sir: My attention having been called to the very evident short weight of some quinine capsules in the market, I determined to investigate the matter. I had believed that the present low price of quinine had removed all incentive to the placing of short-weight capsules on the market, but my investigations have convinced me that such capsules are even now offered for sale. Whether their existence is due to intentional fraud or to gross carelessness I cannot say, but I feel that the attention of the medical profession should be called to the existence of such capsules. These capsules were bought in the market in Detroit in original packages. Each package consists of a tin box, on the uppermost surface of which is a yellow label bearing the following: "Keep in a cool, dry place. Superior gelatin elastic capsules. Prepared from extra French gelatin. The drugs are the best that can be procured. Manufactured by the Merz Capsule Company, Detroit, Mich." On the end of the box is a small white label, bearing the following:

"106.—Quinine sulph. . . . 3 grains.
Capsicum . . . . 1–3 grains."

I obtained four of these boxes, which I will designate by the numbers 1, 2, 3, and 4. In box No. 1 the capsules were not elastic, but were hard. This box contained originally 104 capsules. The short weight of these was easily determined. Twelve of the capsules, taken at random, weighed, gelatin and contents together, 1.858 grammes or 28.67 grains, or a little less than 2.4 grains each. There could be no doubt about short weight in these. The actual amount of quinine in each of 12 capsules was determined as follows: The contents of each capsule were placed in a weighed one-ounce Erlenmeyer flask. The gelatin was washed free from quinine with absolute alcohol, the alcohol added to the quinine in the flask, the alcohol evaporated at a low

temperature, and then the flask, with its contents, was dried at 105° C. to a constant weight. The weight of the anhydrous quinine sulphate multiplied by the factor 1.193 gives the weight of crystallized sulphate, allowing 8 molecules of water of crystallization, the highest amount of water allowed by the U. S. Pharmacopœia. The following table will show the result of these determinations:

No. of capsule	Weight of flask.	Weight of flask and anhydrous quinine sulphate.	Weight of anhydrous quinine sulphate.	Weight of crystallized quinine sulphate.	Weight of crystallized quinine sulphate
	Grammes.	Grammes.	Milligram.	Milligram.	Grains.
1	16.616	16.664	48	57.3	0.88
2	15 310	15.355	45	53.7	0.83
3	13.162	13.200	38	45.3	0.70
4	16.350	16 395	45	53.7	0.83
5	14.405	14.458	53	63 2	0.98
6	11.525	11 567	42	50 0	0.77
7	13.193	13.250	57	68.0	1.05
8	17.408	17.445	37	44.0	0 68
9	12 247	12.299	52	62.0	0.96
10	14.901	14.945	44	52 4	0.81
11	12.248	12.297	49	58.4	0.90
12	13.540	13.594	54	64.4	0 99

It will be seen from the above figures that the average amount of quinine is less than one-third of that which the capsules are advertised as containing. So much for the quinine; how about the capsicum? The contents of several capsules were dissolved in water with the aid of dilute sulphuric acid, and *not the smallest trace of capsicum could be found.*

In box No. 2 the amount of quinine was found to be larger than in the capsules from box No. 1, but again no capsicum could be detected. The method of determining the amount of quinine was the same as given above, and in order to save space I will only report results:

Capsule No.	1 contained	. . .	2.28	grains.
" "	2 "	. . .	2.23	"
" "	3 "	. . .	2.28	"
" "	4 "	. . .	1.85	"
" "	5 "	. . .	2.48	"
" "	6 "	. . .	1.46	"
" "	7 "	. . .	2.03	
" "	8 "	. . .	1.69	"
" "	9 "	. . .	2 47	"
" "	10 "	. . .	1.54	"
" "	11 "	. . .	1 50	"
" "	12 "	. . .	1.22	"

The capsules in boxes Nos. 3 and 4 contained capsicum, and the amount of quinine sulphate was determined as follows: Each capsule was placed in a clean one-ounce Erlenmeyer flask, 5 c.c. of distilled water, and 2 drops of dilute (1 : 5) sulphuric acid added. The flasks were then kept at 38° C. until the capsules had dissolved. The acid solution was then shaken with ether, and after separation the ether was removed and discarded. The contents of the flask were now rendered alkaline with a ten per cent. solution of sodium hydrate, and extracted twice with 25 c.c. of absolute ether. Ths ether was placed in weighed Erlenmeyer flasks and kept at 30° C. until the ether had evaporated, then heated at 105° C to a constant weight. The weight of the anhydrous quinine multiplied by the factor 1.3734 gives the weight of crystallized sulphate of quinine with 8 molecules of water of crystallization $(C_{20}H_{24}N_2O_2)_2H_2SO_4$, $8H_2O$.

Twelve capsules taken at random from box No. 3 contained the following amounts of crystallized sulphate of quinine:

Capsule No.	1 contained	. . .	2.62	grains.
" "	2 "	. . .	2.54	"
" "	3 "	. . .	3.01	"
" "	4 "	. . .	2.96	"
" "	5 "	. . .	2.43	"
" "	6 "	. . .	2 22	"
" "	7 "	. . .	1.93	"
" "	8 "	. . .	2.78	"
" "	9 "	. . .	2.39	"
" "	10 "	. . .	1.99	"
" "	11 "	. . .	1.95	"
" "	12 "	. . .	2.30	"

Twelve capsules taken at random from box No. 4 contained the following amounts of crystallized sulphate of quinine:

Capsule No.	1 contained	. . .	2.62	grains.
" "	2 "	. . .	2.57	"
" "	3 "	. . .	2.53	"
" "	4 "	. . .	2.17	"
" "	5 "	. . .	2 86	"
" "	6 "	. . .	1.65	"
" "	7 "	. . .	2.16	"
" "	8 "	. . .	3.01	"
" "	9 "	. . .	2.86	"
" "	10 "	. . .	1.76	"
" "	11 "	. . .	1.74	"
" "	12 "	. . .	1.63	"

It will be seen that, out of 48 capsules assayed, only 2 contained the amount of quinine claimed on the label.

Respectfully, V. C. VAUGHAN, M.D.

UNIVERSITY OF MICHIGAN, ANN ARBOR.

THE EFFRONTERY OF PROPRIETARY MEDICINE ADVERTISERS.

To the Editor of THE MEDICAL NEWS,

SIR: Two notable instances of the unscrupulous methods of pushing proprietary medicines have lately presented themselves which should be held up as a warning to those who permit their names to be used by advertisers.

A few weeks ago I received a folded card, which was widely distributed to the profession, on the outside of which was printed, in large capitals, "BELLEVUE HOSPITAL MEDICAL COLLEGE." This appeared like an official issue by the College. It contained the following: "The expressions of the Medical Profession regarding the efficacy of 'Vin Mariani' in therapeutics can be summarized as follows:

"As a tonic in laryngeal and gastric complications; as a diffusible stimulant in anæmia, nervous depression, melancholia, tardy convalescence, general 'malaise,' and in all those cases in which there is much depression and atony.

"Topically in convulsive cough, laryngitis, stomatitis, etc.

"We refer by kind permission to the following physicians, members of the Alumni of Bellevue Hospital College."

Then follow the names of 142 physicians residing in

different cities. Like circulars were distributed with the headings, "Jefferson Medical College" and the "University of Pennsylvania," and I am told that the names of other reputable colleges have been used in the same way. However these signatures may have been obtained, I venture to say that no one of the signers imagined that his name would be used in a broadcast advertisement, apparently issued with the approval of the college from which he had been graduated. This advertisement should teach the profession a lesson of the danger of giving testimonials under any circumstances. In the first place, no reputable physician makes use of testimonials, this method of advertising being confined to charlatans. In the second place, few if any can testify, from their own knowledge, to the truth of statements with regard to proprietary medicines. I think, also, that the profession does not now regard it as safe to put in the hands of patients, for use according to their own judgment, preparations containing cocaine. As a matter of fact, the enterprise shown by the Mariani Company will probably prevent those whose names have been used from prescribing the "wine," and will have a like influence on the alumni of the colleges the names of which have been used.

The other instance of effrontery in advertising is in the case of the "Lactopeptine Medical Annual" sent as an advertisement by the "New York Pharmacal Association." In this remarkable publication are process-reproductions of photographs of some of the professors in the Bellevue Hospital Medical College. The New York Homœopathic Medical College, the Medical Department of the University of Pennsylvania, the American Medical College (Eclectic) of St. Louis, and the College of Physicians and Surgeons, of Chicago, are treated in the same way. These colleges are therefore presented as giving countenance to the "Lactopeptine" remedies.

The publication of my portrait in the "Lactopeptine Medical Annual" is my excuse for a notice of the claims for "Lactopeptine" as a therapeutic agent. It is advertised that "Lactopeptine contains the five active agents of digestion—pepsin, ptyalin, pancreatin, lactic acid, and hydrochloric acid—combined in the same proportion as they exist in the human system. These digestive agents comprise all known substances employed by nature in the preparation of food for assimilation."

Let it be assumed that the pepsin has been extracted from pigs' stomachs by the best methods, and even that the ptyalin is pure, which is very improbable. According to the best authorities, ptyalin acts only in a neutral, or an alkaline medium. It is destroyed by hydrochloric acid, or by digestion with pepsin. Lactopeptine contains hydrochloric acid, or, if the pepsin be active, the influence of ptyalin must be *nil*. There is no such substance as pancreatin. The digestive constituents of the pancreatic juice are amylopsin, trypsin, strapsin, and a milk-curdling ferment. It is difficult to imagine that all these are contained in lactopeptine. Amylopsin is supposed to be identical with ptyalin, and all conditions which affect the action of ptyalin have a similar influence on amylopsin. The protolytic action of trypsin takes place in an alkaline medium only, and never in the presence of acids. An artificial digestive agent containing hydrochloric and lactic acids and trypsin is an impossibility, so far as any action of trypsin is concerned. Strapsin is a very unstable substance, and nothing need be said with regard to its possible action or the action of a milk-curdling ferment, as these substances exist, if they do exist, in such a compound as lactopeptine purports to be.

Lactopeptine, so called, as an aid to digestion, is a physiological absurdity. Anyone who prescribes it in digestive disturbances, does so in opposition to universally accepted facts in physiology and sound therapeutic principles. Austin Flint, M.D.

VIENNA.

To the Editor of The Medical News,

Sir: There have been some changes in the medical faculty here that are worthy of mention. The famous physiologist, Professor Brücke, now more than seventy years old, has become tired of the strain of a professorship and has resigned. The faculty thus lose one of their brightest lights, for his name stands high in the annals of physiology. The faculty have selected Professor Exner, now extraordinary professor of histology, as his successor—subject to royal approval. Dr. Buecz-asy, whom many Americans remember as Schnitzler's first assistant in laryngology, and who was one of our favorite teachers, has also resigned; it is said that he may conduct private courses on throat and nose later in the season.

At present there are two University clinics in internal medicine—Nothnagel's and Kahler's, and Parliament has decided to erect a third, with Schrötter as Professor and director. For the two surgical clinics—Billroth's and Albut's—more room is to be given in the spring.

One of the most interesting clinics here is Neuman's on skin and syphilis. He shows about six cases a day, has them stripped entirely naked, and standing on an elevated platform before the class. He shows men and women on alternate days, and gives excellent demonstrations, paying special attention to the genitals, and giving most of the men present a chance to examine each case. Neuman is very witty, and constantly joking with his patients. Partly because he is such an excellent teacher, and partly because he is popular, his courses are very well attended.

Professor Monti gives one of the best courses in Vienna on diseases of children. Though he speaks miserable German, he gives points of great practical value, shows very interesting cases, and demonstrates them in such a manner that children's diseases become a fascinating study. He states that of the 6000 cases annually treated in his clinic four-fifths are rhachitic, and as he has thoroughly tried the phosphorus treatment without satisfactory results, he condemns it. Hygienic treatment, with abundant fresh air, is the only means that he employs for relieving the disease. In croup he gives salicylate of sodium, quinine, or morphine *pro re nata*, but insists that shortening of the disease or a cure has never taken place. Last week he showed us a case of congenital pemphigus. The child was three months old and was literally covered with vesicles, the back being one huge blister, the heels and palms denuded of epithelium by the breaking of the vesicles, and the patient presented a horrible spectacle. It had pneumonia in addition, and showed all the signs of chronic dyspepsia.

Professor Reuss has a new method of treating kera-

titis, based on the following reasoning: Atropine and all mydriatics contract the iris and increase intra-ocular pressure. Eserine and myotics lessen the intra-ocular tension. In keratitis if we can increase the blood-supply to the inflamed spot in the cornea we shorten the process and prevent its spreading; and by reducing intra-ocular tension we open the spaces between corneal layers and allow blood to circulate more freely. Hence in simple keratitis he always uses myotics. When, however, perforation threatens and iritis is a complication, he asks: Will synechiæ do more harm as regards the usefulness of the eye, in that particular case, than large *maculæ corneæ*, and on the answer bases his treatment. If the *maculæ* be in the centre, and a subsequent iridectomy gives better chances for good vision, he continues eserine, caring nothing about synechiæ; but if the *maculæ* be near the limbus, preservation of a good pupil becomes the leading indication, and atropine must be used. As an antiseptic for the corneal wounds, and when the inflammation has disappeared, he uses calomel or iodoform.

The Paris *Journal de Médecine* accuses Pasteur of issuing incorrect reports upon his work in hydrophobia. It states that he reports but eleven deaths, while the records show twenty-six, and that taking the real ratio of deaths to cases treated his results are no better than those of ordinary treatment. Dr. Rascol, of Murat, even accuses Pasteur of introducing the disease and directly causing the death of one of his patients. Two men had been bitten by the same dog at the same time. The more severely injured man was treated at home, was not inoculated, and recovered; the other was sent to Pasteur, and soon died of hydrophobia after the inoculation treatment. We hear nothing about Pasteur here now—a suggestive silence.

The Americans here have had many a laugh about the telegraphic reports in American papers, especially in the *New York Herald*, concerning the influenza bacillus. It is now settled that no new bacterium was discovered as a cause of influenza. There is no Professor Jollies in Vienna, so the wide-awake reporter was slightly mistaken, or perhaps the victim of a practical joke, and his whole story, as the *Herald* told it, was simply a newspaper canard.

It is another proof of how little reliance can be placed on telegraphic reports concerning scientific work.

There have been a number of rare and interesting cases here lately. A few days ago Albert operated for the removal of an ovarian tumor; there were all the physical signs of ovarian cyst, yet when it came to ligating the pedicle it was discovered that the growth was a true uterine cyst, not resulting from partial central necrosis of a fibroma. There are but few similar cases on record. Dr. Hochenegg, Albut's first assistant, also showed us a peculiar case. An old woman, whose son had died of tubercular caries, had nursed him during his illness and had scratched her finger on a spicula of diseased bone. This was two years ago, and now her index finger, the one then injured, shows a typical tuberculous ulcer. Along the dorsum of the hand and forearm there is a well-marked chain of hard lymphatics, the ducts are evident to touch, like strings, while the glands feel hard and as large as cherry-stones. It is strange that but one chain of lymphatics exists, and that in this case they should be so hard from tuberculosis, when generally tubercular infiltration causes degeneration. The etiology is so clear that an operation removing the finger and extirpating all the glands is advised.

Hochenegg has introduced a new operation into gynecology for removal of the uterus in severe cases of cancer. It is a modification of Kraske's operation for removal of the rectum from behind. He makes a crescentic cut with the convexity upward, from the left sacro-iliac synchondrosis to one inch to the right of the end of the coccyx. Cutting down to the bone and dissecting back the coccyx, about one inch of the latter is chiselled off. This gives a free opening for working on the rectum—so far Kraske's method. Now, Hochenegg goes in between the rectum and cellular tissue, pushing the former to one side, and thus reaching the uterus, which can, with the infiltrated tissues around, be easily extirpated. The great advantage is plenty of light and room for working, the ease with which hæmorrhage can be controlled and all the diseased parts can be seen and removed. Of course, the severity of the operation makes it advisable only when the neoplasm is so large and the infiltration so great that colporo-hysterectomy or laparotomy would not give sufficient room to remove the whole mass. He has operated in eight cases, in all of which operations were declared impossible by the gynæcologists here, and has had seven recoveries; certainly a brilliant result.

Professor Rydygier, of Krakau, has a new treatment for uterine fibroids, when the patients refuse to submit to oöphorectomy or excision of the tumor. He simply ties all the arteries entering the growth—of course, after laparotomy—and reports good results in several cases.

We had an interesting case in Nothnagel's wards last week. An old woman who had had a scirrhus of the breast removed ten years before, was perfectly well until several months ago. Since then she has gradually grown weaker, has noticed that she could not walk in the dark or with closed eyes, and that her legs were becoming numb and too feeble to carry her weight. In her legs sensation is perfect, the patellar reflex almost absent, muscular sense good; but voluntary motion markedly feeble. In her arms the reflexes are increased, motor power somewhat diminished, and muscular sense almost gone, so that when she closes her eyes motions with the arms are markedly ataxic. The eye reflexes are all present; there is slight facial paresis on the left side. She has excruciating pains in the spinal column. There is considerable cachexia, and on her back we found a number of hard nodules, which examination showed to be metastatic carcinomata. In the left axilla there is a bunch of hard infiltrated glands, and even in her lower limbs a few nodules exist. No known nervous disease will explain the symptoms of the case, so metastatic carcinomatous nodules in the spinal cord become a probable diagnosis. There are but very few such cases on record, and the excruciating pains in the column were present in all.

On the 14th of April the European Congress for Internal Medicine meets in Vienna, and a large attendance is anticipated, for many of Germany's best clinicians have announced papers and accepted parts in the discussions. Nothnagel is President.

Another former assistant of Billroth has reached distinction. Dr. Mikulicz has been appointed successor to the famous Volkmann, at Halle. Other former assistants from this great Vienna clinic are Czerny, of Heidelberg, and Wölfler, of Graz.

NEW YORK.

First Annual Reunion of the Society of the Alumni of Bellevue Hospital.

To the Editor of THE MEDICAL NEWS,

SIR: This active and rapidly growing Society held its first annual reunion on April 8th, 9th, and 10th. The first session was in the evening, and was held in the Mott Memorial Hall. Dr. Charles Phelps presented a very thoughtful and earnest paper on "The Treatment of Simple Fracture of the Patella by Wiring," in which he spoke emphatically against what he considered the excessive conservatism which prevented the general acceptance of this method of treatment. The paper was based solely upon his own extensive experience with this operation. The paper was discussed by Drs. Abbe, Bryant, Dennis, Leale, L. A. Stimson, and Stephen Smith; all of whom acknowledged the excellence of the results obtained by Dr. Phelps; but they were about equally divided as regards the advisability of recommending it to the profession at large as the best method of treating this fracture.

On the morning of April 9th, the Society attended a clinic held by Dr. L. A. Sayre at Bellevue Hospital; and in the afternoon of the same day listened to a paper on "The Ultimate Results of Injuries of the Hip-joint," by Reuben A. Vance, M.D., of Cleveland, Ohio. The paper was discussed by Drs. L. W. Hubbard, R. H. Sayre, J. McG. Woodbury, and J. Ridlon; all of whom looked upon the cases described in the paper as cases of chronic hip-joint disease.

Papers by Drs. John Warren and Brandreth Symonds on "Transient Glycosuria," and "Delicate Tests for Sugar in the Urine," then followed.

These papers referred particularly to the bearing of this condition upon life insurance. There was a lengthy discussion, in which Drs. H. M. Biggs, A. Flint, G. B. Fowler, R. W. Greene, and W. H. Thomson participated. The weight of opinion was in favor of Fehling's test and the fermentation test as being the best for clinical guidance. Drs. Flint and Thomson considered more especially the physiology and pathology of this important but decidedly obscure subject of transitory glycosuria.

The exercises of the day were closed by a banquet held at the Hotel Brunswick, which was very largely attended. The President, Dr. Richard Kalish, delivered a short address, in which he related the circumstances connected with the founding of the Society, and then referred to its rapidly increasing membership, and its present prosperous condition.

Dr. William H. Draper responded to the toast "Old Bellevue," and referred to the days spent there as truly the happiest of his life. He spoke of the many great teachers there in his time, only two of whom, Drs. Barker and Sayre, were still living. He closed his remarks by bidding the Society drink in silence to the memory of "Those who died in the discharge of their duty." Rev. S. MacArthur, D.D., responded to "The Parson." He spoke of the power and influence wielded by a well-rounded character, and of the importance of a good preliminary, as well as a complete professional education. He said that this country must soon have a true University, which would probably be located in New York City. Speaking of the personal characteristics of "the parson" and "the doctor," he urged that both should be more careful to bring into the sick-room a flood of sunlight rather than gloomy forebodings. Dr. A. L. Loomis, in responding to "Progressive Medicine," remarked that it was a very hackneyed subject; but he treated it nevertheless in a novel manner, pointing out, as evidences of this progress, the higher fees now obtained; our less frequent wrangling with the homœopaths, who, in consequence, were busily engaged in cutting each other's throats; the use of trained nurses; and the establishment of gynæcology as a separate and lucrative speciality. "The Law" was responded to by Frank Loomis; "The Patient" by Charles B. Alexander; "The Press" by Chester A. Lord. President H. H. Porter, in responding for "The Commissioners," said that he had always endeavored, although often in the face of great obstacles, to advance the best interests of Bellevue Hospital. "Bellevue Hospital in its Relation to Medical Education" drew forth from Dr. Austin Flint the fact that as long ago as 1807 Bellevue Hospital was mentioned, and that in March, 1848, the new amphitheatre was opened, and the first clinic held in it by Professor Van Buren. After the establishment of the Board of Commissioners of Charities and Correction in 1860, the progress of the hospital was much more rapid. Many successful and brilliant men had been graduated from that institution; but he did not favor the extensive preliminary education demanded by some, as he thought such a provision savored of old educational ideas which were not applicable to the present times. Dr. William M. Polk then drew a vivid picture of the old-time Bellevue nurses, and contrasted them with the educated and skilful ones of to-day. He thought that they might prove a very important factor in case of pestilence or war.

This interesting series of meetings ended with a clinic in Bellevue Hospital given by Professor W. T. Lusk. An exploratory laparotomy was performed; and then a demonstration was given of Mr. Tait's operation for ruptured perineum.

NEWS ITEMS.

Niagara University Commencement.—On April 15th the Medical Department of Niagara University graduated a class of fifteen. This school has a three years' graded course.

Legacy to the New York Post-graduate Medical School and Hospital.—Among the legacies of the late Hon. Daniel B. St. John, of Newburgh, N. Y., was one of ten thousand dollars to the above-named institution.

Prostatic Operations.—Dr. William T. Belfield, 612 Opera House Building, Chicago, Ill., U. S. A., solicits information concerning unpublished cases of operations upon the prostate, especially for the relief of the so-called hypertrophy of the organ.

A Study of Diabetic Urine.—The undersigned, who is desirous of making an original research of the constituents of the urine in diabetes mellitus, *especially of acetone* and its supposed relations to the *coma diabeticum*, would be under obligation to any physician who would let him have the urine of such patients.—G. METZLER, University of Pennsylvania, 36th and Woodland Avenue, Philadelphia.

The Philadelphia Polyclinic Hospital.—The Board of Trustees of the Polyclinic Hospital at their regular meeting on April 21st created an additional Chair of Gynæcology, and elected W. H. Parish professor to that chair. W. H. Sudduth, M.D., D.D.S., was elected Professor of Pathology and Dentistry.

The Building Committee reported that contracts had been awarded for $37,430, and that work on the portion of new building, Eighteenth and Lombard Streets, would be completed prior to June 1st; and that $11,560 would be needed to finish the interior ready for occupancy in September. To meet this amount Mr. Theodore Kitchen, Mr. C. C. Roberts, John B. Roberts, M.D., and the Ladies' Aid Society started a subscription paper for $250 each. A similar paper has been started for running expenses, and already fifteen names were down for $150 each as an annual contribution.

To avoid the delay in waiting for money to be contributed, Mr. Charles B. Baeder offered to loan, without security, the amount necessary to push the new building on to completion without delay.

The Treasurer's report showed:

Cash on hand	$4424	
Invested funds	5680	
R. J. L. testimonial free bed fund	3580	
Due from State, last instalment	2500	
		$15,184
Liabilities for new building		15,000
Maintenance		2000

The recent investigations of charitable institutions had stimulated the trustees to institute a most searching investigation into the minute details of the Polyclinic Hospital. The House Committee reported that it had weekly inspected every part of the present temporary building, and could not too highly commend the efficient services of the matron and the apothecary.

The Ladies' Aid Society had been most efficient during the past three months by untiring devotion to their work. A large amount of money is now in their treasury for the children's play-room, the children's ward, and the bed for cripples.

A very successful tea was given at the Hotel Stratford on the evening of April 21st for the benefit of the building fund.

Vital Statistics of New York City in 1889.—The annual report of the Health Department shows that there were 39,583 deaths in New York City in 1889. The population being taken at 1,571,000, the death-rate was 25.1 per 1000. There were only 37,527 births recorded; marriages 14,400. Of smallpox there were two cases, with one death. There were 1414 cases of typhoid fever reported, and 351 deaths; 8849 cases of scarlet fever, and 1163 deaths; 6489 cases of diphtheria, and 1734 deaths; 6443 cases of measles, and 452 deaths; 128 cases of cerebro-spinal meningitis, and 110 deaths. The number of vaccinations was 74,500. The summer corps of physicians visited 34,500 houses, and prescribed for 16,150 sick persons.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM APRIL 22 TO APRIL 28, 1890.

By direction of the Secretary of War, ROBERT H. WHITE, *Major and Surgeon*, now on duty at Fort Myer, Virginia, will report in person to the Superintendent of the U. S. Military Academy, West Point, New York, for temporary duty as Post Surgeon during the absence of Henry McElderry, Major and Surgeon, as a member of the Army Medical Board, New York City. Upon the return of Major McElderry to duty at West Point, Major White will return to his proper station.—Par. 4, *S. O. 94, Headquarters of the Army, A. G. O.*, April 22, 1890.

By direction of the Secretary of War, the following changes of stations of officers of the Medical Department are ordered:

KILBOURNE, HENRY S., *Captain and Assistant Surgeon.*—From Vancouver Barracks, Washington, to Willet's Point, New York.

GRAY, WILLIAM W., *Captain and Assistant Surgeon.*—From Fort Maginnis, Montana, to Fort Sherman, Idaho.

BANISTER, JOHN M., *Captain and Assistant Surgeon.*—From Fort Sherman, Idaho, to Fort Stanton, New Mexico.—Par. 1, *S. O. 93, A. G. O.*, April 21, 1890.

RAYMOND, HENRY I., *Captain and Assistant Surgeon* (Newport Barracks, Kentucky).—Is hereby granted leave of absence for twenty-five days, to commence on or about May 2, 1890.—Par. 5, *S. O. 91, Division of the Atlantic*, April 19, 1890.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING APRIL 26, 1890.

SCOFIELD, W. K.—Commissioned a Medical Director from February 8, 1890.

MCMURTRIE, DANIEL.—Commissioned a Medical Inspector from February 8, 1890.

BOGERT, E. S.—Commissioned an Assistant Surgeon from April 16, 1890.

SPRATLING, D. W.—Commissioned an Assistant Surgeon from April 16, 1890.

MARTIN, H. M., *Surgeon.*—Reported his return home, and granted sick-leave.

WOOLVERTON, T., *Medical Inspector.*—Detached from the Navy Yard, Washington, D. C., and wait orders.

BEYER, H. G., *Passed Assistant Surgeon.*—Ordered to delay reporting on board the "Yantic" until further instructed.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FROM APRIL 7 TO APRIL 19, 1890.

FESSENDEN, C. S. D., *Surgeon.*—To proceed to Marion, Ky., on special duty, April 16, 1890.

BAILHACHE, P. H., *Surgeon.*—Detailed as Chairman of the Board for Physical Examination of Officers of Revenue Marine Service, April 12, 1890. To proceed to Portland, Oregon, Tacoma, Seattle, and Port Townsend, Wash., as Inspector, April 16, 1890.

HUTTON, W. H. H., *Surgeon.*—Detailed as Chairman of the Board for Physical Examination of Officers of Revenue Marine Service, April 10, 1890.

LONG, W. H., *Surgeon.*—To proceed to Marion, Ky., on special duty, relieving Surgeon Fessenden, April 18, 1890.

KALLOCH, P. C., *Passed Assistant Surgeon.*—Detailed as Recorder of the Board for Physical Examination of Officers of Revenue Marine Service, April 12, 1890.

MAGRUDER, G. M., *Assistant Surgeon.*—Detailed as Recorder of the Board for Physical Examination of Officers of Revenue Marine Service, April 10, 1890.

GUTIERAS, G. M., *Assistant Surgeon.*—To report to the Superintendent of Immigration, New York, for special duty, April 12, 1890.

ORIGINAL LECTURES.

AMPUTATION OF A "TAPIROID" CERVIX. ENUCLEATION OF A UTERINE FIBROID.

A Clinical Lecture
delivered at the Hospital of the University of Pennsylvania.

BY WILLIAM GOODELL, M.D.,
PROFESSOR OF GYNECOLOGY.

GENTLEMEN: I have not seen this patient before, but I have learned the facts of her history from Dr. Taylor, who tells me that she has had five labors—all instrumental, and at all of which the child was born dead. The trouble about which she consults me to-day is an enlargement of the cervix, which protrudes from her body whenever she stands on her feet, and which she takes to be the prolapsed womb. She is, however, wrong in this surmise. The real cause of her trouble is, that in some one of her labors she has received a stellate laceration of the cervix, two of the three tears passing one on each side of the anterior lip, and the third tear passing through the posterior lip, so that the os is divided into three parts. From the congestion set up by this constant irritation there has resulted an unusual hypertrophy of each one of these parts, which is most marked in the anterior. This is five inches long, and it so strikingly resembles the male organ in a state of erection, that a woman with this misfortune might seem to the ignorant to be an hermaphrodite. The elongations of these divisions of the cervix bear a resemblance to the tapir's snout, whence the origin of the expression tapiroid cervix.

What I purpose to do to-day is to amputate this enormous cervix at a point above the cicatricial tissue of the tears. The chief dangers in this operation are penetration of the bladder anteriorly, which would cause a vesico-vaginal fistula, and cutting into Douglas's *cul-de-sac* behind and thus possibly causing peritonitis. In order to guard against the former accident, I pass the sound into the bladder and thoroughly define the vesical limits. Having thus settled where the bladder ends, I penetrate the cervix just below it with a needle armed with a stout thread. By this thread I have the cervix and womb completely under my control.

I now begin my amputation, and soon find to my chagrin that I have penetrated Douglas's *cul-de-sac*. I say to my chagrin, not because it is a serious mishap in these days of antisepsis, but because no surgeon likes to find that his knife has gone where he did not intend it to go. It is not the fear of the result to the patient that makes me chagrined, but the pardonable vanity of a surgeon. Closing this opening with two fine sutures, I resume the operation and in a few moments have the cervix removed. I shall carefully preserve it, as it is the best example I have ever seen of a tapiroid cervix. As there will be a subsequent tendency to stenosis, I dilate the cervical canal, and, while I am operating on the next patient, Dr. Taylor will complete the operation by coaptating the mucous edge of the circumference of the cervical wound to the mucous edge of the external os by sutures radiating from the latter. In other words, he will, by sutures resembling the spokes of a wheel, approximate the tire of this raw cervical wheel to the edge of its hub. These sutures will not be touched for at least two weeks. During that time the object of lessening uterine congestion and cervical elongation will be attained, not only by actual shortening from the operation, but also by retrograde metamorphosis caused both by the repair of an open sore and by the seton-like action of each suture.

ENUCLEATION OF A UTERINE FIBROID.

I began this operation ten days ago before a ward-class, and I shall try to finish it to-day in your presence. In fact, it might be said that I began it two weeks ago, as I shall explain in the course of my lecture. The woman is thirty-two years old, married for fourteen years, but sterile from a large uterine fibroid of the variety known as soft myoma, reaching up above the umbilicus. She is slowly being killed by the hæmorrhages and by her sufferings. What is to be done with it? The tumor is growing rapidly, and, if left to nature, it will carry off this woman within a year. How shall it be removed? Its position is neither on the outside of the uterus (subperitoneal), nor within the uterine cavity (submucous), but within the very uterine wall itself (interstitial). It is situated in the right wall of the womb; it has grown to a size larger than that of the adult head, and it has pushed the uterine cavity before it to the left. The sound penetrated five inches, showing that the uterine cavity had been enlarged, but not in proportion to the size of the tumor. When I first examined it, the cervix had become obliterated by pressure, and the lower uterine zone was bulging into the vagina. The *os uteri* readily admitted the finger. There was milk in the breasts, and the tumor, which is soft and gives a false sense of fluctuation, was very naturally mistaken for pregnancy by more than one physician.

I debated in my mind what was best to be done. If I made an abdominal section I should find it difficult to get a pedicle for the cervix is effaced. On the other hand, the tumor was evidently trying to escape *per vaginam*. So I decided to aid its efforts in that direction. Accordingly, with scissors, I incised the cervix in various directions to enlarge it, and then cut open the capsule of the presenting portion of the tumor with Adams's subcutaneous saw. I used the saw, both because the wound made by it is jagged, and does not bleed so much as a clean cut; and because the linear motion of the saw takes up far less room than the open blades of the scissors. With my finger I then stripped off the capsule from the tumor as far as I could reach.

Ergot was given in decided doses with the hope that the uterine contractions would force the tumor out. But,

while the tumor did protrude in a measure and slowly enlarged both the *os uteri* and the opening into the capsule, it was not a success, for necrosis of the fibroid took place, the discharges became excessively fetid, and septic symptoms set in. So I brought her before a ward-class and removed piecemeal, and with much difficulty, about half of the tumor. The fragments were not weighed, but I should say they must have amounted to five pounds. The best instruments for this purpose are the obsolete guarded obstetric crotchet forceps and a very large and heavy pair of fenestrated polypus forceps. I have performed this operation many times. In one it took five sittings before a very large tumor was removed, and the stench from the portion left behind at each sitting was very great, yet by dint of intra-uterine injections of corrosive sublimate the patient recovered. By the use of the same antiseptic measures our patient of to-day has progressed very well, and is in good condition for the operation of enucleation, by which I hope to remove the remaining half. The lower portion of the tumor has become rotten from being denuded and from the injuries it sustained at the last operation.

I twist off fragment after fragment with the fenestrated forceps. The rotten portion has now been wholly removed, and I introduce the guarded obstetric forceps. With this I tear up the living portion and again remove some fragments with the polypus forceps. Occasionally the parts are irrigated with a 1 : 2000 solution of corrosive sublimate.

I was in hopes to get all the tumor away at this sitting, but the woman's pulse is becoming too frequent and feeble. These signs, whenever a patient is under ether, mean danger—danger here from shock, not from loss of blood, which has not amounted to much. So I shall have to leave the rest of this tumor for another sitting. I therefore syringe out with vinegar the large cavity in the wall of the womb and also the uterine cavity. This will stop all bleeding. I next most thoroughly wash out the same cavities with the sublimate solution, taking care that none of it remains behind to poison the patient.

To save our patient from blood-poisoning, to which she is liable from the fetid discharges which will assuredly come from the rotting tumor, I shall have the cavity syringed out twice or even three times a day with a 1 : 4000 solution, telling the nurse to press the perineum backward after each cleansing, so that none of the solution may lodge in the curve of the vagina. I would rather have our patient run the risk of mercurialization than the risk of septic infection. When she has fully recovered from the shock of to-day's operation I shall remove the remainder of the tumor.

NOTE.—At the next clinic Dr. Goodell informed the class that this patient rallied well from the operation, and was seen in an apparently excellent condition by the resident physician in his last round at ten o'clock of the night of the operation. Twenty minutes later he was summoned to find her dead. It was evidently a case of heart-clot formed during the repeated operations, and Dr. Goodell expressed the regret that he had not removed the tumor by abdominal section. He said that in that case he would have formed his pedicle from the uterine shell left after the enucleation of the tumor.

THE LABYRINTH OF THE EAR.[1]

BY B. ALEX. RANDALL, A.M., M.D.,
PROFESSOR OF DISEASES OF THE EAR IN THE PHILADELPHIA POLYCLINIC; OPHTHALMIC AND AURAL SURGEON TO THE EPISCOPAL AND CHILDREN'S HOSPITALS.

ONLY some forty years ago, as the treatment of diseases of the ear began to receive some attention from medical men, one of the greatest German authorities used to ascribe a very large proportion of his cases of impaired hearing—more than one-half—to "nervous deafness." Further study has shown that such a diagnosis was akin to that of "amaurosis" in eye disease, and comprehended numerous forms of unknown trouble, later recognized as distinct and unrelated; and the tendency to exclude such terms, as being mere cloaks of ignorance, went too far in explaining away such views. To-day more scientific methods enable us to determine with far greater accuracy whether a lesion of the nervous portion of the apparatus exists or not; and there is promise of notable development, not only in the diagnosis, but also in the therapeusis, of affections of the internal ear. In asking attention, therefore, to the anatomy of the labyrinth, it is not merely that we may study an exquisitely complex apparatus and marvel over its beauties, but that we may endeavor to grasp what is known of its structure and of its functions, and utilize this knowledge to the present benefit of humanity and the further advance of otology.

The internal ear of man is a marvellously delicate and complicated apparatus, walled in by bone of stony hardness, and offering considerable difficulties to the investigations of the anatomist; but thanks to the many modern methods of investigating it, the task is becoming easier. Its normal anatomy, embryology, and physiology are fairly well understood, and its pathology is advancing with every year. The student can find good descriptions of it in the text-books, and can readily memorize them for examination requirements; but since the actual dissection of the organ of hearing is rather infrequent, even among aurists, a working knowledge of its anatomy is by no means commonly retained, and the need of reiteration of the most elementary details is very evident to one who endeavors to teach otology. This is my excuse for going over ground already well trodden.

The internal ear, or labyrinth, consists of three principal parts — the vestibule, the semicircular canals, and the cochlea—and is the seat of the termination of the fibres of the acoustic nerve. Some points in its physiology are not yet determined, but

[1] The substance of a lantern-lecture delivered at the Philadelphia Polyclinic, April 15, 1890.

the anatomy has been elaborately studied in almost every detail, and its exquisitely complex arrangement clearly revealed. Here the waves of the atmosphere which we call sound are received after passing through the external and middle ear, and here these impulses are transmuted into nervous force and passed on to the centres of hearing in the brain. If we consider that the ear has to take cognizance of vibrations of very varying length, comprising not less than eleven octaves—twelve times as wide a range as the spectrum-scale of the eye—it will be evident that the mechanical arrangement must be very complete; and the marvel is that it should have been so thoroughly discovered and studied.

The generally accepted view which designates the labyrinth as the *receiving* apparatus, in contrast to the *conducting* apparatus external to it, has abundant practical and theoretical foundation. Anatomical points mark a total change as we pass from the tympanum to the inner ear. Air-cavities, most curiously contrived, make up the external and middle ear; but in the labyrinth all the cavities are filled with fluid. Further, there is a most singular doubling of the labyrinthine structures—a membranous labyrinth floats within a bony capsule, which repeats in most respects, but in larger dimensions, the configuration of its several parts. As the bony labyrinth has long been known, and its rigid shape seemed to give and maintain the form of the membranous labyrinth, the latter has generally been described as moulded within the osseous walls; in fact, however, the membranous structure is developed first, and is far advanced in its growth before its capsule begins to take shape or undergo ossification. In point of time, therefore, the beautiful bony capsule is secondary; and investigation shows that its importance is also secondary to that of the delicate structure within. To this, then, let us first give attention.

The membranous labyrinth originates as a pouch from the ectodermal surface, and, separating early, it forms an independent spherical sac, the otic vesicle. This vesicle differentiates by the outgrowth of tubular processes, the first of which, growing inward and backward, forms the endolymphatic duct, while three processes bud out from the posterior portion to curve through the surrounding tissues and return again, constituting the semi-circular canals. From the lower anterior portion a single tubule grows forward to wind spirally inward and form the cochleal canal. Nerve-fibres from the posterior cerebral vesicle early unite the otic vesicle and the group of ganglion cells pertaining to the cochlea to the central nervous system; and the mesoblastic tissues differentiate about the developing otic vesicle to form the supporting structures of the labyrinth. An inner layer contributes a close-fitting sheath to the epithelial tissues, while an outer layer, separated by the developing perilymphatic spaces, forms the outer capsule, which becomes, later, the bony labyrinth. The endolymphatic structure of epiblastic tissue sheathed by a delicate mesoblastic layer forms, then, the membranous labyrinth. As fully developed this consists of the cochleal canal anteriorly, the semicircular canals posteriorly, and the vestibular sacs, the saccule and utricle, between them; the cochleal canal communicating by a narrow *canalis reuniens* with the saccule, the semicircular canals opening into the utricle, and these two distinct sacs communicating with the membranous vestibular

Fig. 1.

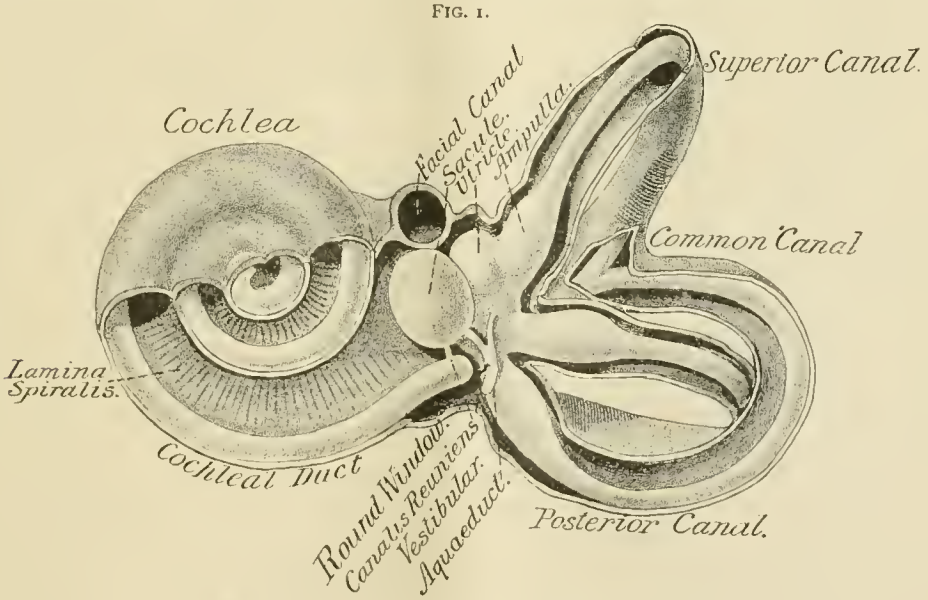

Diagram of the membranous, within the bony, labyrinth.

aqueduct, which thus furnishes an indirect union. The relations of these several parts are clearly shown in the diagram.

The cochleal canal consists of a tube, triangular in section, which winds spirally inward and upward for about two and three-fourths turns from its blind cæcal extremity in the vestibule to its blind end in the apex of the cochlea. Throughout its length it is abundantly supplied with fibres of the acoustic nerve, and its minuter structure shows most elaborate differentiation. Even in the infant, the accessory apparatus of the cochleal capsule and axis obscures its primary simplicity; and as these have bearing upon its function, further study of it may be deferred until these parts have been considered.

The semicircular canals at the posterior extremity of the membranous labyrinth show at almost all stages their peculiar character. They are three C-shaped tubes arising from the utricle and occupying planes almost exactly at right angles to each other—one horizontal, one transversely vertical (frontal), and one longitudinally vertical (sagittal). While the vertical canal may be most conveniently designated in accordance with the cranial sutures with which they nearly correspond in direction, it should be noted that the axes of the pyramids of the temporal bones converge strongly forward, and that it is really in relation to these axes that the canals are transverse and longitudinal. Each canal consists of a cylindrical tube 0.5 mm. in diameter, which broadens at one end into a pear-shaped ampulla 1.5 mm. wide before joining the utricle, while the other end joins it with little widening. The ampullæ of the frontal and horizontal canals are close together above, while that of the sagittal or posterior canal is below. The simple end of the horizontal canal is but little to the median side of its ampulla, while the undilated extremities of the two vertical canals unite into a common trunk before joining the upper median portion of the utricle. Each canal consists of a delicate hyaloid tube lined with flattened epithelium, and, except in the ampulla, is destitute of acoustic nerve-supply or of differentiation suggestive of important function. Each ampulla, however, receives a special nerve-trunk which supplies a differentiated area of terminal apparatus, a *crista acoustica* of cylinder epithelium carrying stiff hairs which extend out to the middle of its lumen. This acoustic crest extends across the side of the ampulla continuous with the convex wall of the canal, where a deep furrow, into which the nerve enters, indents the pyriform sac. Above the hair-like cilia of each crest floats a delicate gelatinous membrane.

The *utricle*, or larger vestibular sac, with which the semicircular canals connect, is of irregular, rather crescentic form, its greatest length of 5.5 mm. being up and forward from the mouth of the ampulla of the posterior canal. It receives the five extremities of the semicircular canals principally on its posterior wall, while from its anterior surface a narrow tube joins the endolymphatic duct. Its convex anterior wall is in contact with the adjacent saccule and the connective tissue here binds them closely together, but without communication of lumen or fusion of their walls. The smaller sac, or *saccule*, is of a slightly flattened elliptical shape, and communicates by two narrow tubules with the other portions of the endolymphatic cavity—the one below being the *canalis reuniens*, which connects it with the lower end of the cochleal duct; the other, one of the Y-like arms of the endolymphatic duct. Each of the vestibular sacs consists of a delicate fibrous membrane lined with epithelium and receives a branch of the acoustic nerve, which terminates in a differentiated area of its wall, the *macula acoustica*. In structure these are similar to those in the ampullæ, but are less prominent, with smaller hairs projecting from the nervous epithelium, and with the gelatinous layer overlying them enclosing numerous crystals of lime—the otoliths. The last constituent of the membranous labyrinth is the endolymphatic duct, or membranous vestibular aqueduct, which is really one of the first portions to differentiate from the otic vesicle, and is well developed when the other divisions are only appearing. It becomes narrowed off from the vestibular sacs until the connection is but a narrow, forked tube, while its blind extremity expands into a flattened sac between the layers of the dura in the cranial cavity. Such, then, is the membranous labyrinth: the result of the growth and differentiation of the otic vesicle, reinforced by a layer of mesoblastic tissue.

The mesoblastic tissues surrounding the otic vesicle form three layers, of which the inmost ensheathes that structure as stated. The outer layer undergoes chondrification as a preliminary to the ossification which converts it into the bony labyrinth, while the intermediate tissue is hollowed out into spaces which intervene at most points between the two structures and are filled with the perilymph. While this fluid separates the membranous labyrinth at most points from its capsule, and it may, therefore, be said to float within its protecting structures, it is, in fact, firmly anchored throughout its extent. The convexities of the tubular portions and one side of each of the sacs adhere to the capsule and the structure occupies an eccentric position.

The bony labyrinth, or capsule, is a structure formed about the fully developed membranous labyrinth and conforming to its size and shape, except in so far as it is held away from it by the intervening lymph-spaces. It consists of the osseous cochlea, vestibule, and semicircular canals and the narrow aqueduct of the vestibule, and as the cribriform bot-

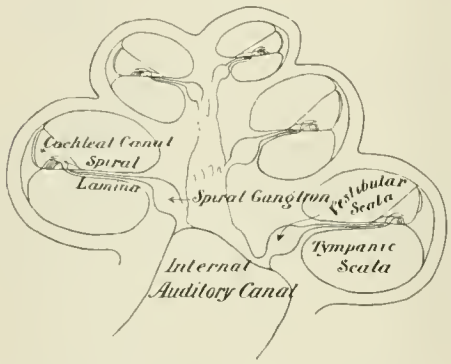
tom of the internal auditory meatus forms a part of its median wall, this meatus is often reckoned with it as part of the internal ear. The bony semicircular canals correspond closely with the membranous tubes which they surround, but are three times as wide (1.5 : 0.5 mm.), the lymph-space being in the concavity of the turn, while the membranous tube is attached to the convexity. They present distinct ampullar enlargements, yet these are but little larger than the contained sacs (2 : 1.5 mm.). The bony vestibule is much simpler in form than its contents, and presents but a single cavity with depressions upon its median wall corresponding to the points of attachment of the sacs. One of these is quite distinctly marked, and by its hemispherical shape indicates that it lodges the rounded saccule; another furnishes a bed for the irregular utricle, while a third receives the cæcal commencement of the cochleal duct. The bony cochlea closely resembles the snail-shell, from which it takes its name, and consists of a tube arising from the lower anterior part of the vestibule to pass forward and wind its narrowing coil two and a half times around a conical axis. The membranous tube, as in the semicircular canals, clings to the convexity of its turns, and the remainder of its lumen is divided by a shelf of bone projecting from the axis—the spiral lamina—into two distinct perilymphatic spaces. The upper of these is a direct continuation of the cavity of the vestibule and is called the vestibular scala; the lower is shut off from the vestibule by the attachments of the cochleal duct, but communicates with the tympanum by means of the round window and is hence called the tympanic scala. This opening of the round window is occupied by the secondary tympanic membrane, so the tympanic scala is closed at its lower extremity; and while free communication is generally supposed to exist at the apex of the cochlea, there is reason to doubt if this is true. The round window, with its membrane, is simply an unossified portion of the bony labyrinth. The membrane is so tightly stretched inward that it can yield little to pressure from the tympanum, while it can yield to the pressure from within; and it may probably be regarded as a mere safety-valve for the cochleal tension. There is another window into the labyrinth, however, which is far more important—the oval window of the vestibule, which is occupied by the foot-plate of the stapes. The slight, piston-like movements which this last of the chain of ossicles makes in response to vibrations communicated to the tympanic membrane find their parallel in all well-differentiated ears, and interference with them at once lowers or abolishes the perception of aërial vibration, as sounds can then be heard only by bone-conduction. Everything in the normal and pathological study points to the great mechanical importance of this window; and we are learning that if this be filled with an elastic structure hearing may still be useful, even if all the ossicles are lost and the conducting apparatus is a mere wreck. The margins of this window are covered with cartilage and articulate with the similarly covered edge of the stapes-base, while the entire inner surface is covered with the delicate periosteum. Quite a space—the *cisterna perilymphatica*—intervenes between the stapes and the membranous labyrinth, so that the vibrations imparted to the perilymph are transmitted about as freely to all portions of the auditory apparatus as to the saccule which lies just opposite. It is noteworthy, as Rüdinger points out, that the acoustic area of the saccule is on the far side of that sac and with its hairs directed toward the stapes-base, while that of the utricle is upon its nearer anterior wall and with its hair-cells directed away from the stapes.

Here, then, is the usual entrance-point of the vibrations given off by sounding bodies, and from this point we must try to follow them if we wish to grasp their method of transmission. The impulses given by the stapes-base probably affect, first of all, the saccule and utricle close at hand, setting the perilymph in undulation and causing movements of the gelatinous mass which floats just above the hair-cells of the acoustic area of each of these two sacs. The stimulation of these nerve-cells, conveyed as nerve-force to the cranial centres, gives rise to quantitative impressions of noise. But no mechanical arrangement is here seen suggesting a perception of the quality or pitch of the sound or sounds—only differences of loudness or faintness distinguish one from another. So, too, the examination of the other areas having acoustic nerve-supply—the acoustic crests in the ampullæ—shows no such differentiated structure. These nerve-cells may have a quantitative hearing function or they may serve merely as indicators of the motion of the perilymph in the semicircular canals occasioned by the movements or the position of the head. In the latter case, like the visible bubble of a spirit-level, they afford the constant suggestions of the position of the head so essential to equilibrium.

It is in the cochlea, therefore, that we must look for the apparatus of qualitative hearing, and the marvellous complexity of the structure here found accords well with such a function. We have spoken of the cochleal canal as a triangularly compressed tube rising in spiral turns around the axial cone of the cochlea and having a perilymphatic space on each side which accompanies it in its windings. A section longitudinally through the conical bony axis shows this and more. We see that the modiolus or osseous cone is hollow, and its multitude of small channels are practically continuous with the internal auditory meatus and transmit, piecemeal, the bun-

dles of nerve-filaments into which the cochleal branch of the acoustic nerve separates at the cribriform plate. These bundles turn at right angles to the axis of the cochlea to pass out between the two plates of bone constituting the osseous spiral lamina. On their way they pass through a ganglion mass of cells which appears round on section, but in reality is cylindrical and winds spirally upward parallel to the cochleal duct. The bony spiral lamina which projects out to meet the nearest angle of the cochleal canal has a continuation to the opposite wall of the capsule afforded by the basal or tympanic side of this canal—hence, often called the membranous

Fig. 2.



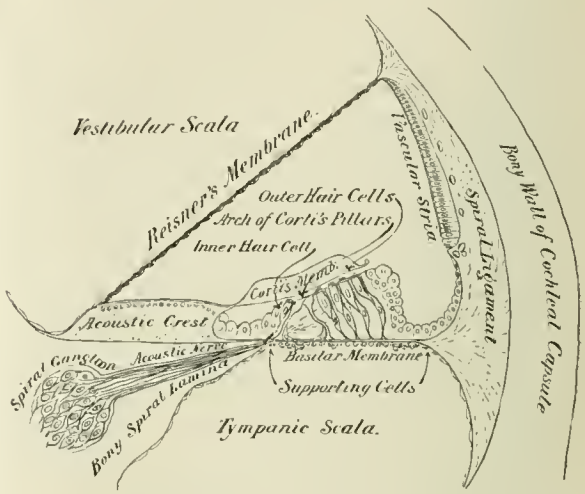
Section of cochlea, from apex to base.

spiral lamina—which expands into a crescentic cushion of fibrous tissue to form its insertion upon the outer wall. This spiral ligament consists of fibrous bands, practically continuous with the strong fibrous tissue of the membranous spiral lamina or basilar membrane, radiating from its outer extremity (to which the name spiral ligament is sometimes restricted) and blending with the periosteum of the capsular wall. The curious point is clearly shown in such a section that while the bony spiral lamina becomes shorter, and almost every other element of the apparatus decreases in size toward the apex of the cochlea, the membranous spiral lamina, or basilar membrane, grows longer. Beginning with a length[1] of less than 0.05 mm., it increases rapidly to some 0.2 mm. in the middle of the first cochleal turn, is full 0.3 mm. in the second turn, and about 0.4 mm. near the apex (0.495 mm., Hensen). As minuter study shows this membrane to be formed of a series of parallel fibrous cords, we reach the important fact that the cochlea possesses a system of cords of greatly varying length stretched tightly across from the firm bony shelf toward the opposite wall and comparable to the strings of a harp or piano, except that their number is estimated at from 13,000 to 24,000.

[1] This dimension is more strictly the breadth, if we consider the basilar membrane in its entirety and not in section, as here seen. Its length, from apex to vestibule, is nearly 35 mm.

The natural assumption of the great importance of such an arrangement is strengthened by further study of the minute anatomy of the organ, for a highly differentiated structure, forming the nervous end-apparatus, rests upon this basilar membrane. The organ of Corti, as this is called, consists of arches formed of stiff pillars, which support series of columnar cells provided with hairs and receiving the terminal nerve-fibrils — the "hearing-cells." There is a single row of these to the inner and three to five rows to the outer side of the tunnel formed by the unbroken series of arches, and all are but-

Fig. 3.



Section of cochleal canal, showing Corti's organ.

tressed by complicated sets of what are generally called supporting cells. The pillars arise from broad bases upon the basilar membrane and converge to form the arches, their enlarged heads being compressed to form close, regular articulations, while expansions from these reach outward as a network through the meshes of which the hair-cells protrude. Much that is curious and beautiful in the structure of Corti's organ must be passed over in silence, while we consider only its more essential parts. The hearing-cells are crowned, as has been said, by tufts of hairs or stiff cilia, shorter and much more numerous than those of the somewhat similar hair-cells of the vestibular sacs, and to these cells have been traced the ultimate nerve-fibrils which leave their medullary sheaths in the bony lamina spiralis and emerge through small openings at the bases of the inner pillars. Evidently, then, these hair-cells are the nervous end-apparatus. Above Corti's organ lies a thick gelatinous membrane, comparable to those which float above the hair-cells in the vestibular sacs, except that it lacks otoliths; and while its function is uncertain, it is doubtless important, if we may judge from its development before the differentiation of the adjacent parts. It extends out-

ward from a fibrous crest which rises from the bony shelf; but its other end, which is generally free, has been described as fastened either to the outer part of Corti's organ or to the projection on the external wall opposite to it (Deiters). It is not known, then, whether it floats free or is fast at both ends and stretched across above the hair-cells, nor whether it normally rests in contact with these or is slightly separated from them. Whether it acts as a damper to check vibration or as a point of impact for the excitation of the hair-cells is not clear, but the latter seems more probable.

The cochleal canal consists, then, of a triangular tube whose epithelial layer has been variously modified from its primitive simplicity; while its mesoblastic sheath retains its undifferentiated character only in its upper wall or Reissner's membrane; the acoustic crest, the basilar membrane, and the crescentic spiral ligament representing the remainder of its extent.

Some idea of the function of the cochlea must be apparent from these details of structure. In the series of tightly stretched cords of the basilar membrane we have the mechanically receptive elements, each attuned to a certain wave-length and responding whenever such vibrations are transmitted by the labyrinthine fluids. The longest of these cords are in the apex of the cochlea and these are tuned for the lowest tones for which the ear is adapted—about fifteen vibrations to the second. The shortest cords are at the beginning of the first turn and some of them are probably attuned to higher tones, with shorter wave-lengths, than the conducting mechanism of the ear will generally convey. Blake has shown that tones of 80,000 or more vibrations, generally inaudible, can be heard when a perforation in the tympanic membrane admits the vibrating air direct to the windows of the labyrinth. The limits of the audible scale vary in different ears and so do the maxima and minima lengths of the basilar fibres, according to the most accurate measurements. Pathology confirms this relation of the different parts of the cochlea to these different tones; and deafness for low notes has been shown to be associated with lesions in the apex, while deafness for high tones has marked the cases with lesions about the base.

Complex as is the construction of Corti's organ, the function of its parts is largely secondary, for in birds they are lacking. The arches formed by the pillars probably serve as weights to tune the underlying cords to the proper pitch or as bridge-points between which the cord is free to vibrate. As confirming the latter view, it is noteworthy that the pillars increase in length regularly from base to apex (the inner 48–70 μ, the outer 62–103 μ) and the span of the arch grows from 48 to 90 μ. In the basilar membrane, therefore, there are present cords fitted to vibrate to any tone which is transmitted to them, and to communicate this movement to the terminal nerve-cells which rest upon them. These nerve-cells are somewhat less numerous, the inner hair-cells being about one to seven of the cords, and the outer hair-cells, in their three or four rows, only about four times as numerous as the inner, yet their placing is such that doubtless every pair of cords is in special relation to a hair-cell. Of the least numerous inner hair-cells there are about 300 for every octave of the musical scale, or 40 for each tone; and experiment has shown that intervals of $\frac{1}{64}$ of a tone are the minutest distinguishable by the human ear. Just as in the retina the limits of visual acuity are dependent upon the size of the cones and their closeness together, so in the ear the acuteness of acoustic perception depends upon the similar relations of the hearing-cells. Some details of structure and function have not yet been fully decided for either organ, but enough is known to show a most interesting parallelism and to furnish us with many resting-points for working hypotheses. Physiological and pathological students are busy with these matters, testing, correcting, and expanding these hypotheses; and every year is adding to the power of the aurist to differentiate the various diseases heretofore confounded in clinical work and thus to locate and combat them.

GYNECOLOGICAL ELECTRO-THERAPEUTICS.

BY HORATIO R. BIGELOW, M.D.

My reason for continuing the discussion of a subject already nearly threadbare from excess of wear and tear, and sadly handicapped by the amount of the personal equation, is to be found in the very readable article of Dr. Baldy which appeared in this journal of March 22d. Dr. Baldy writes as a thoroughly equipped surgeon, speaking from ripe experience, and drawing his inferences from a careful weighing of his own excellent record, as well as from a patient examination of the work of others. His paper may be received as the type of polemic argument of most other surgeons who occupy themselves with abdominal surgery. In his chosen field he is so far ahead of me, his personal experience so much greater, and his knowledge of it so much more absolute that I have no right to gainsay him when he speaks as an operative surgeon. Moreover, the article he has published is well written, logical, and not without much truth. If it hits us who believe in electricity rather hard, the punishment is healthful and was deserved. I should like once more to place on record my own views in regard to gynecological electro-therapeutics, detailing its merits, its dangers, and its shortcomings. To do this at all fairly the word of any professional brother who has carved out

for himself recognized standing must be accepted without the shadow of a doubt, whether he be electrician or surgeon; and no man may consider himself a more accomplished diagnostician than his equally intelligent neighbor, since it would be a matter of much difficulty to find two men who would agree upon any given point. Experience, training, and study give us all a right to deferential hearing, and anyone who has encompassed these prerequisites may demand a respectful consideration of his theories. The diagnosis of A. may be diametrically opposed to that of B., but if both of them are well trained in their profession the opinion of the one is quite as valuable as that of the other. If A. be a surgeon skilled in the field of the abdomen and B. a good, thorough-going gynecologist, A. can have no possible right to conceive that the knowledge he gains by looking into the cut he has made, and which he applies in formulating a diagnosis before beginning the operation, is any more accurate than the conclusion which B. reaches with an educated sense of touch and a knowledge of pathological processes. I have seen and felt hundreds of diseased tubes from *above*, but I do not believe that it is at all necessary in arriving at a diagnosis; and as compared with the sense of touch which grows out of the examination of hundreds of women, and with a knowledge of pathological processes learned in the dead-house, it amounts to nothing. A ripe observation of the work of some of the best abdominal surgeons in the world, a constant association with Continental men for several years, has convinced me that the surgeon often arrives at a *just* diagnosis only after he has opened the woman's abdomen. So, upon questions of diagnosis, I would feel more inclined to agree with B. than A., though in the argument I should consider them both of equal value.

Clinical Testimony and Actual Experiment.—In a very just criticism of my book which appeared in the *Lancet*, November 2, 1889, the writer says:

"The methods of electricity are fully explained, but at the present date it is not too much to expect some proof of the effects of electricity on living tissues. While discussions of this subject seem to occupy much time in societies, facts are conspicuous by their absence. Before statements as to the effects of electricity on the uterus, fibroids, etc., can be properly discussed we ought to be able to read some accounts of actual experiments on fibroid and other tumors on the external and accessible regions of the body. That so much clinical statement should at this time exist side by side with so little scientific research seems to us to be a reproach to all who claim to erect electro-therapeutics into a great curative system."

It *is* a reproach to us, and my critic strikes the keynote. We can never hope for a rational, systematic, and scientific system of electro-therapeutics unless we go to work with our sleeves tucked up and furnish to the inquiring mind of the surgeon the *how* and the *why* of these things. If we are to do anything in the future with electricity we must go backward and learn the A B C of its alphabet. If a galvanic current will diminish a myoma we must be able to demonstrate *how* it does so, and not content ourselves with mere guesswork. It is not enough to cite clinical evidence of its power, we must add to this a demonstration of the actual processes at work. I feel very keenly our shortcomings in this particular, and I am mortified at my own inability to furnish immediately the proof.

My Own Experience.—Only because some of my critics persist in attributing to me claims which I have *never* urged for electricity—accusing me of viewing it as a panacea, etc., mistakes, I take it, which have arisen from a superficial reading of what I have written, do I deem it necessary to reiterate:

1. That I have *never* seen a myoma anatomically cured.

2. There are some myomas which should never be electrically handled.

3. I have *never* seen a pyo- or hydro-salpinx anatomically cured.

4. There are many of these cases which should never be electrically handled.

5. Dr. Apostoli, my master, has *never* claimed in his writings that he cured these cases anatomically.

6. I have *never* denied the possibility of accident and bad results. It would be exceedingly strange if such did not occur.

What I do claim:

1. Myomas may be *symptomatically* cured, and this permanently.

2. Myomas may be reduced in size.

3. Some conditions of salpingo-ovaritis may be *symptomatically* cured.

4. Cases of exudates may be relieved of all painful symptoms. I am not ready to say that they are anatomically cured.

5. Endometritis and metritis are *always* satisfactorily treated by electricity.

6. Malpositions of the uterus are well treated by electricity.

7. Ovarian pain may be cured by its use.

Such is my own experience. Others advance larger claims, and since these emanate from honorable men I am as justified in receiving them as valuable statistics as I would be in receiving the statistics of any surgeon. One man's statistics are just as valuable as those of another.

Question of Cost.—This is a lame argument—very lame indeed. Any man, with a little expenditure of time and ingenuity, can make a battery for himself for ten or fifteen dollars. The whole armamentarium need not cost him within one hundred dollars as much as do the tools of the full-fledged,

ambitious abdominal surgeon. The *cost to the patient* generally is much less under electricity, at least I should think so, when I hear of women paying one thousand dollars and the charges of a private hospital to be rid of an ovarian tumor. It seems to me this whole affair is one of the individual and does not admit of discussion.

Bad results have happened, undoubtedly, and are happening daily. Chadwick's cases—too bad that these things should be so bruited about, for the notoriety is unfortunate—are fondly quoted by surgeons daily. But I wonder how many deaths happened in the early days of abdominal surgery, and how many are still happening of which we know nothing. If the argument holds good for electricity, how much more seriously must it apply to abdominal surgery. How are the young surgeons of the day to win their spurs, if not through a mortifying experience of bad results. In the Rue du Jour I have *never* seen a bad result, and I soon shall have been nearly a year in attendance upon Apostoli's clinic. In fact there has not been even an alarming symptom since I have been associated with Dr. Apostoli. This is due, I think,

1st. To accurate diagnosis.

2d. To an intelligent differentiating of the treatment required.

3d. To a *thorough knowledge of the subject.*

4th. To thorough preliminary precautions.

5th. To never attempting to accomplish too much.

Of course, as the subject enlarges and draws to itself new disciples and new patients, want of experience will have its train of mourners, both in electricity and in surgery. It may go without saying that many men are much more competent to practise electricity than others, and I still believe that even a brilliant abdominal surgeon would not have flattering results from electricity, simply because it is not his *métier*, and his training has not been such as to make him a master of the subject. The same argument will hold good of the electrician attempting the practice of abdominal surgery. I do not find that many bad results ever occur in the practices of competent persons. The popularity of electricity is its greatest danger. It will be practised by people who know little or nothing about it, who even do not know one current from another; so it is bound to suffer. It is a mistake to suppose that anyone can take it up after reading a text-book. It is a mistake for the surgeon to condemn it because of his own bad results, because, I say it with all politeness, I do not believe that many of them have given it the careful study that it requires. Another danger to us is that of claiming too much. We should recognize that electricity is not a panacea; that the cures are not *always* permanent; that many cases should *never* be treated, and *that no case should be over-treated.* There will always arrive a time in the handling of a myoma, when treatment should be suspended for months, otherwise we will be sure to have inflammatory symptoms. Puncturing should be performed by the best men only, and I am not at all sure that I am fond of it, although I have seen some marvellous results in Apostoli's hands. There will always be a certain contingent of danger, but I do not believe that bad results will ever follow the handiwork of the honest, competent man who knows what cases to treat and which not to treat; who makes haste slowly; who does not expect to work a miracle, and who will claim for his work only that which rightly belongs to it.

Dr. Baldy's objections are:

1st. The treatment must be a local one and must be given by the physician himself.

Answer. An evident argument in its favor.

2d. The apparatus is too expensive for any but a specialist to possess.

Answer. Only a specialist, and he a competent one, should possess it.

3d. The patient must submit to a prolonged vaginal manipulation several times a week, sometimes for months.

Answer. No vaginal manipulation necessary. Speculum is *never* used. Sound and electrodes introduced by sense of touch.

4th. It is necessary to remove a great part of the woman's clothing in order to administer the treatment properly and thoroughly.

Answer. No exposure whatever. It can all be done under cover. But what does this objection amount to when opposed to the exposure that a woman undergoes upon the operating table of the surgeon?

Diagnosis.—If we analyze carefully these disputes over points of diagnosis we will find them usually matters of individual unpleasantness, and not of scientific moment. Much writing has succeeded in complicating intelligent diagnosis to a wonderful degree. These things that follow I hold to be absolutely necessary:

1. Careful study in the dead house.

2. Careful attendance upon clinics, especially watching the condition of affairs from above.

3. Careful study of specimens.

4. A large experience in the examination of women.

These facts fresh in our minds, generally speaking, diagnoses are not difficult. Rare cases occur in which the diagnosis requires much care, and even then may be doubtful. It is scarcely modest to dispute the diagnosis of men as eminent as ourselves, because their hobby is not the one that we ride, because this presupposes an assumption of superior

knowledge. Neither do I at all concede that because a man has opened the abdomen a hundred or more times that thereby he is better qualified to render an intelligent opinion. The great features of pelvic disease are readily recognizable. Myomas, as a rule, are made out, mapped out, and located without much trouble. Intra-ligamentous growths and encysted exudates are sometimes troublesome. Backward displacements of the uterus, with or without a myomatous complication, and ectopic gestations, may give rise to doubt. But if we have our anatomy fresh in our minds; if we know, so to speak, and that by heart, the "lay of the land," the refinements of modern text-books are simply embarrassing, and a little mental picture of the relations of the parts will help us toward a solution. In a recent article in the *Annals of Gynæcology and Pædiatry*, Dr. Cushing says: "Keith has recently published the histories of over one hundred cases of myoma, or what he diagnoses as such," etc. Now, if Keith, with an exceptional experience, is not competent to make out a myoma, is there a man among us who can claim such distinction? When Keith reports his one hundred cases and the results of his treatment; when he says that they were myomas, I certainly should be as fully justified in accepting this statement as fact as I would be in accepting as fact Dr. Cushing's own opinions. Neither have we the least right to "analyze" Keith's position simply because, as an honest man, and in the face of personal abuse, he has had the courage to give up a line of treatment in which he had unequalled success, and to take hold of another plan, which in his hands has given him better results. Why praise him for the work he did as a surgeon, and then damn him with faint praise for equally good work as an electro-gynecologist? Out of one hundred cases reported by him, one died from the effects of the treatment. Out of one hundred cases treated by the abdominal surgeon how many die? Can any responsible gynecologist for one moment believe that Keith would mistake a "subinvoluted uterus with metrorrhagia" for a myoma? And is anyone so omniscient as to hazard a diagnosis with any assurance of certainty upon merely reading the history of a case? There has been much useless writing about this whole matter of diagnosis. If the electrician happens to have success, up jumps the surgeon, and says that his diagnosis must have been bad, simply because the struggling brother has been able to put a few hardly earned pennies in his pocket; and then he proceeds to surround this myoma, or this salpingitis, with such an aggregation of adhesions, he so buries it in omentum and intestine, he so overlays it with bladder, and so complicates it with peradventures and sophisms, that the whole college would be put to their wit's end to know what really ailed the woman. I would like very much to know how many hundreds of tubes and ovaries have been extirpated by surgeons who previously diagnosed pathological change, but which failed to reveal such changes under the microscope after they had been taken out. I have seen many operators, in many climes, but I have never seen a more careful nor a better diagnostician than Apostoli, and I believe his experience in myomas to be as large, if not larger, than that of any other living man. So, when Apostoli asserts that such and such was the case, I should believe him without question.

Chronic Pelvic Inflammatory Diseases.—Dr. Baldy's article is concerned solely with this form of pelvic disorder. It may be objected to my list of disorders in which I believed electricity to be beneficial, that I had confined it within very narrow limits. But in stating my belief that it would cure endometritis and metritis I cover a wide territory, since the endometrium is the *fons et origo* of a vast number of diseases that are propagated by contiguity of structure to organs more remote. The chief symptoms—the most troublesome ones, the only ones for which a woman consults us who suffers from the conditions referred to—are pain during menstruation, coition, walking, and defecation, and a general sense of malaise. I *know* that electricity will dissipate all these pains, and while I do not believe that it will cure the case thoroughly in its anatomical relations—I am speaking now of the old chronic forms—yet it does cause some degree of absorption. Some cases that were treated nine months ago, receiving only a few *séances*, have not felt obliged to return so far for renewed treatment. Electricity finds here one of its most important and valuable fields, and its success will admit of no question. I have much more faith in its powers here than I have in the absorption of myomas. Now, if it will so thoroughly cure the case symptomatically, that the woman will not be conscious that there is anything anatomically wrong about her, why disturb the afternoon siesta of the surgeon? A disease is known to the patient and to us by its symptoms; hence, for our purpose, if the symptoms be cured, the disease does not exist. The surgeon does not do even as well as this by operating, for he does not always cure the symptoms, and he has mutilated his patient. Anyone of ripe experience can remember many cases in which bad reflex neuroses have followed after an abdominal section. Electricity will do vastly more for a woman with chronic pelvic trouble than the surgeon can with his knife. If Dr. Goelet says that he has dissipated these adhesions, I cannot conceive why we should not accept his statement, although clothed in poetic language. The science must go forward or backward, it cannot stand still, and improvements will be made upon

Apostoli's plan by his disciples as experience and knowledge increase. So that it is most probable that you will have more extended results in America than here, because there are more workers, and it would be surprising if these men should not accomplish more than is done in the Rue de Jour. I have not seen a case of chronic adhesions absolutely cured anatomically, but I am quite ready to believe that it is possible. There is much more that I would like to say, but reserve it for a future occasion, perhaps. The possibilities of electricity are great. What is needed is original work in regard to its action.

Paris, April 16.

GASTRO-ENTEROSTOMY AND PYLORECTOMY.

By H. TUHOLSKE, M.D.,
PROFESSOR OF SURGICAL PATHOLOGY AND CLINICAL SURGERY IN THE MISSOURI MEDICAL COLLEGE, CONSULTING SURGEON TO THE ST. LOUIS CITY HOSPITAL, SURGEON TO THE ST. LOUIS POLYCLINIC AND HOSPITAL, ETC.

In the beginning of October, 1889, I took charge of the case of O'N., a mechanic, aged thirty years, whom I had seen in consultation about five weeks previous.

History.—Of healthy parentage, the patient had enjoyed fair health until two years ago, when, he claimed, he contracted syphilis, and had a primary sore on the penis, which, two months later, was followed by mucous patches in the mouth and throat. There were no other demonstrable lesions. He was treated with mercury and potassium iodide. In the spring of 1889 the first symptoms of stomach trouble appeared. Patient would vomit, without much nausea, without any pain, and at irregular intervals, large quantities of fluid. Vomiting was usually followed by shorter or longer periods of comparative comfort. Treatment yielded no results to speak of, and on the recommendation of his medical attendant the patient tried a change of climate. Gradually losing in weight, he dragged on through the summer, and returned to his home in the latter part of September. It was then that I saw him in consultation and diagnosed an obstructive trouble at or about the pylorus. Toward the end of October I took sole charge of him, and found the following conditions: Height of patient, 6 feet 2 inches; weight, 118 pounds; emaciated to an extreme degree, the hands presenting the wrinkled, brawny appearance of starvation. Physical examination revealed nothing abnormal in the lungs or heart; no disturbance referable to the urinary apparatus; nervous system fairly normal; intellect bright and clear; abdomen flat, even sunken at the lower part; the epigastrium was prominent. The contour of the stomach was easily demonstrated, the greater curvature, beginning in the right hypochondriac region, passed through the epigastric region, reaching its lowest point two inches above the umbilicus, and, ascending gradually, filled the median half of the left hypochondriac region. Peristalsis visible through the parietes; no enlarged glands in the inguinal or supra-clavicular regions; no tumor. Patient was extremely weak, as he had been living on nutrient enemata for sixteen days, only small quantities of water having been occasionally administered by the mouth. Even then vomiting occurred every forty-eight hours. Bowels were obstinately constipated.

Diagnosis.—Pyloric obstruction and great dilatation of the stomach. Under the careful administration of beef-juices and peptonized milk by the stomach, patient gained somewhat and was able to sit up in bed, but vomiting occurred whenever the stomach became full. Nevertheless, he rallied so that after two weeks I felt justified in ordering washing out of the stomach to be performed every other day. Finally, my assistant, Dr. Perkins, reported that the long-suspected tumor could be felt low down in the right hypochondrium. I then informed the patient of the necessity of operative interference and urged a gastro-enterostomy. Under the washing-out treatment, however, he was improving wonderfully, and gained some twenty pounds during December, and returned to work in January. He would not entertain my proposition for the operation. The improvement was of short duration, and by the end of the month he was again in a state of great debility and emaciation, and, while lending a more willing ear to my proposal, insisted on trying the efficacy of the Hot Springs in Arkansas.

For a time he improved and sent glowing reports, but returned home March 25th almost dead. He now clamored for an operation. Rectal feeding and stimulants revived him somewhat, and on the 29th, at 9 A.M., with the patient in a miserable condition, after having washed out the stomach and bowels, I proceeded to operate, with the assistance of Drs. Carson, Brokaw, and the clinical staff.

Operation.—The incision, four inches in length, was made over the site of the tumor. The centre of the incision was two inches to the right of and on a level with the umbilicus and upon an imaginary line drawn from the centre of Poupart's ligament to the cartilage of the right ninth rib. The peritoneum was opened to the same extent, after having stopped all bleeding. I found the pylorus at once, presenting in the wound, without adhesions, freely movable, and about the size of a walnut. Considering the extremely weak condition of the patient, I had determined first to make the gastro-enterostomy, and, if the patient seemed able to bear it, then to resect the pylorus.

But a short time is required for a gastro-enterostomy with our improved technique. The introduction by Senn of decalcified bone apposition-plates marks an era in abdominal surgery. I have had the privilege of seeing him use the plates in an experimental operation upon a dog. Like most great devices, it is exceedingly simple. But for the difficulty of procuring the plates, and of proper size, when needed, their use would become universal. This difficulty has, however, been completely overcome by Dr. Brokaw's ingenious substitute. The segmented rubber ring (see The Medical News, December 7, 1889,) can be rapidly made and of any

size, of a strand of catgut or a piece of rubber tubing. A ring composed of four or six segments is most readily applied, and, quoting Dr. Brokaw, is used as follows: "Compress the ring, pass it into the lumen of the bowel or stomach through the opening previously made, pass the threads at the end of the oval first, through the intestinal wall from within outward, then the lateral threads; make slight traction to ascertain whether the ring rests well in place, and proceed to the second. Apply this in the same manner, appose, and tie the apposition threads, after scarification of the marginal serous surfaces, as suggested by Senn."

I now drew the stomach out of the cavity, covered and surrounded it with warm sponges, found the beginning of the jejunum without difficulty, brought it forward until it was above the middle of the great curvature of the stomach, and emptied the contents from about three inches, and placed the clamps in position. I then made an incision an inch in length on the convex border, compressed a segmented ring two inches in diameter into a long ovoid,

Fig. 1.

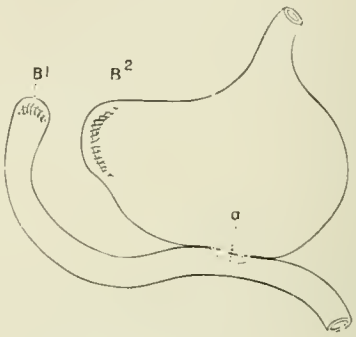
C. Malignant growth.

introduced it into the gut, and passed the needles armed with fine, strong silk thread. A corresponding incision was then made in the stomach at the point indicated; a similar ring introduced, and the needles passed close to the ring at its outer circumference. I then secured the openings in both stomach and gut by interrupted sutures, tied the apposition threads, and completed the anastomosis by the addition of eight Lembert sutures surrounding the anastomosis.

The second step of the operation—the pylorectomy—then became comparatively simple. I separated the great omentum along the greater curvature and the gastro-hepatic along the lesser curvature of the stomach by cutting between double ligatures, as suggested by Billroth. I then applied clamps some distance from each side of the growth, and resected with the scissors. Then, an assistant holding the duodenum with the clamp, I passed a number of interrupted sutures, completely closing the bowel; then removed the clamp, invaginated the bowel, and secured broad peritoneal contact by interrupted Lembert sutures, closely applied. The stomach-wound was closed in the same manner.

Fig. 3.



A. Anastomosis.
B^1. Closed end of duodenum.
B^2. Closed pyloric end of stomach.

Three enlarged glands were removed with the omentum. The bleeding was slight. No stomach or bowel contents escaped into the cavity. After a careful toilet of the peritoneum I closed the parietal wound in the usual manner. Patient had a number of sinking spells, and whiskey and digitalis had to be administered frequently during the operation, which was completed in one hour and forty-five minutes. He seemed to react from the operation; there was no vomiting, and the intellect remained clear and calm. Pulse varied from 120 to 140 per minute. He complained greatly of pain and thirst during the day, the latter being relieved by warm-water enemata. During the night he constantly grew weaker, and died twenty-six hours after the operation. Microscopic examination proved the tumor to be epithelioma.

Remarks.—In attempting to gauge the merits of the various surgical procedures advised for the relief or cure of pyloric obstructions we at once meet with an all-important obstacle, viz., the limited number of reported cases. We find, therefore, not only great diversity of opinion on the subject, but diametrically opposed statements from the most illustrious in the profession. Some high authorities, who put before us the results of closest investigation, speak most discouragingly and doubt the propriety of the performance of pylorectomy.

In Mr. Greig Smith's classical work on *Abdominal Surgery*, page 392, we read:

"With these results before us, we must admit that if pylorectomy is to be considered anything more than a 'mere surgical exercise,' it is to be contemplated only in a very carefully selected class of cases. If the patient is not in fairly good condition, if the stomach is greatly dilated, if the growth is large, fixed and displaced, the operation should not be contemplated. And even when the opposite conditions are present it is doubtful if it could ever be a surgeon's duty to advise the operation; he ought to undertake it only at the patient's urgent request, and after fully and honestly explaining to him the hazardous risk which he undergoes."

The inadequacy of the statistics on the subject may be readily appreciated by reading from the section on the surgery of the abdomen by Mears in the *Annual of the Universal Medical Sciences* for 1889, page 25.

Professor Buchanan, with regard to the propriety of performing the operation in carcinoma, quotes the opinions of Butlin, and of Billroth, as given by his assistant Salzer. The former says:

"The excessive mortality due to the operation, the rapidity of recurrence in what have appeared to be most favorable cases for operation, the return of the symptoms of obstruction in some, if not in many, of the cases, and the fact that there does not appear to be one case which can be claimed as a genuine cure, lead me to doubt whether the operation of resection of the pylorus for cancer is ever a justifiable operation."

Salzer states that

"Billroth does not only consider the operation of resection of the stomach a justifiable one, but he continues operating with good results in many cases. Of course, he does not operate in cases of carcinoma if there are already infiltrations and adhesions to the liver and pancreas. In these cases he prefers Woelfler's operation of gastro-enterostomy."

Mikulicz, of Cracow, collected thirty-two cases, of which only eight recovered from the effects of the operation.

The unfavorable results which have so far attended this operation may probably be attributed to the following causes, of which some may be classed as unavoidable, others as avoidable. First, and most important, the mutilation of an organ of such paramount importance; and secondly, the injury of greater or less extent inflicted on the sympathetic nervous ganglia. The former might cause a marantic condition later on; the latter, severe and fatal shock. Future statistics will determine the importance of these factors. Among other prominent causes are the long duration of the operation, lasting, in the hands of even the masters of the technique, three hours or more; imperfect sewing; an extensive separation of the omentum, producing gangrene of the colon; the numerous causes of sepsis, such as the escape of stomach- or bowel-contents into the peritoneal cavity. It is unnecessary to say, that the careful selection of cases is, *cæteris paribus*, of prime importance. The patient upon whom I operated presented locally the most desirable, constitutionally the most undesirable condition. At last, almost *in extremis*, pleading for the operation, I performed one which I claim has some decided advantages over those heretofore in vogue. The first step, the gastro-enterostomy, made in the manner described, probably does away with two important factors of failure, for it requires but little time, and fairly guarantees complete apposition and closure. In the future, with a very weak patient, I would defer the pylorectomy for two or three weeks. With the patient in an improved condition, this form of pylorectomy would appear less hazardous. Whenever a pylorectomy is indicated, gastro-enterostomy, followed by the resection of the pylorus, as described, appears the shorter, the more complete, the more secure, so far as closure is concerned, hence the better operation. When done for carcinoma. even if there is recurrence, obstruction, which causes the most disturbing symptom, would be prevented. But carcinoma of the pylorus, although the most frequent, is not the only cause of obstruction; simple stricture, external adhesions, and the pressure of a tumor may produce similar symptoms. An early and exact diagnosis, therefore, is of vast importance. I believe that just as soon as dilatation of the stomach, due to obstruction at the pylorus, has been diagnosed, it is eminently proper, with the consent of the patient, to make an exploratory laparotomy, and to examine the pylorus; if the cause of the obstruction be found in adhesions which can be severed, to sever them; or, if that be not feasible, to make a gastro-enterostomy with the apposition rings.

If due to a tumor which cannot be removed the same should be done. If the disease is confined to the pylorus, it is proper to open the stomach at a place convenient for a gastro-enterostomy, to introduce the finger through the opening and into the pylorus. If a simple stricture is found we should proceed according to Loreta, dilate, and close the opening in the stomach. If the obstruction is due to carcinoma, the opening should be used for a gastro-enterostomy, and the pylorus resected as suggested.

I hazard the opinion that operations for obstruction at the pylorus will yield better results in the future. We will operate upon patients in fairly good conditions and we will find large pyloric carcinomata with extensive adhesions as rarely as we now find very large stones in the bladder or huge ovarian tumors—such condition being diagnosed early and removed.

In conclusion I would mention, that after a number of experiments upon dogs, Dr. Brokaw, of St. Louis, found the segmented rubber ring of great

value in circular pylorectomy. After resection, a segmented rubber ring is introduced into the cut extremity of the duodenum, the apposition threads passed through the intestinal walls one-half to three-fourths of an inch from the free edge. The stomach is then sutured, beginning at the lesser curvature, reducing the opening until it exactly corresponds to the diameter of the duodenum. Through the opening in the stomach a segmented rubber ring is now introduced, the needles are passed and the operation finished as in any other anastomosis. I believe that this method may find its uses in non-malignant obstructive strictures of the pylorus. For the carcinomatous obstruction, I think the operation which I have devised is preferable.[1]

THE HODGEN SUSPENSION-SPLINT.

By H. H. MUDD, M.D.,
of St Louis, Mo.

The chief reliance of physicians in the treatment of fractures of the femur appears to be upon Buck's extension, but with this method the necessary movements of the patient, the irregularities of the bed, with consequent difficulty in adjusting the padding, or the carelessness of the surgeon, not infrequently result in over-lapping or in "angling," with a resulting crooked and shortened bone. The after-care of a case treated in a properly adjusted Hodgen splint is so trifling, compared with that required by Buck's method, that I am tempted again to present the claims of the suspension-splint of Dr. John T. Hodgen. Surgeons use with Buck's extension from twelve to twenty pounds pull, and shortened legs attest its inefficiency. The comparatively perfect result to be obtained by the judicious use of a Hodgen suspension-splint is not, I believe, to be attained with any other method, and the amount of the extending pull need not exceed ten pounds.

Extension is so universally admitted to be of prime importance in the treatment of the fractured femur that I shall not here endeavor to prove its value, nor do I deem this the place to compare and discuss the relative merits of the various procedures resorted to in the effort to secure equable and continuous extension. Many and various are the methods devised. A description of Hodgen's suspension-splint is found in many of the text-books. Few authors, however, seem to appreciate fully the benefits to be derived from suspension and extension as combined in this splint; yet its use is certainly becoming widely extended, though rather by example than by force of authority. It is a splint which will win its way into favor by its own virtues after it is once understood by surgeons of mechanical tact. I hope, since the splint is simple in its construction and theory, to make its application and principles so plain that every surgeon can use it with comfort and advantage to his patient.

Simple and effective continuous extension was, I think, first obtained in oblique suspension by Nathan R. Smith, when he introduced his anterior splint, of which the Hodgen suspension-splint is a modification. The advantages of the Hodgen splint are:

1. Easy adjustment.
2. It leaves the thigh exposed to inspection.
3. The muslin supports on which the leg and thigh rest can be separately adjusted, so that the tension on any one of them can be easily changed.

This splint in the hands of an expert secures nearly perfect immobilization, with extension so equable and effective as to give practically perfect results; and the freedom of motion allowed the patient does not interfere with the union of the broken bone—the splint and leg move with the body of the patient. The only motion is at the hip-joint, and there is no possibility of angling at the fractured point by the dragging of the leg on the bed as the patient moves from one side to the other. The patient can sit upright in bed or use the bed-pan without disturbing the fracture.

Description.—The splint itself, as originally devised, is composed of a single piece of No. 2 wire, bent as shown in Fig. 1. The sliding hooks D D′ and E E′ are used for attaching the suspending cords to the splint. The use of the arch O is to maintain the proper width of the splint at its upper end, viz., 8 or 10 inches. This arch is loose and is easily slipped into position over the ends of the wire which form the splint before the latter is applied to the leg. The width of the splint at the foot is about 5 inches, and is determined by the bend in the wire which forms the body of the splint. The wire hooks E E′ and D D′ present at one end a free loop for the attachment of the supporting cords, while the other end is coiled somewhat snugly around the lateral bars of the splint at D and E. The lateral bars extend upward on each side of the leg, so that the two ends of the wire reach, the one to a point *above the pubes*, and the other, on the outside, *nearly to the crest of the ilium*. The bend of the splint at the knee permits slight flexion of the leg.

The distance from the foot of the splint to the bend in the knee is 22 inches. From the bend at the knee to the upper end of the splint is 20 inches. The suspending apparatus is composed of, first, the pulley A, which is fixed in a high framework extending 8 feet above the bed, or preferably, in the ceiling; secondly, of the perforated sliding block B and the cord B A C; thirdly, of the two cords D C E and D′ C E′, of equal length with a loop at each end for attachment to the wire hooks at D D′ and E E′. These cords are passed through

[1] Since writing the above I have read with pleasure that the same operation has been performed successfully by the eminent surgeon, Dr. Bull, of New York, on April 10th.

a loop in the cord B A C at its end C. The suspension of the leg and splint is readily accomplished by sliding downward the block B on the cord B A C. The amount of the extension is determined by the degree of obliquity of the cord B A C. It is transmitted from the splint to the leg through the adhesive strip H, which, extending from one tuberosity of the tibia to the other across the board N at the sole of the foot, is fastened by a cord to the cross-bar at F, and thus securely holds the leg in the splint.

The splint, as represented in Fig. 1, is the simple solid-wire splint, as above described, and is readily made by any blacksmith.

In Fig. 2 an adjustable splint, easily fitted to any leg, long or short, is shown. It is composed of hollow tubes and sliding-bars, as described below. The lateral bars B C are square tubes, furnished with thumb-screws at their extremities, B and C. These tubes are of sufficient size to admit the terminal ends of the lateral bars, and by pushing in or pulling out the extremities of the lateral arms the length of the splint may be varied. Its width can also be changed by sliding the lateral arms into the hollow tube A A, which is furnished with thumb-screws at A and A. The hooks D D′ and E E′, for suspending the splint, slide on the lateral bars B C, but should be kept near the end of the hollow tubes B C. The splint is used in the same manner as the one before described.

Fig. 1 shows the splint in use. The leg is resting on muslin strips, which pass under it. These are secured by pins at each end, after overlapping the arms D E and D′ E′ of the splint. Each strip supports its proportion of the weight of the leg. These strips extend from the heel to the gluteal fold. The adhesive strip H (Fig. 1), softened by warmth or by turpentine, is applied to the leg, and secured in

Fig. 1.

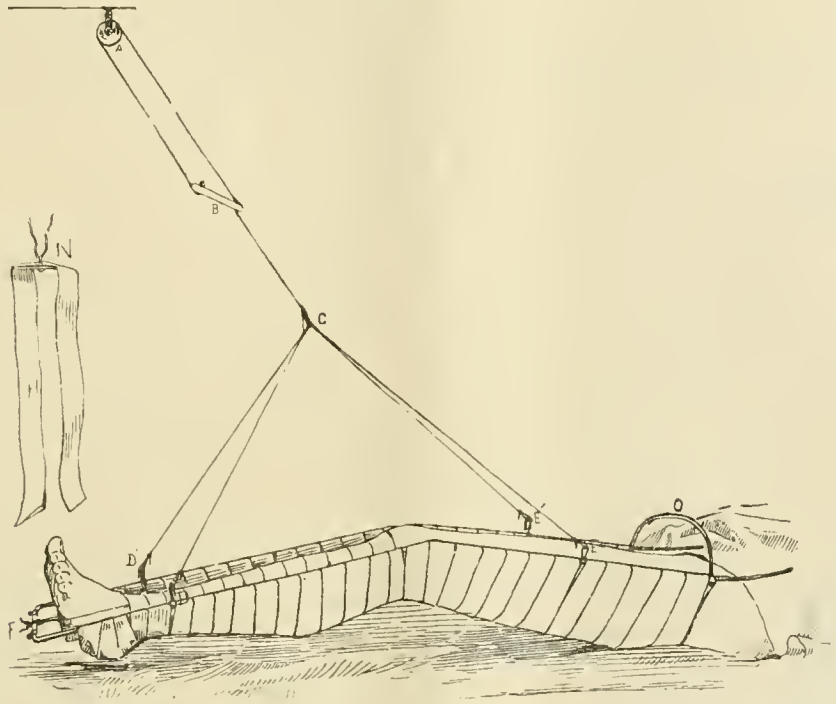


Fig. 2.

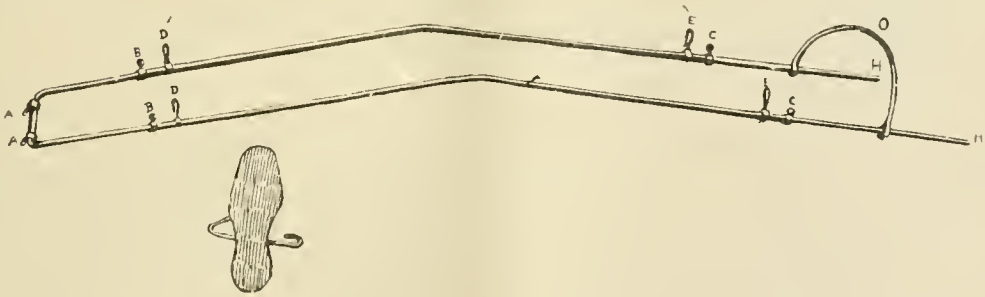


position by a roller, which extends as high as the knee. This strip secures the leg in the splint, since it is fastened by the cord and block N to the foot of the splint at F. The block N, at the sole of the foot, should be as wide as the adhesive strip, and about three and one-half inches long. It then protects the malleoli from the lateral pressure of the adhesive strip, through which the extending force is applied.

The Suspension of the Leg and the Adjustment of the Fracture.—The application of the Hodgen suspension-splint is simple, and in skilful hands painless. Suppose the leg, with its fractured femur, to be resting upon the bed. The adhesive strip H, with its foot-piece and cord, is placed in position, an assistant grasps the foot with one hand, and, with the other hand under the knee, lifts the leg from the bed, while at the same time he makes steady extension of the femur. The surgeon then applies the roller as high as the knee-joint, binding the adhesive plaster to the leg. The leg is again allowed to rest upon the bed, but the assistant maintains moderate traction on the foot, so as not to relax the extending force applied to the fractured bone. The splint is then put into position. A lateral arm is placed upon either side of the leg, and the cross-bar is brought close to the sole of the foot. The cord and block N, with the adhesive strip, is now fastened to the foot of the splint. Strips of muslin are passed under the leg—one at the ankle, one at the knee, and perhaps two under the thigh. These are secured by pins to the lateral arms of the splint, while it is held so that the inner arm extends above the pubes, and its outer arm, reaching nearly to the crest of the ilium, has its upper extremity not far from the anterior-superior spine of the ilium. The lower end of the splint is on a level with the malleoli. The inner wire arm may need to be shortened or bent upward, so as to give the patient opportunity to sit upright, but it should always extend well above the pubic bone. The leg can now be suspended by attaching the cords D C E and D′ C E′, and adjusting the slide B so as to lift the splint and leg from the bed. The cradle of cloth strips upon which the leg is to rest is now made complete by adding strips of muslin, and adjusting them to the outline of the leg, as indicated in the cut. No special or violent attempt at the adjustment of the fractured bone is made, except where there is marked lateral displacement, as in some transverse fractures. The free swing of the leg, and the efficiency of the extending force, secure a perfect adjustment in a few hours. The fracture "sets" itself.

The flexion of the leg on the thigh should not be very sharp, for if the bend approaches a right angle the elevation of the knee is necessarily great and most of the extending force applied to the thigh would be through the muslin strips on which the upper part of the leg rests (those just at and below the bend of the knee). The angle of flexion at the knee may be varied from that of the splint by lengthening or shortening the strips which support the thigh. The foot may be elevated or lowered and the support rendered by the muslin strips under the thigh varied, by sliding the loop at C downward toward the foot or upward toward the groin.

The flexion of the knee is only sufficient to put the leg in a comfortable position, relaxing slightly the tension of the hamstring and gastrocnemius muscles. The slight flexion of the thigh on the pelvis puts at rest the psoas and iliacus, and the rectus extensor of the thigh. The muscles are placed in a state of equilibrium.

External rotation, if it occurs, can be obviated by securing the foot to a foot-piece, or by a muslin strip passed around the outer border of the ball of the foot and fastened to the inner arm of the splint.

The degree of extension necessary to accomplish the result desired may be determined in part by the sensations of the patient. The position of comfort is often the position of safety, as extension is required only to overcome the tonic contraction of the muscles. The counter-extending force is the weight of the body. Much less extension is required in splints that suspend the leg and remove the resistance of friction of the leg on the bed than is required when the leg rests upon the bed, and weight and friction are first to be overcome. It is never necessary, when using this splint in an adult, to apply (as recommended by Hamilton when speaking of other methods of making extension) twenty pounds as an extending weight; or, as he states in his work on *Fractures and Dislocations*, published in 1880, "one pound for a child one year of age, two pounds for a child two years of age, and so on, adding one pound for each year up to the twentieth." An extension of twenty pounds, applied through an adhesive strip to the leg, and pulling upon the knee-joint and femur, is a serious trial to the patient's endurance, and it taxes the surgeon's ingenuity to maintain steadily such a force.

The amount of extension required in this suspension-splint is much less, being only from three to ten pounds, for there is no friction to overcome, and so long as the patient remains in bed there is no appreciable variation in the extending force provided the point of support is eight or ten feet above the plane of the bed. It is a quiet, persistent, non-irritating and effective pull. There is no perineal band to fret and worry the patient. The extending force is determined by two factors, and these are entirely within the control of the surgeon, viz., the obliquity of the extending cord and the

weight suspended. The first can be varied by the relative position of the bed and the suspending pulley, and the latter can be increased, if desired, by placing sand-bags across the lateral bars of the splint.

It seems difficult for some persons to understand how extension can be applied to a fractured thigh by a direct traction upon the leg, without counter-extension through the perineal band. They fail to recognize the efficiency of the weight of the leg as an extending force and the stability of the body as a counter-extending force. The amount of the extending force that is transmitted through the adhesive strip in the suspension-splint, may be measured by substituting a spring balance for the cord, which in the cut connects the block N with the foot of the splint. A small portion of the extending force is, however, transmitted through the strips which support the limb in its cradle, and those who wish can, by mathematical formulæ, compute the absolute amount of the extending force obtained by oblique suspension.

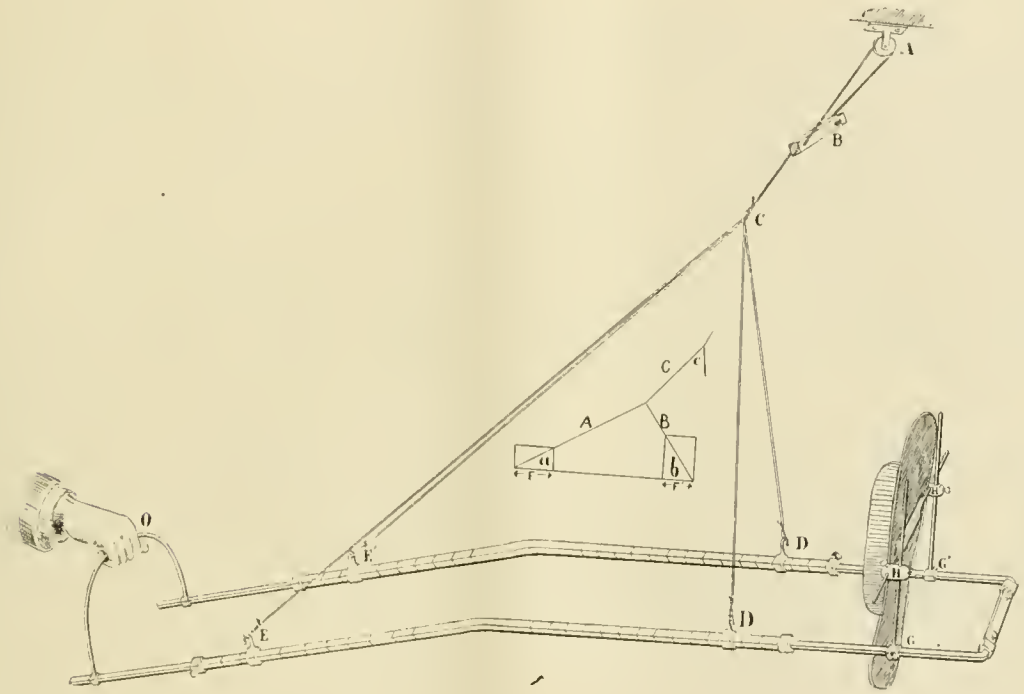
Professor Francis E. Nipher, of the Washington University, and Dr. A. K. Worthington, now of Denver, used the following formulæ for determining the extending force. The line D in the diagram (Fig. 3) represents, approximately, the line of the splint and the femur.

The pull on the cords C E and C E′ and also on C D and C D′ (Fig. 3), can be accurately measured. The angles a and b (see Diagram, Fig. 3) can also be measured. The traction force along C E and C E′ is represented by A, and that along C D and C D′ (Fig. 3) by B. The forces A and B being known as also the angles a and b, we can readily calculate the horizontal components F and F′.

The resultant of F and F′ will represent the direct traction force exerted along the line D, or the amount of efficient extension applied in the line of the femur.

In a particular case where the patient weighed 150 pounds, and the suspending cord, C (or in Fig. 3, A B C) formed an angle of 15° with the perpendicular :

Fig. 3.



It was found that the pull	A	= 11.5 pounds.
And the pull	B	= 10.5 "
The angle	a	= 40°
The angle	b	= 75°.
Hence by trigonometry	F	= A cos. a.
And	F′	= B cos. b.
Whence by substitution	F	= 11.5 x cos. 40 = 8.8 pounds.
" " "	F′	= 10.5 x cos. 75 = 2.7 "
Therefore the resultant of	F and F′	= 6.1 pounds.

F and F′ act in different, opposing directions, hence their resultant is the difference between them, or 6.1 pounds, which represents the amount of the extending force applied to the femur in this case. If the angle C was increased to 36°, it was found :

That the angle a = 35°
" " " b = 105°.

Here the forces F and F' are exerted in the same direction, since the angle b is greater than a right angle, and their resultant is the sum of the forces, which (by the same formula as before) is found to be 14.7 pounds. The weight of the leg was estimated at 21 pounds.

The loop C in the cord B A C (Fig. 3) is loose and can be slipped along the cords D C E and D' C E' so that the angle made by these cords with the splint can be changed with the obliquity of the suspending cord B A C. The lower leg should be parallel with the bed, while the heel is not more than two or three inches above the bed.

If the pulley through which the cord passes is fixed in a ceiling which is 9 to 12 feet high, a perpendicular line dropped from the pulley should fall beyond the foot of the adult patient. In the case of a child, where the weight of the leg is less, the obliquity of the cord should be greater. The obliquity of the cord should be sufficient to make an angle of from 15° to 35° with the perpendicular. If there is any tendency for the patient to slide toward the foot of the bed, it may be obviated by raising the foot of the bed by means of blocks. In the case of a child, it may be well to pass a cord loosely about the body under the arms, and fasten it to the head of the bed, to serve as a check to any great change in the position of the patient. The leg is open for inspection and the supporting strips can be readjusted as the parts atrophy. The slight natural anterior curve of the femur can be maintained. The circulation is undisturbed, for the nutrition is not interfered with by the pressure of retentive apparatus and it is as perfect as it can be during enforced quiet. The leg can be kept cool or warm as desired. The patient may sit up or lie down as comfort suggests. The bed-pan can be used without disturbing the fracture, and the best possible result in fracture of the shaft can generally be obtained, viz., no appreciable shortening and early union. This is obtained without bed-sores or any of the constitutional complications which are liable to follow confinement in a fixed position. The splint is well adapted to the treatment of all fractures of the femur, whether they are intra- or extra-capsular, through the trochanters, the shaft, or the condyles. The results of the treatment of fractures of the neck of the thigh in the splint are very satisfactory in the great majority of cases. Most of the unsatisfactory results obtained are probably due to imperfect adjustment of the fractured ends. The feeble aged persons who are most liable to this injury, derive comfort from its use and greater freedom of motion than they can enjoy with any other apparatus, or than pain will permit if allowed to go without treatment or a splint.

After a long experience with the splint in private practice and hospital work, and after having observed its employment by the late Dr. John T. Hodgen during the last fifteen years of his life, I know of but one practical difficulty which arises in its universal and immediate use in all fractures of the femur. This objection pertains only occasionally to the fractures of the middle third of the bone in children. These exceptions are rare, and if a perfect adjustment of the extending force to the necessity of the individual case could be obtained at once, they would be reduced to a minimum. The objection is found in the spasmodic contraction of the muscles, which at times is so frequent and violent, immediately after injury, that some lateral pressure is necessary for the comfort of the patient. This spasm may in part be controlled by lateral supports to the thigh or by permitting the leg to rest upon the bed for a few days with extension applied after Buck's method. No form of dressing will uniformly control it. After this irritability subsides, the leg is more comfortable and more efficiently treated in the suspension-splint. This clonic contraction of the muscles is more likely to be present if the extending force is in excess of the necessities of the case. The excessive tension acts as an irritant.

The only obvious change effected by the motion resulting from the spasm is an increase in the amount of the provisional callus. It does not delay union, but provokes by irritation an increased inflammatory deposit about the break. I find that a sand-bag partly full placed on the thigh while it is in the suspension-splint materially mitigates this spasmodic action. Fortunately, these cases are rare. Clonic contraction will, in isolated cases, occur with any splint and under any plan of treatment, for no lateral support or compression can prevent the contraction which accompanies a muscular spasm. Opiates are sometimes useful, in the case of nervous children, for a few days after such an injury is received. The plaster-of-Paris dressing is not, I think, admissible except in children less than eighteen months old.

This splint, and this manner of applying extension, afford a most perfect means of neutralizing the tonic contraction of the muscles which so often determines shortening. The oblique suspension gives continuous and equable extension of an amount sufficient to accomplish a perfect result, without the waste of any force, and it insures to the patient the most perfect liberty attainable by any known means compatible with comfort and safety.

The point of support, the pulley A, Figs. 1 and 3, should never be brought nearer the plane of the bed than eight feet. This gives the patient the full liberty of the bed without changing materially the extending force.

The foot-piece shown in Fig. 3 is one which I have used with some satisfaction in fractures of the neck

of the femur. It is also useful where the splint is used in the treatment of compound fractures of the leg. It will prevent rotation, it obviates drooping or extension of the foot, and is easily adjusted.

Dr. J. Freund, of Champion, Michigan, has devised a foot-piece which answers a good purpose. It is held in position by two transverse slips of wood fastened by thumb-screws to the lateral wires of the splint. The inclination of the foot-piece is fixed by a third thumb screw, which controls the inclination of the foot. It can be used with either splint and is an effective foot-piece.

MEDICAL PROGRESS.

Magnesia-isinglass Bandages.—DR. JOSEF ENGLISCH states in a communciation to the *Wiener medicinische Wochenschrift* that in his experience isinglass is preferable to plaster-of-Paris for rigid bandages, on account of its lightness and extraordinary firmness. According to the author, it is especially adapted to cases in which the patient intends entirely or partly to follow his usual occupation. Its disadvantage is, that it takes a long time to harden, and he mentions this as the reason why it has not yet been generally adopted. To obviate this disadvantage, he has used for the last eight years magnesia isinglass, which he claims is very satisfactory. Four parts of a solution of soda isinglass are by slow boiling reduced to the consistence of thick syrup, and then triturated with one part of finely powdered magnesia, till the mixture becomes whitish with a slight yellow tinge. The unrolled bandages are well stirred in this pultaceous mass, and then carefully rolled upon a wooden roller. The prepared bandages must not be exposed to the air for more than fifteen or twenty minutes, and before their application the limb is covered with a double layer of an ordinary calico bandage. No cotton-wool or flannel must be used. Four or five layers of the magnesia isinglass bandage are sufficient for the arm, but five or six layers are required for the lower extremity. When the apparatus is intended to remain undisturbed for a longer time than usual, strips of the same material, or of thin leather or cardboard, may be inserted between two successive layers. From ten to twenty minutes after its application the apparatus ceases to be sticky, and in from three to ten hours, according to the temperature of the room, it is perfectly hard.—*Therapeutic Gazette*, April 15, 1890.

The Use of Iodol in Syphilis.—DR. SZADEK, of Kiew (*Therapeutische Monatshefte*, April, 1890), has employed iodol externally in a number of cases of syphilitic ulceration and concludes:

1. That the tertiary gummatous ulcerations heal very rapidly under the application of iodol, and that the drug acts as a specific.

2. That the effect of iodol on soft chancres and open buboes is less satisfactory than that of iodoform, and it requires a longer time to effect a cure.

3. The absence of disagreeable odor makes the drug much preferable to iodoform, particularly in private practice.

Internally the author administered iodol, in doses of from 5 to 15 grains three times daily, to 22 patients suffering from syphilis, 5 with secondary manifestations, and 17 with tertiary. No acne or other disagreeable symptoms were produced and the influence on the disease was marked, though not as rapid as that of potassium iodide. He thinks that it is to be preferred to the potassium salt where a rapid and energetic action is not important.

The Treatment of Varices by Injection.—According to the *Wiener medicinische Presse* MOLLIÈRE employs the following coagulating injection in the treatment of varicose veins:

R.—Iodine	. . . . .	1 part.
Tannic acid	. . . . .	9 parts.
Distilled water	. . . .	10 " —M.

This solution, it is said, is not irritating and quickly causes coagulation of the blood. For half an hour before the operation the patient is required to walk about in order that the varices will be distended. A moderately tight band is then placed around the limb above the point chosen for the operation, and one drop of the solution is injected into the most prominent vein. On withdrawing the needle the orifice in the skin is closed with iodoform collodion. The bandage is allowed to remain in place and the patient is required to keep absolutely quiet for fourteen days. At the end of this time the vein is felt under the skin as a cord and gradually diminishes in size. The author has had no bad results from this method of treatment.

Peruvian Balsam in Local Tuberculosis.—According to the *Provincial Medical Journal* DR. JASINSKI, of Warsaw, has used Peruvian balsam in thirty-one cases of local tuberculosis of the bones and skin with excellent results. The drug was used either in substance or in an alcoholic mixture, and was in some cases applied as a dressing, in others was injected into tuberculous cavities. In all but one of the cases healing ensued more or less rapidly.

The Inefficiency of Sand Filters.—DRS. FRÄNKEL and PIEFKE, of Berlin, have recently made an exhaustive study on the filtration of drinking-water through sand (*Zeitschrift für Hygiene*, No. 1, 1890). Their experiments conclusively prove that the danger of infection from impure water is only slightly reduced by filtration through sand; bacteria passing through at all times, but in larger numbers just after the filter has been cleaned and again after it has been in use for some time.

Intestinal Diseases of Infants.—In an interesting article published in the *Archives of Pediatrics*, May, 1890, DR. W. S. CHRISTOPHER ably advocates the theory that all the so-called summer complaints of infants are due to ptomaine poisoning. The following is a summary of his conclusions:

1. Various forms of abnormal fermentation occur in the bowels, and when they occur in infants, and produce symptoms, they constitute the immediate cause of the collection of diseases known as summer complaint.

2. Summer complaint so defined includes putrefactive constipation and all forms of diarrhœa and dysentery

not diphtheritic in origin nor symptomatic of septicæmia.

3. The three great predisposing causes of summer complaint, viz., hot weather, overcrowding, and bottle-feeding, are to be regarded as acting solely as adjuvants to fermentation.

4. The diet during summer complaint should be determined entirely by the conditions within the bowels, and not by theoretical ideas as to Nature's food.

5. At least two well-marked forms of abnormal intestinal fermentation may be recognized clinically, viz., the putrid and the acid.

6. In the putrid fermentation, carbohydrates should constitute the food, and in the acid form albumin should be the only food.

7. Milk, containing, as it does, both proteids and carbohydrates, should be prohibited in all forms of intestinal fermentation. If properly sterilized, other food can be given; nursing babies with severe summer complaint should be taken from the breast.

8. All food administered, of whatever type, should be aseptic.

9. In addition to regulating the diet on the foregoing principles, the treatment should include laxatives and intestinal antiseptics.

10. The lesions are to be regarded as the results of the fermentation, and are more marked in proportion to the duration of the disease.

11. The lesions assist in prolonging the disease, and in all probability act by providing a habitat for the microörganisms, and by their secretions furnishing the germs with material with which to maintain their biological activity.

12. In chronic cases, where well-marked lesions may be supposed to exist, lavage of the large intestine and of the stomach, with appropriate antiseptics, is indicated.

13. Opium is contraindicated except in persistent acid fermentation which threatens to produce anatomical lesions.

The Abortive Treatment of Herpes.—M. LELOIR employs the following solutions in the abortive treatment of herpes:

R.—Resorcine	30	grains.
Hydrochlorate of cocaine	7½ to 30	grains.
Tannic acid	1½	drachms.
Alcohol (90 per cent.)	3	ounces.—M.

or

R.—Hydrochlorate of cocaine	15	grains.
Extract of cannabis indica	150	grains.
Spirit of peppermint	150	minims.
Alcohol (90 per cent.)	3	ounces.—M.

Bryonia Alba as a Hæmostatic.—According to PROFESSOR PÉTRESCO, of Bucharest, bryonia alba is a common remedy in Roumania for the arrest of hæmorrhage, and he has made a number of experiments on man and animals to determine its value (*Les Nouveaux Remèdes*). He found that it caused marked contraction of the capillaries, and was surprised at its power in arresting hæmorrhage. His preparation was made by boiling 6 drachms of the dried root in 10 ounces of water until the decoction was reduced to 5 ounces. After filtration and the addition of sugar this amount may be given in three or four doses at intervals of half an hour.

He has also treated cases of metrorrhagia, hæmoptysis, hæmatemesis, and epistaxis with the alcoholic extract in doses of 30 grains daily, and places the drug first in the list of hæmostatics.—*Medical Chronicle*, April, 1890.

Bromide of Ethyl Anæsthesia.—For nearly two years DR. E. HAFFTER employed bromide of ethyl as an anæsthetic, and during that time he has administered it to more than 200 patients (*Correspondenz-Blatt für Schweizer Aerzte*, March, 1890). He believes it to be a safe and valuable anæsthetic for minor surgical operations. Merck's preparation is the best according to the author, and its purity can be determined by the fact that if poured upon the hand it should evaporate rapidly and without leaving any residue; that if shaken with water and filtered, the filtrate should be neutral, and give no reaction with nitrate of silver; and that the addition of concentrated sulphuric acid should not cause a brown color to appear.

The author concludes his paper with the following summary:

1. Bromide of ethyl acts with great rapidity, and usually without a period of excitement; it is perfectly safe when used in small amounts, and there are seldom any unpleasant after-effects.

2. The best method of administration is to pour the entire quantity to be used (1 to 5 drachms) on an impermeable mask, which is placed close to the patient's mouth and nose.

3. In most cases the operation can be begun in from fifteen to twenty seconds after the first inhalation, though the duration of anæsthesia will be very short, and only suitable for minor operations, opening abscesses, etc.

4. There are a few patients, chiefly alcoholics, who cannot be anæsthetized by the agent.

5. There are no contra-indications to the use of bromide of ethyl employed in small amounts and for short operations.

Prescription for Pruritus Vulvæ.—The following formula for pruritus vulvæ is quoted in the *Kansas City Medical Record*:

R.—Carbolic acid	16	grains.
Dilute hydrocyanic acid	2	drachms.
Tincture of opium, Glycerin	of each ½	ounce.
Distilled water sufficient to make 4 ounces.—M.		

To be applied as often as required.

Antiseptic Application for Diphtheria.—The following antiseptic mixture is recommended as an application to diphtheritic patches (*Internationale klinische Rundschau*, April 13, 1890):

R.—Borate of sodium, Chloride of calcium	of each 75	grains.
Carbolic acid	3½	"
Glycerin	2½	drachms.
White honey	3½	ounces.—M.

To be applied by means of a soft brush.

PARACENTESIS THORACIS.

LIEBERMEISTER'S communication upon pleuritis, referred to in our last issue, ably discusses the question of operative interference with effusions. While nothing new is brought out, the present state of the best professional opinion is clearly and judicially set forth.

Paracentesis has become more frequent since improvement in operative methods has diminished the liability to untoward result. Still, considerable difference of opinion exists concerning the indications for removal of non-purulent effusions in acute or subacute cases.

In order to render the indications entirely clear, Liebermeister argues, it is necessary to bear in mind that, with removal of the exudate, the disease is by no means brought to an end; but, on the contrary, so long as inflammatory processes in the pleura continue, the effusion will likewise continue to reaccumulate. On the other hand, it must be taken into consideration that in certain cases the operation is the direct means of saving life; and that, in many other cases, only through paracentesis can a favorable prognosis as to ultimate result be given. An urgent indication for operative interference is presented when an extensive effusion seriously embarrasses respiration or circulation. If the interference with respiration has not reached a high grade, and especially if during rest there is no considerable dyspnœa, the indications are not so urgent. So long as the exudation is increasing, and febrile symptoms continue to be manifested, paracentesis can be of but temporary benefit, because, as a rule, the exudation soon again reaches and even exceeds its former height. Moreover, when the effusion has reached its greatest point, it is in most cases judicious to wait a short time and observe whether resorption will not take place, either spontaneously, or under the influence of sorbefacient remedies. In this way many cases reach perfect recovery without unpleasant sequelæ.

One must not wait too long, however, for there is danger that the elasticity of the compressed lung may be so seriously damaged that complete re-expansion is no longer possible. How long the lung may bear compression without losing its elasticity cannot be definitely stated, but Liebermeister would say that we can no longer expect perfect re-expansion when an extensive effusion has remained within the pleural sac longer than four to six weeks. Thus, paracentesis must sometimes be performed not with the idea of permanent result, but for the purpose of bringing about, if only for a time, re-expansion of the lung, and thus averting the danger of complete loss of elasticity.

The period of expectancy, too, varies in individual cases with the individual indications. With small effusions, one can wait longer in the hope of absorption; on the other hand, when the exudation fills the entire pleural cavity, it is only in children that complete resorption can under any circumstances be expected. Furthermore, extensive exudation may suddenly and unexpectedly place life in immediate danger; so that in these cases, as a rule, paracentesis should not be delayed. Above all, must the operation be immediately undertaken when marked dyspnœa is manifested, even during perfect rest, or when the circulation is seriously interfered with. As a general rule, it may be stated that too early a resort to paracentesis is less to be deprecated, and less likely to be dangerous, than too long a delay. Purulence of the effusion is, in itself, sufficient indication for operation.

Paracentesis may be performed in either of two ways: The smallest possible opening, sufficient to secure removal of the fluid with the help of aspiration, may be made with trocar or needle, and this opening closed immediately after the operation; or the so-called radical operation may be made. In

the latter, a large opening is made in the wall of the thorax, and is kept patent. According to Liebermeister, it is best performed by resection of one or more ribs. The rule may be laid down that aspiration is the best procedure for non-purulent effusion, resection and drainage for purulent effusion. In either case, as a matter of course, strict aseptic precautions must be taken; the skin at the point of operation, as well as all instruments employed, being thoroughly disinfected.

Considerable difference of opinion has been expressed as to the effect of entrance of air into the pleural cavity during paracentesis. Repeated experience, on the one hand, has shown that this accident is often attended with very serious results, and not seldom quickly followed by death. On the other hand, certain surgeons assert that air may be allowed to enter the pleural sac during paracentesis without fear. Liebermeister would reconcile these contrary opinions by suggesting that the latter surgeons have most frequently, or even exclusively, had to deal with old empyemas, which must be managed in every respect as other large abscesses. A large opening is made, through which air must necessarily enter, and if sufficient care be taken to keep the region of operation aseptic air is not to be feared; for in such cases the pleura is thickened, and overlaid with inflammatory tissue, and for this reason but slightly irritable. Matters are very different, however, in acute pleurisy, and especially in a case with sero-fibrinous exudation; and it is in the latter class of cases, as repeated experience teaches, that entrance of air may be followed by fatal results, and is to be most scrupulously guarded against.

In Liebermeister's clinic, sero-fibrinous exudations are, as a rule, aspirated in the following manner: The patient lying in bed in a comfortable position upon his back with a somewhat elevated trunk, the thorax is penetrated by a hollow needle connected with a long rubber tube through which the fluid is allowed to siphon out into a vessel placed upon the floor. The rubber tube is interrupted by a section of glass tubing through which the passage of the fluid can be observed. It is sometimes desirable, but with copious effusions not absolutely necessary, to fill the tube and needle before operation with carbolic acid solution or other antiseptic fluid which is retained by compression of the tube and allowed to flow out at the moment of puncture. Entrance of air into the pleural cavity is by this means absolutely prevented. Before use, the needle is disinfected with boiling water and the tubing with carbolic acid solution. The skin at the site of puncture is carefully cleansed with alcohol, ether, carbolic acid solution or corrosive sublimate solution. The puncture is made as a rule in the 4th, 5th, or 6th intercostal space, midway between the mammary and axillary lines. As a usual thing, the exudation is not entirely removed, the procedure being interrupted as soon as the lung has sufficiently expanded, or when somewhat severe paroxysms of coughing occur. One or two quarts are usually drawn off at a time. When reëxpansion of the lung is attended with difficulty, it is judicious to remove but a small quantity of fluid at first, and after a while to repeat the operation. If after aspiration the effusion again reaches its former height, experience teaches that it is still judicious to wait; for resorption will soon begin. Only in case respiration again becomes seriously embarrassed should the operation be repeated.

A trocar may sometimes be employed in place of the needle, the canula having a second branch to which the siphon tube is attached. This is especially applicable in cases where it is intended to remove the effusion completely; because in such cases the lung in its expansion might be wounded by coming in contact with the point of the needle.

Special consideration must be given to those cases in which the effusion is so limited that no excess of pressure over the pressure of the atmosphere on the pleural cavity is developed, but in which on the contrary a so-called negative pressure exists; as also to those cases in which the effusion has been in great measure re-absorbed, in consequence of which the intra-pleural pressure has again been rendered negative. In such cases, as may be understood from reflection upon the fact that but little or no displacement of neighboring organs has taken place, paracentesis will be but seldom indicated. If, however, it be attempted with simple puncture or the use of the trocar, the fluid will not flow through the siphon, but on the contrary air will be aspirated into the pleural sac. In such cases it is necessary either to fill the tube before making the puncture or to employ other means of creating a vacuum, as in the aspirators of Bowditch and of Dieulafoy. As a rule, however, unless decided aspiratory force is to be employed, Liebermeister considers these apparatus much less convenient than the simple siphon. When an aspirator is employed it should be used with great caution: for if the apparatus is mechani-

cally perfect, a pressure of one atmosphere may develop, more than fifteen times that which is exerted by the column of liquid of 40 to 60 cm. in the depending siphon tube. Such a pressure must, if the lung is not capable of prompt and sufficient re-expansion, cause rupture. In this way, Liebermeister would explain the not very rare cases in which pneumothorax has been observed after aspiration of a pleural effusion, notwithstanding the fact that entrance of air from without has been prevented. This danger of rupture of the lung can be avoided if the aspirator be not too rapidly used and sudden strong pressure never allowed. The appearance of blood in the aspirated fluid is a signal for immediate cessation.

Among the ill results which may follow paracentesis may be noted pulmonary œdema, which is to be explained by removal of pressure from the vessels of the compressed lung, permitting transudation of fluid through their walls. This is manifested by copious expectoration of frothy liquid at times somewhat blood-stained. It is also possible that this may in part be aspirated into the sound lung and bring about danger of suffocation. Less frequently, symptoms of œdema are manifested in the sound lung. In certain cases in which thrombi have formed in the heart or in the constricted branches of the pulmonary artery, the freer circulation following paracentesis may lead to dislodgement, giving rise, in exceptional instances, to hæmorrhagic infarcts in the lung, or other manifestations of embolism. Too rapid expansion of the lung may cause severe and distressing paroxysms of cough, an indication for slow and deliberate procedure, or as already noted, for interruption of the operation.

REVIEWS.

A Syllabus of Obstetrical Lectures in the Medical Department of the University of Pennsylvania. By R. C. Norris, A.M., M.D. Philadelphia: W. B. Saunders, 1890.

In the short space of 154 pages Dr. Norris has placed a very thorough and useful summary of the lectures of Professor Hirst in the University of Pennsylvania, and has certainly succeeded in producing one of the best, if not the best, book of its kind which we have yet seen. Unlike many books of its size which attempt too much, Dr. Norris seems to have possessed the knack of putting in just the right amount of information to be of service to the student and not so much as to make him think that he knows everything, when in reality he knows comparatively little.

No student can read this book without feeling the necessity for a larger work, yet it will give him the hooks upon which he may hang the fruits of his studies when they become sufficiently ripe for him to consider them as ready for permanent assimilation.

The Medical Annual and Practitioner's Index for 1890. New York: E. B. Treat & Co., 1890.

At the present time the chief aim of several prominent publishers seems to be the placing upon the market of books which will contain in a brief, concise manner the chief points of progress in medicine during the past year. The one which is before us seems to be an improvement upon that of 1889, but, at the same time, we think it is to be regretted that the arrangement of the type and the character of the printing are not better than they are. These have little to do, however, with the value of the material which it contains, and concerning which many of our readers are already familiar. The changes which have been made in the present issue consist in a still further extension of the pages of the book by the appointment of collaborators upon the subjects of electro-therapeutics, life insurance, and thermo-therapeutics. Altogether the book is one which, when used in conjunction with several other works of the same kind, will place before the physician a large amount of information which he could only obtain otherwise through very wide reading and by subscribing to a large number of journals.

SOCIETY PROCEEDINGS.

PHILADELPHIA ACADEMY OF SURGERY.

Stated Meeting, April 7, 1890.

Joseph Hearn, M.D., in the Chair.

Dr. John B. Roberts reported

A CASE OF SUPPURATION IN SECONDARY CARCINOMA OF THE CERVICAL GLANDS.

Some time ago a man had been brought to him with a small ulcerated nodule on the left side of the upper lip and with a mass of enlarged glands on the left side of the neck below the angle of the jaw. The history, which was rather indefinite, was that about a year or two previous the man had received an injury near the mouth and that this had not healed, or if it had, there remained thickening and hardening. Nothing was done for this, and, later, enlargement of the glands of the neck appeared. He was seen by Dr. Keen, who, according to the patient's statement, advised removal of the cervical glands. For some reason he then came to Dr. Roberts, who considered the case to be one of epithelioma of the lip with secondary involvement of the glands of the neck, and advised against any operation, because he believed it impossible to remove thoroughly the infiltrated tissue. He sent the man to Dr. Mears, who thought that the glandular tumor could be removed, and that it was probably due to tubercular disease, the man having a cicatrix on the neck where a gland had suppurated in early childhood. The patient was then admitted to a private room in St. Agnes's Hospital and carefully watched, anti-syphilitic treatment being tried during this time. In a short time, however, he left the

hospital. A few weeks later it was evident that there would be suppuration in the tumor in the neck, the nodule on the lip remaining unchanged. He was again seen by Dr. Mears, who incised the cervical swelling and scraped away a quantity of softened tissue and treated the man on general principles. Subsequently the glands increased in size, and it was decided to excise the tumor of the lip as a diagnostic measure. An assistant made some sections of the excised nodule, which were shown under the microscope. Dr. Mears had some slides prepared of the matter removed from the glands, but, unfortunately, he was absent and had not sent the slides. The subsequent history of the case is that the glands above the clavicle began to enlarge and the side of the neck presented the appearance commonly seen in secondary glandular involvement of carcinoma of the lip. The patient has since died with swelling and tumefaction of the front and side of the neck.

Dr. Roberts thought that the clinical history clearly proved that this was a case of epithelioma of the lip, and that the suppuration occurred in the glands secondarily involved. Such a complication is rather unusual, and may, perhaps, have been due to the fact that these glands had been the seat of tubercular disease in early life; the irritation of the epithelioma lighting up the old trouble and leading to suppuration.

DR. O. H. ALLIS, in discussing this report, said that he had seen one case in which suppuration occurred in carcinoma of the cervical glands, but in that case the disease was primary.

DR. DE FOREST WILLARD said that some some six years ago a careful surgeon had removed an epithelioma of the lip. A year later the glands in the submaxillary region were involved and the growth had returned at the seat of operation. One of the glands in the submaxillary region suppurated and discharged a considerable quantity of creamy pus. The patient finally died from these secondary growths involving the submaxillary and cervical glands. He saw no reason why the irritation of an invading growth, like that of secondary deposit, should not set up an inflammation in the glands which would result in true suppuration. Such pus formation is not the same as cancerous suppuration; it is a simple inflammation set up by the irritation, and may, perhaps, involve parts of the gland which are not even the seat of cancerous deposit.

CORRESPONDENCE.

ST. LOUIS.

To the Editor of THE MEDICAL NEWS,

SIR: Some weeks ago there was in the St. Louis poorhouse a patient who presented some peculiar and interesting symptoms. He had peculiar recurring spasmodic paroxysms involving first the left platysma, then the flexors of the left hand and arm, then those of the left lower extremity, then crossing over and involving the right lower limb and usually extending no further. The first symptom, which appeared a number of months prior to the development of the spasms, consisted in an involuntary clasping of the hand upon some part of the chest or neck, continuing for several minutes and then relaxing. The movements occurred once or twice daily, later more frequently, and as time went on spasmodic movements and contractions occurring.

In the early part of his affection he was seen by Dr. L. Bremer, of this city. Later he went to the East, visited New York and Philadelphia, and was treated there with no material benefit, and finally returned to St. Louis. The attention of Dr. A. B. Shaw, one of the consulting physicians of the poor-house, was called to the patient by Dr. Fleming, the physician in charge and by Dr. Walters, one of the assistant physicians at the Female Hospital near by. Dr. Walters suggested that the case was one of myotonia. Dr. Shaw concurred in the diagnosis, and after watching the case with some care presented the man before the St. Louis Medical Society as a case of that rare affection, and made a variety of electrical tests which he thought demonstrated the correctness of the diagnosis. Drs. J. K. Bauduy and C. H. Hughes took part in the discussion of the case and accepted the views of Dr. Shaw. Dr. L. Bremer, on the other hand, recognizing the patient as the one whom he had formerly treated, took a different view of the case, and very positively and emphatically disputed the diagnosis. He denied the significance of the electrical tests and asserted that the symptoms had been incorrectly interpreted. When pressed for another diagnosis, he simply said that he could not yet make a positive diagnosis, but that it certainly was not myotonia. The discussion was carried on for several meetings with considerable interest, and those who were present assure me that Dr. Bremer was treated with scant courtesy by some of the other specialists.

Later Dr. Bremer removed the patient from the poorhouse and kept him for some weeks at a private hospital that he might have the opportunity to study carefully the symptoms, make exact tests, and reach a positive diagnosis.

While he admitted the absence of one of the usually most marked and earliest symptoms of cerebral tumor, he finally concluded that the symptoms were only to be explained by the presence of a tumor in the motor area at the centre for movements of the platysma. He presented the patient and elaborated the course of reasoning by which he had reached his diagnosis at a meeting of the Medico-Chirurgical Society, closing with the remark: "The neurologist has located the lesion. It remains for the surgeon to operate."

This was undertaken by Dr. N. B. Carson, on March 26th, at the St. Louis Mullanphy Hospital. He removed a disk one and one-half inches in diameter and then enlarged the opening with chisel and hammer and removed a cystic growth about the size of a small hickory-nut from the point which Dr. Bremer had assigned as its site.

At the meeting of the St. Louis Medical Society, Saturday, April 5th, Dr. Bremer presented a detailed report of the case, illustrated with large drawings, reproduced from instantaneous photographs, and colored drawings showing the microscopical structure of the growth, which was pronounced by Drs. Bremer and Dean to be a cavernous angioma.

Dr. Carson reported the operation and announced that the patient was doing well, the wound healing by first intention, with no elevation of temperature, and that there had been no recurrence of the spasms since

the operation. Following the report of the case by Drs. Bremer and Carson, Dr. Shaw took the floor. He complimented Dr. Bremer on his diagnosis, though he thought the symptoms were hardly such as to warrant it, and congratulated him upon the successful result of the operation as confirming the diagnosis. Nevertheless he himself still believed that the patient did present the condition of myotonia. Whether this resulted from or was simply concurrent with the tumor he could not say, but he was as sure of the existence of myotonia then as Dr. Bremer had been of its non-existence. Dr. Hughes took much the same position.

The St. Louis College of Physicians and Surgeons is again attracting a good deal of attention in the local profession. Seven of the professors who took chairs in that institution at the beginning of the last course of lectures have resigned. These are Drs. Y. H. Bond, A. M. Carpenter, Charles Barck, Hugo Summa, P. French, I. N. Love, and J. R. Lemen, who filled respectively the chairs of gynecology, principles and practice of medicine, ophthalmology and otology, physiology and histology, surgery, diseases of children, therapeutics, and physical diagnosis. Besides these Dr. C. H. Hughes, who had been notified of his proposed election to the new professorship of diseases of the nervous system, when he heard of the action of these gentlemen, sent word to the trustees declining the proposed honor.

The reason for the action taken by these gentlemen as stated by themselves is that an amendment to the constitution under which the institution acts has been adopted, by which "The appointment of all members of the faculty shall be made annually at the meeting of the Board of Trustees. The Dean, with the concurrence of the executive committee, shall nominate for approval by the board, all those who are to compose the faculty for the ensuing year."

The aforesaid executive committee consists of Dr. Louis Bauer, Dean, his son Dr. Joseph L. Bauer, and Dr. A. S. Barnes. The only other member of the faculty who has a voice in the board of trustees is Dr. C. W. Cale, who graduated at the institution three or four years ago, and was a special pupil of Dr. Bauer. From this it is apparent that the chairs in the faculty are held for periods of one year only at the individual behest of Dr. L. Bauer, a "man who," in the words of one of his former associates, "came to St. Louis and attacked its best surgeon, Dr. Hodgen, in a manner so contemptible that Dr. Bauer was kicked out of the St. Louis Medical Society."

The most remarkable fact in this statement of those who resigned is that this condition of things came to their knowledge only after they had undertaken their work for the year. It was generally understood by the profession long ago, and much surprise was expressed when these gentlemen consented to enter the institution under such circumstances.

In an interview with a representative of the daily press, Dr. Bauer cast a slur upon the Beaumont Medical College by a remark to the effect that it was organized by a number of ex-professors of the College of Physicians and Surgeons who had resigned upon ascertaining that they were to be dropped.

In response to a demand from a member of the Beaumont faculty, Dr. Bauer sent a card to the daily paper above referred to, stating that only three of those who withdrew from the faculty of the College of Physicians and Surgeons six years ago had entered into the organization of the Beaumont Medical College.

The latest phase of this matter appears in the filing of a petition in the circuit court for the incorporation of a new medical college to be called "The Marion-Sims Medical College." The petitioners are those who resigned from the College of Physicians and Surgeons with Dr. Hughes, who declined a professorship. It can hardly be said that another medical college in our city is a long-felt want except on the part of those who are anxious to have the title "Prof." prefixed to their names.

A patient by the name of Brennan, who has been for some months past at the Quarantine Hospital, died Tuesday, April 8th, of leprosy. His case has been discussed by the medical societies and has been the subject of dispute and even of litigation. He had been pronounced a leper by those most competent to diagnose that disease, and as such had been taken in charge by the health department of the city and sent to the Quarantine Hospital. Repeated attempts were made by those who could not accept the diagnosis to have him released, but they never succeeded in convincing the authorities that an error had been made, and he was cared for in what was deemed the best way to prevent him from becoming a source of danger.

At the annual meeting of the Augusta Free Hospital Association satisfactory reports were presented by the several officers.

Mr. Charles Parsons offered to give to the hospital $15,000 upon condition that as soon as possible the name of the institution shall be changed to the "Martha Parsons Free Hospital for Children" with a pledge that that name shall be retained as long as the hospital shall exist. The association voted to accept the offer of Mr. Parsons, and the necessary steps to effect such change of name will be taken forthwith. The name is to be given as a memorial of Mr. Parsons's deceased wife, who was actively interested in the founding of the hospital.

HAVANA.

The First Cuban Medical Congress.

To the Editor of THE MEDICAL NEWS,

SIR: For two years preparations were being made by the medical fraternity of this island for the Medical Congress which was held in Havana from the 15th to the 22d of last January. Never before have the physicians of the different cities and towns of Cuba had the opportunity of meeting to discuss medical matters, for Havana is the only place on the island where medical societies exist. Here there are two, the Academy of Medical, Physical, and Natural Sciences and the Society for Clinical Studies. At one time there was a strong probability that the plan of organizing the Medical Congress would be abandoned, for it was feared that papers of real scientific value would be scarce; but at the eleventh hour good counsel prevailed, and the Congress was held. A general invitation to all physicians who wished to honor the Congress with original papers was published in the Cuban medical journals, and to this happy thought it is due that Professor Guyon and Drs. Albarran and

Lluria, of Paris, and Dr. Augustin M. Fernandez, of New York, sent valuable contributions.

It is said that the number of papers sent to the Secretary of the Committee of Organization was nearly one hundred, and that fifty-four of these were actually read before the Congress. The total number of members present was one hundred and ninety-four, among them a woman physician, Dr. Laura Carvajal de Lopez, the first female graduate of the University of Havana. Dr. Fernandez, who came as a delegate from the Medico-Legal Society of New York, was the only representative from abroad.

Of the scientific value of the papers read I will say nothing until the volume in which they will appear is published; however, some novel topics were discussed, such as "congenital tetanus in infants," and the treatment of the chronic diarrhœa peculiar to hot climates by what the author of the paper calls "intestinal dyalization." This "dyalization" is carried out by him in the following manner: First, he administers early in the evening one or two grammes of ipecacuanha, with the view of promoting emesis, and repeats the dose each time the patient complains of pain in the stomach; in the morning he gives from one to two grammes of calomel, repeating the dose on the second, and sometimes on the third, day. Three or four hours after the administration of these heroic doses of calomel, he gives from fifteen to thirty grammes of sodium sulphate, which he repeats if after two or three hours "the patient has not had free passages." This treatment he keeps up for several weeks! The author claims that this method of treating chronic malarial diarrhœa gives a greatly reduced mortality.

There are no epidemic diseases here at present, other than the amount of typhus and typhoid fever, croup, and diphtheria usual at this season of the year. On account of the mildness of the past winter we have had a number of cases of yellow fever. In the Hospital Mercedes there were in January four cases, in February five, and in March one, making a total of ten cases, with four deaths. In the Military Hospital there have been so far this year twenty-five cases and seven deaths. In the small private hospitals, of which there are five in this city, twelve cases have been treated during the three months, with a mortality of four.

Concerning the management of this disease, which is too old an acquaintance here to be dreaded as it is in the United States, the Cuban physicians generally pursue a symptomatic treatment, beginning with a purgative, and without particular preference for any special drug. Good nursing is considered essential. One of the papers read before the Congress was on the recent mortality statistics of yellow fever, in which the author severely criticised the results obtained by Dr. George M. Sternberg with his bichloride of mercury treatment.

A matter that is going to produce some commotion here in the summer is the enforcing of the recent regulations of the Marine Hospital Service in regard to the introduction of lepers in the United States. The sanitary inspector of this port, good old Dr. Burgess, is to have, in my opinion, his hands full of business with the protests and clamor from the rejected would-be tourists.

Havana is well provided with physicians, for, according to the *City Directory*, there are 307, which number, divided among its 200,000 inhabitants, gives a ratio of 1 for every 650. This is without counting the many army and navy medical officers residing in the city.

In my next letter I shall speak of the hospitals and other medical institutions of Havana.

BALTIMORE.

To the Editor of THE MEDICAL NEWS,

SIR: The annual meeting of the Medical and Chirurgical Faculty of Maryland has just closed. It was held in the hall of the Faculty, which contains a library of more than six thousand volumes. The sessions occupied the mid-day hours of four days, the evening of Thursday being devoted to a banquet in honor of the county delegates. About 125 new members were received—a notable event in the history of the Society. The Faculty was chartered nearly a century ago, and was given the right to examine persons who wished to practise in Maryland, and to confer upon suitable applicants licences to practise. This chartered right would, if strictly and generally enforced, have given a very high standing to the profession in Maryland, and would have saved the State from the curse of quackery and the slow and laborious task of restoring medicine to its former prestige. Unfortunately, laws have been passed by the Legislature giving to anyone who so desires, whether trained in medicine or not, the right to practise and to collect fees, and the Faculty, in consequence of dissensions among its members and want of public spirit, has never had the courage to oppose such enactments, which are probably unconstitutional. Recently a bill for a Medical Licence Board, endorsed by all schools, as it gave representation to those who profess to practise homœopathy and was very lax in its requirements, was passed by both houses of the Legislature. The Governor, however, vetoed it.

The Medical and Chirurgical Faculty has now entered upon a new phase of existence, and is aiming to become the State Medical Society, with a membership of more than one thousand. It is hoped that this change will result not only in a new impetus to medical work of the higher sort, and to the formation of branch societies in the counties, but also in the development of public spirit and union of effort among physicians which shall lead finally to the establishment of much-needed medical licence laws. The holding of a semi-annual meeting of the Faculty in Hagerstown during the past summer excited great interest among the practitioners of Western Maryland and led to the formation of a county Society there. This year a similar meeting will be held on the Eastern Shore of Maryland. Dr. Ashby, formerly the editor and proprietor of the *Maryland Medical Journal*, is the leading spirit of these new ventures.

Another matter of general interest is the entrance of Dr. Rohé upon his duties as Commissioner of Health in Baltimore. He exhibits a strong desire to promote the sanitary welfare of the city and to perfect the statistics of the Board of Health, the previous inaccuracy of which is indicated by such facts as the reported excess of deaths over births. Unfortunately, Dr. Rohé has no control over his subordinates in the office, and no power to choose or to dismiss them. The sanitary inspectors are ex-saloon keepers, etc., who happen to be upon the rolls

of the political parties and out of work. There is a strong feeling among physicians against inspection of their patients' homes or persons by such men, especially as the physician is required to call them in. Mumps, whooping-cough, and diphtheria are upon the list of diseases to be reported. Individual physicians of intelligence and influence declare that as the law has been a dead letter for many years, and as they believe it to be unjust and unconstitutional, they will not notify the Health Commissioner unless they choose to do so. Under these circumstances we need not expect much improvement in our statistics of contagious diseases. It seems only fair that notification of births, nuisances, and contagious diseases should be required of the family of the patient, not of the physician. The day seems far distant when competent physicians will act as inspectors for the Health Board in Baltimore, the only condition upon which accurate notification is likely to be secured.

Important changes are taking place in the Medical School of the University of Maryland. Dr. Miltenberger has resigned the Chair of Obstetrics and Dr. Michael has taken his place, leaving the Chair of Anatomy vacant. Extensive improvements in the Hospital are proposed.

It is reported on good authority that certain women of wealth in this city will presently offer to the Trustees of the Johns Hopkins University the sum of $100,000 for the equipment of the Medical School (the establishment of which has been postponed for want of funds) on condition that female medical students shall be admitted on the same footing as male students—the co-education of the sexes being aimed at. The co-education of students in the scientific and literary courses of the University has, so far, been discouraged, if not forbidden, by the Trustees. Some wonder is expressed that these ladies do not devote their means, instead, to the endowment of the Woman's Medical College, already established here, which has a good corps of professors and maintains a very high standard of graduation.

CARBOLIC ACID GANGRENE.

To the Editor of THE MEDICAL NEWS,

SIR: I wish to add the reports of two cases of gangrene following the external use of carbolic acid to those published by Dr. Warfield in THE MEDICAL NEWS of April 12th. The notes of these two cases were published by me in the *Canada Lancet*, March, 1877, eleven years before the first of those noted by Dr. Warfield, and are as follows:

CASE I.—"About six years ago (in 1871) a gentleman brought his daughter, aged nine years, to consult me about an injury which she had sustained in one of her fingers. Whilst playing with a straw-cutter, with other children, the finger had passed between two cog-wheels, bruising the soft parts and bone down to the first joint. The medical man who was called in to dress the wound applied to it some strong carbolic acid and wrapped up the injured part in a rag. On removing the dressing in a day or two the whole finger was completely blackened and withered, in fact dead. Annoyed at such an unlooked-for result, the child was brought to me, and under the rhigolene spray the finger was removed."

CASE II.—"A lady who undertook to decapitate a chicken, unfortunately missed her aim and very nearly severed the end of her left middle finger. The doctor in attendance directed carbolic acid lotion to be applied. A quantity of the acid poured into a half-teacupful of water formed the wash, saturated with which a rag was bound around the injured finger. The next day, on removing this dressing, the parts which it had enveloped presented a bleached appearance; they were also numb and painless. This was very soon followed by a blackening of the skin and a shrivelling of the whole finger. When I saw the finger five weeks afterward, the line of demarcation was complete, nature's process of amputation slowly going on near the base of the finger. I accordingly anticipated this process by the knife and forceps, and removed the mortified portion."

J. D. KELLOCK, M.D.

PERTH, ONTARIO.

To the Editor of THE MEDICAL NEWS,

SIR: In your issue of April 12, Dr. R. B. Warfield, of Baltimore, says that the literature of carbolic acid gangrene dates only from the end of December, 1888.

If he is interested in this matter, I am quite sure he can find a considerable number of reported cases scattered through the medical journals of the last ten years. In addition to several referred to in the Index Catalogue of the Surgeon-General's Library, he will find one reported by Dr. J. B. Garrison, of Garretson's Landing, Arkansas, in the *Western Medical Reporter*, 1882; another by Dr. J. W. Hamilton, of Columbus, Ohio, in the *Ohio Medical Recorder*, 1880; and another by Professor T. G. Thomas, in the *New York Medical Journal*, 1880.

J. F. BALDWIN, M.D.

COLUMBUS, OHIO.

DEATH FROM ELECTRICITY.

To the Editor of THE MEDICAL NEWS,

SIR: It seems to me unfortunate that we should appeal to foreign learned societies for the *opinion* that currents from commercial dynamos, when passed through human or other living bodies in sufficient strength, produce death through disintegration of tissue. No opinion could be less substantially justified. No one has yet recorded the strength of current that has killed a man, or the order in which the vital organs have given out. Whatever opinion is at present held upon this last question must, therefore, rest upon inferences drawn from experiments upon lower animals.

The state of the case in regard to dogs is as follows, when either continuous or rapidly alternating currents are passed between the head and thigh; and anyone who will take the trouble to perform about a dozen experiments, of simple detail, can readily substantiate the results:

1st. It is easy so to adjust the current-strength that, by an application lasting only a small fraction of a second, the heart shall be arrested, infallibly and past resuscitation, while respiration is not at once stopped—may, indeed, maintain its rhythm and force for several minutes—and while the functions of all the muscles except the heart; of the nerves and their distal endings; and of the blood in the heart and great veins, all remain apparently normal.

2d. It is not possible to discover a strength of current, or mode of applying it, through a dog's body as described, that will either arrest respiration or cause any lesion in muscles, nerves, or blood without the simultaneous, or still earlier arrest of the heart.

It is not meant by this to deny that electrical currents may be passed in sufficient strength through animal tissues to produce any lesions which could be produced by heat, or perhaps some that could not; it is meant simply to show that one of the vital organs is so fatally susceptible to electrical currents, that somatic death from such currents is practically always initiated directly in it.

Yours, very truly,

EDWARD TATUM, M.D.

YONKERS, N. Y.

NEWS ITEMS.

Competitive Hospital Appointments in Philadelphia.—The examinations for hospital positions in this city have all been held within the last two weeks. The Mayor, on the pretext of doubting the fairness of examinations at Blockley Hospital, within the past two years, had the examining board reconstructed so that there should be some one present, as he said, to watch the examinations. Several medical schools of the city joined in the cry of favoritism, which resulted in a number of very competent members of the visiting staff being displaced. Heretofore the graduates of the University of Pennsylvania have held a majority of positions as resident physicians at this hospital.

The result of the examinations held in the past week has been the continuation of this majority, and the fact that the examining board was made up of such conscientious men as Drs. R. G. Curtin, William F. Waugh, and Henry Chapman, representing, as they did, three of the principal schools of the city, is sufficient evidence that for once, at least, all competitors were put on an equal footing.

The result of the examination at Blockley Hospital for resident physicians was as follows: Women's Medical College of Pennsylvania, 3; Medico-Chirurgical College, 3; University of Pennsylvania, 13; and Jefferson Medical College, 1. The results of the other competitive examinations are as follows: Presbyterian Hospital, University of Pennsylvania 4; St. Agnes's Hospital, University 4; Howard Hospital, University 1, Jefferson 1; German Hospital, University 2, Jefferson 1; St. Mary's Hospital, University 3; Camden Hospital, University 2; St. Luke's Hospital, Bethlehem, Pa., University 2.

Lectures on Abdominal Surgery at the Chicago Polyclinic.—The recent special course in abdominal and pelvic surgery, by Drs. Senn, Fenger, Parkes, and Belfield, at this institution, seems to have met with general commendation among the physicians—one hundred and twenty-seven in number—who attended. At a meeting of the class held at the completion of the course, the following resolutions, presented by Dr. E. P. Cook, of Mendota, Ex-President of the Illinois State Medical Society, were unanimously adopted:

"WHEREAS, We desire to give expression to our appreciation of the successful and satisfactory manner in which the course has been conducted to its conclusion; be it, therefore,

"*Resolved*, That we would hereby convey to the Faculty and officers of the Chicago Polyclinic our thanks and appreciation of the discernment and skill that have conceived and executed a course demonstrative of the recent marked advances in the surgical treatment of abdominal and pelvic injuries and diseases.

"*Resolved, further*, That we are under special obligations to the several distinguished surgeons who, by their lectures and demonstrations have made this, as we believe, the best course in advanced surgery ever delivered in this country.

"*Resolved, finally*, That it is our deliberate conviction, that we have here in Chicago and in the West every requisite in skill and knowledge among teachers, and in abundance of clinical material, to qualify thoroughly all who would engage in the profession of medicine and surgery."

The course will be repeated by the same lecturers, on a more elaborate and complete plan, next winter

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM APRIL 29 TO MAY 5, 1890.

By direction of the Secretary of War, leave of absence for twenty-one days is granted RICHARD S. VICKERY, *Major and Surgeon*.—Par 17, *S. O. 103, A. G. O.*, May 2, 1890.

By direction of the Secretary of War, NATHAN S. JARVIS, *First Lieutenant and Assistant Surgeon*, is relieved from duty at Camp Wade, Kingfisher, Indian Territory, to take effect on the expiration of his present leave of absence, and will report in person to the commanding officer Fort Verde, Arizona Territory, for duty at that station.—Par. 12, *S. O. 102, A. G. O.*, May 1, 1890.

By direction of the Secretary of War, leave of absence for one month and fifteen days is granted JAMES C. MCKEE, *Lieutenant-Colonel and Surgeon*.—Par. 4, *S. O. 98, A. G. O.*, April 26, 1890.

By direction of the President, JOHN DE B. W. GARDINER, *Captain and Assistant Surgeon*, will report in person to Brigadier-General Wesley Merritt, President of the Retiring Board at Fort Leavenworth, Kansas, for examination by the Board.—Par. 4, *S. O. 99, A. G. O., War Department, Washington, D. C.*, April 26, 1890.

By direction of the Secretary of War, the ordinary leave of absence granted LOUIS A. LA GARDE, *Captain and Assistant Surgeon*, in Order No. 70, current series, Fort Assiniboine, Montana, is changed to a sick-leave; and the extension of said leave on surgeon's certificate of disability, granted him in Special Order No. 43, April 14, 1890, Department of Dakota, is further extended one month, on surgeon's certificate of disability.—Par. 5, *S. O. 97, A. G. O.*, April 25, 1890.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING MAY 3, 1890.

WOOLVERTON, T., *Medical Inspector*.—Detached from Navy Yard, Washington, D. C., and wait orders.

BEARDSLEY G. S., *Medical Inspector*.—Ordered to the Navy Yard, Washington, D. C.

HARVEY, H. P., *Surgeon*.—Detached from the "Ranger," proceed home, and wait orders.

HEFFENGER, A. C., *Passed Assistant Surgeon*.—Ordered to the "Ranger."

GAINES, J. H., *Surgeon*.—Detached from Hospital, Hot Springs, Arkansas, and granted sick-leave.

SPRATLING, L. W., *Assistant Surgeon*.—Ordered to Hospital, Hot Springs, Arkansas.

BOGERT, E. S., JR., *Assistant Surgeon*.—Ordered to the "Vermont."

OLCOTT, F. W., *Assistant Surgeon*.—Ordered for examination preliminary to promotion.

AUZAL, E. W., *Passed Assistant Surgeon*.—Detached from the "Yantic," and resume duty on board the "Galena."

ORIGINAL LECTURES.

TWO SUCCESSIVE CASES OF LAPAROTOMY, FOR OVARIAN CYST AND FOR OVARIAN INSANITY.

A Clinical Lecture
delivered at the Hospital of the University of Pennsylvania.

BY WILLIAM GOODELL, M.D.,
PROFESSOR OF CLINICAL GYNECOLOGY.

DOUBLE OVARIOTOMY.

GENTLEMEN: You will kindly excuse me from talking as much as usual this morning, because I have two laparotomies to perform within my hour, and I must get through with them so as not to intrude upon my colleague's time.

To begin then: The patient, now etherized before you on the table, is twenty-seven years old. She menstruates regularly, is married, but has no children. Last year she discovered that she had a tumor. Upon examination I found a cystic growth. By the sound I learned that it had no close relation with the womb, and that it began on the right side. Hence, it ought to be a cyst of the right ovary. Before beginning the operation I shall have the pubic hair removed, because it might become the nidus for septic matter. Formerly I had the pubes shaved on the day before the operation, but the effect upon my patients was too much like that of the "toilette of the guillotine," and I had to give it up until they were anæsthetized. This tumor was discovered not quite one year ago, and by operating early I shall be less likely to find adhesions than if I waited until it had grown larger. So far this session you have seen little but laparotomies in this amphitheatre; but, bear with me for a while, and you will be repaid by other operations of a more practical character, such as a physician ordinarily meets with.

The first thing I do in this case is to pinch up the abdominal wall in order to estimate its thickness. Next, I make a bold incision straight down through the fascia to the præ-peritoneal fat. This is cut and teased apart until the peritoneum is exposed. All bleeding points are now secured by catch-forceps. The peritoneum is picked up and nicked open, and a finger introduced. Thus far it is easier work than that of a simple oöphorectomy, because here I have a tumor between my knife and the bowels, and I am, therefore, not afraid of wounding the latter. You can now see the tumor exposed between the lips of the wound. It is of a pearly hue, which is pathognomonic of ovarian cysts. The next thing to be done is to empty it. This I do by puncturing it at the upper end of the wound, so that the trocar may have room to travel down with the collapsing cyst, and not slip out as it otherwise would. The fluid is chocolate-colored, and it sparkles with minute crystals of cholesterine. There are several daughter-cysts inside of the mother-cyst, and these I puncture separately, each one yielding a differently colored fluid. In the last one it is quite clear and limpid, much like that of a par-ovarian cyst. There are but few adhesions, and these I break off, or rather wipe off, from the abdominal wall by means of a sponge. A few bleeding points I catch with the hæmostatic forceps. The pedicle is very broad, and so short that the lower end of the mother-cyst dips down into uterine tissue. This portion I carefully peel out, and then catch the short pedicle by two large forceps. I shall tie this broad pedicle by the Staffordshire knot, but I do not trust to a single transfixion, which would not securely strangle so much tissue. I, therefore, transfix the stalk three times with the aneurism-needle. The transfixion must be done an odd number of times, once, thrice, or five times, else the Staffordshire knot cannot be made. The knot I am now tying is half cobbler's and half Staffordshire. After tying this knot I take the additional precaution of threading two needles with the free ends of the ligature, and of passing them through each extreme edge of the pedicle so as to prevent slipping, and then tying one more loop very tightly. I now examine the other ovary and find that it too is diseased—so badly diseased that in a few months it would also have become a large cyst, demanding removal. Its pedicle I transfix but once, because it is slender and long. This ovary I shall put on a plate and hand round to you to examine. Observe how hypertrophied it is, and note also the cyst at one end of it as large as a walnut. The ovarian stroma shows cystic and interstitial degeneration to a marked degree. My son has placed several sponges inside of the abdomen to protect the viscera from the atmosphere, and to guard them from any blood that may drop in from the wound. The sutures are now inserted, and I take the sponges out of the cavity through the incision, which grows shorter and shorter as the elastic abdominal wall, distended by the tumor, contracts. These sponges are so clean that I know that no oozing is going on. I now count them, as well as my instruments, for sponges and forceps have repeatedly been left behind by not observing this rule. Finding the number is correct I proceed to tie the sutures. The dressing consists of: 1. Powdered iodoform, which is sprinkled over the incision, especially about the navel. 2. Iodoform gauze. 3. Bichloride cotton. 4. Baked cotton, secured by adhesive straps and a stout flannel bandage around the whole abdomen, which bandage is in this case only provisional.

OÖPHORECTOMY FOR OVARIAN INSANITY.

The next patient is thirty-five years old. She has been married nineteen years, and is sterile. Three years ago she began to have pains in both groins, especially on the right side. This condition went on from bad to worse until she was too crippled to do housework. Early in this year she came to me to have her ovaries removed. I did not then consider the case bad enough for a radi-

cal operation. So she was kept in the hospital for some time, had a retroverted womb replaced by a pessary, and she improved under general treatment. After leaving us she became worse again, and at my recommendation went to the Orthopædic Hospital, where she staid seven weeks under the treatment of massage and electricity. While there she gained flesh, and when discharged was feeling very much better. This improvement, however, lasted but a short time. She rapidly grew worse, and two weeks ago she wrote me a most disheartening letter, and soon afterward came here for further treatment. She is fat, and I have never been able to outline her ovaries to my satisfaction. Yet, after repeated unfruitful examinations, I have come to the conclusion, from her history, that she is suffering from much more than a mere neurosis. For after a close cross-questioning I find, from the symptoms detailed, that she must have had a peritonitis. If so, the ovaries are probably fixed by adhesions, and so flattened and so high up on the pelvic wall that I have not been able to reach them. Sometimes the ovaries are so thinned out, spread out, and, as it were, plastered on the pelvic wall, that they elude the examining finger.

With these facts before me, I have yielded to her solicitations, and I shall now proceed to at least an exploratory incision. Since no tumor lies between the bowels and the abdominal walls I cannot cut down so boldly to the peritoneum as I did in the former case. When I come to the præ-peritoneal fat I tease it open, and pinch up the underlying serous membrane with two catch-forceps. This is raised up away from the bowels and nicked open with the knife. Bleeding vessels are now caught by forceps, and I insert two fingers into the abdominal cavity.

Finding the womb, I search for the right ovary by running my fingers along the fold of the broad ligament. It is found with some difficulty, flattened against the pelvic wall, high up, and adherent to it. These adhesions are with difficulty severed, but now the ovary and tube are released, tied, and cut off. The pavilion of the tube has disappeared, and it and the ovary present one coherent mass. The left ovary is not so closely adherent to the pelvic wall, but several fiddle-string bands of adhesions need to be broken before it can be removed. The tube is here free, but I wish you to notice how completely absent through destructive inflammation the fimbriated extremity is, and how dense and hard the tube itself is from interstitial salpingitis. Note also the long bands of adhesions which hang from the ovary, and the flocculent fringe of adhesions which floats in the water in which it is placed. It looks almost like the shaggy coat of the chorion, and it represents the points of close attachment to the pelvic wall.

Why did she suffer so much from groin pains? Because the adhesions caused a blood stagnation in the ovaries, and because these organs were dragged upon at every movement of the womb. Again the tubes are blocked at either end and their natural mucous discharges, or the unnatural discharges from the salpingitis present, could not readily escape. Hence, they were subjected to a painful distention.

This woman has evidently had pelvic peritonitis, starting as an endometritis and travelling onward as a salpingitis, as an ovaritis, and, finally, as a peri-uterine inflammation embracing the pelvic peritoneum. The cause of this peritonitis I have not been able to discover, for she was unable to throw any light on it, but I think it is specific.

Besides the constant ovarian pain from which she suffered, there exists another strong reason in favor of this radical operation: she has lately exhibited symptoms of mental aberration at the time of her monthly periods. This alone would have prompted me to the removal of her ovaries, for, of all diseases, insanity is the worst, and is to be averted by all possible means. Insanity, when limited to the time of the monthly periods, shows an ovarian origin, and the removal of the ovaries will then very generally cure the mental disease. This has been my uniform experience. But, on the other hand, if the insanity is constant though exacerbated at the monthly periods, the removal of the ovaries does very little good. It may mitigate the monthly outbursts, but it will not restore the reason. These facts have led me to the conclusion that oöphorectomy for ovarian insanity must be performed early—that is to say, while the insane impulse is periodic and not a constant factor. Another important fact that I have learned by experience is, that the removal of the ovaries cannot be depended upon for the immediate cure of nymphomania or of other erotic forms of insanity. In one of my cases excessive masturbation was not only kept up after the operation, but it was actually enhanced by it for at least a year, when the habit was finally overcome. In another case the erotic impulses lasted for over a year; but they ultimately ceased with the complete loss of the sexual feelings. I could tell you more of my experience in this interesting subject, but, as my hour is up, I shall wheel my patient into an adjoining room and there complete the dressing of the wound.

ORIGINAL ARTICLES.

A REPORT OF TWENTY-ONE CASES OF SUPRAPUBIC CYSTOTOMY, WITH REMARKS.[1]

By HUNTER McGUIRE, M.D.,
of Richmond, Va.

During the last two and a half years I have performed, for different purposes, suprapubic cystotomy in the male twenty times, and in the female once. The patients varied in age from six to seventy-six years. One of the cases died: in this instance a pyelo-nephritis, from long-continued obstruction to the flow of urine, was overlooked, or rather was suspected, but in the great urgency of other symptoms was disregarded. He died eight days after operation, of disease of both kidneys. This patient had been a hard drinker for many years, but for two years before his death had entirely abstained from liquor.

Another case, a child aged six years had suffered for many months from frequent and painful micturition. No cause could be found for the almost con-

[1] Read before the meeting of the American Surgical Association, Washington, May 14, 1890.

stant and frightful pain which the child suffered. He had no cystitis, no stricture or phimosis; his urine was normal; the general health good. His father, an excellent physician, considered the disease purely neurotic. While on a visit to the city in which the child lived, his father asked me to open the bladder above the pubes to secure drainage in that way. As everything else seemed to have been tried, I consented, and operated. For three days the pain was relieved. At the end of this period the child was seized with high fever and convulsions, and the next day scarlet fever made its appearance, and ran the usual course. The tube was removed from the opening, the lips of the wound became swollen, drainage ceased, and the wound was allowed to close. The boy still suffers as he did before the operation.

Five of the operations were done for stone in the bladder. This reduces the number of cases to which I wish very briefly to direct attention, to thirteen males and one female. In five of the thirteen cases chronic cystitis existed. This disease had resisted in all of the cases for months, and in most of them for years, every form of general and local treatment. One of the first cases in which I attempted suprapubic drainage in chronic cystitis, was that of a man, who, having exhausted all remedial means without help, was operated upon by a distinguished surgeon of Philadelphia. The bladder was opened through the perineum, and a large drainage-tube inserted and kept in for three months. He got no relief from this treatment. Some months later he fell into my hands, still suffering fearfully with his bladder, and along with this a constantly leaking perineal fistula, the result of the last operation. I opened his bladder above the pubes, found a small tumor, which was believed to be a papilloma, in the upper, and back part of the organ. The growth was removed; partly with the curette, but chiefly with my finger-nail. This man has improved, but has not recovered. He keeps the suprapubic fistula open, and through it washes his bladder and passes his urine. The improvement is slow, but continuous, and his life is now comparatively comfortable. Another case was that of a man aged about thirty-five years. He had stricture of the urethra, and six or eight fistulous openings in his perineum, and scrotum. His perineum was a mass of inflammatory indurations, his urine was alkaline and stinking, with mucus, pus, and some blood. After opening the bladder above the pubes, I had very little trouble in passing a sound, first into the bladder through the wound, and then into the urethra, and out at the end of the penis, breaking up the stricture in this way. After drainage for six weeks through the suprapubic wound, it was allowed to close; at the end of two months all the fistulous openings were closed, and the greater part of the indurations of scrotum and perineum had disappeared. A third case is that of a young man with cystitis of four years' standing, following, it was believed, an attack of gonorrhœa. Drainage through a suprapubic opening was kept up for two months with complete recovery.

A fourth case was one of cystitis of two years' duration, which had not yielded to the treatment of five or six surgeons, myself among the number. In seven weeks the man was well, and the suprapubic wound was allowed to close.

A fifth case was that of a physician who had been treated for eight years by different surgeons for chronic cystitis. Six years ago he was attended by me for several months without receiving any permanent benefit. He came to me again, February 10th, suffering terribly and taking two or three grains of morphine every day. I made a suprapubic opening to drain the bladder, and for eight weeks did not permit him to pass the urine through the natural passage. The pain has ceased, the morphine has been abandoned, the urine is nearly natural, and the man is now walking about. He still keeps the fistula open, being afraid of a return of his old symptoms, and cannot yet be regarded as well.

The remaining eight cases of suprapubic cystotomy were done to relieve obstruction from enlarged prostate. None of these cases could be relieved by the simple use of the catheter and irrigation of the bladder. All of them were great sufferers; most of them had reached the period when the introduction of the catheter was very difficult, and would soon be impossible. In several cases the inflammation had extended to the ureters and pelves of the kidneys. In both sexes and at all ages mechanical obstruction to the passage of urine ends in cystitis, ureteritis, pyelitis, and, lastly, pyelo-nephrosis. Two of these cases had, along with the enlarged prostate, stone in the bladder—the existence of which I did not suspect, although I had sounded both for stone. These calculi were found after opening the bladder, in a *cul-de-sac* behind the prostate—in a position in which it would have been impossible to discover them by sounding through the urethra. In two of the cases I found stones before operating. All of these cases are now living and passing urine through the artificial passages.

The first time that I operated above the pubes for stone, I was struck by the fact that the bladder contracted and drove out through the wound every drop of fluid that the organ contained. Afterward it contracted upon my finger and slightly resisted attempts at digital exploration of its cavity. This fact renders the drainage-tube after suprapubic cystotomy unnecessary, except for the first three or four hours to permit the fresh wound to glaze, or, afterward, for

the sake of cleanliness. In none of my cases have I ever had any urinary infiltration. I permit the patient to lie on his back or side, and to change his position whenever he desires to do so. In order to keep the patient clean I generally use a large gum catheter, one end of which is introduced into the bladder through the wound, and the other end lies in a basin placed by his side. The bladder forces the urine through this tube without difficulty, even if it is raised some distance above the level of the surface of the belly. As the wound grows smaller, say to the size of a No. 8 or 10 catheter, and the patient attempts to empty his bladder through this suprapubic fistula, or artificial urethra, a stream is sent out three or four feet from the body, the last part of it coming in jets, as from the natural urethra. If we regard the bladder as a simple bag or receptacle for the urine, it is difficult to comprehend this; but if we look upon it as a distinct organ, with a physiology of its own, and study the mechanism of urination, we can understand it. In cases of complete obstruction from prostatic enlargement, I have kept this suprapubic artificial urethra open for months, in one case for two years. After the fistula is reduced to the size of the natural urethra there is no leaking or dribbling of water, unless the bladder gets too full, and the man retains and expels it at will. The recti muscles keep the walls of the new urethra closed when not in use, and aid in preventing leakage. Indeed, so valuable is the aid of these muscles for the purpose mentioned, that in the next case that I have where an artificial anus is necessary, I will make it, if possible, low down in the middle line, between the recti muscles. This will give an imperfect substitute for a sphincter, but will be better, I am sure, than a simple patulous opening that is constantly discharging.

From my observation of drainage in the cases of suprapubic cystotomy in the male, I find it more complete than in drainage after sections through the perineum. In theory, it may not seem so, but in practice I have found it to be the case.

The other advantages of suprapubic cystotomy for drainage are apparent. The operation is simpler and far less dangerous to life than any cut into the bladder through the perineum. You go through parts less richly endowed with nerves, bloodvessels, etc.; if a fistula is left, and it is above the pubes, it is not constantly leaking or as difficult to manage as a perineal urinary fistula, and there is no danger in suprapubic cystotomy of urinary incontinence, which is often seen after perineal sections, and no danger of impotence, as I have once seen after the latter operation. In drainage through the perineum the man remains on his back in bed, and a tube is kept constantly in the bladder. In the suprapubic method the man can often sit up in a week, or sooner, perhaps, and do without the tube for several hours at a time.

The last case is that in which I performed suprapubic cystotomy in a female. The case was kindly sent to me by Dr. Tucker, of Henderson, N. C. The lady had lost the whole of the urethra and neck of the bladder by sloughing following delayed and difficult childbirth. There was absolutely no trace of the urethra, or sphincter vesicæ left. I determined in this case to make an artificial urethra above the pubes, and to close up the opening from the bladder into the vagina. The case is still under treatment, and I have not yet been able to close the fistula completely, a pin-hole opening being still left, but it has gone far enough to show me that it will be a success, and I mention it now, partly to complete the record I am giving, and partly to induce others to try the operation in similar cases.

The following is the mode of procedure which I have adopted: The night before the operation is to be performed, a purgative should be given, and if this does not act well, the next morning an enema is employed to empty thoroughly the lower bowel. The parts about the pubes should also be shaved and well scrubbed with soap and water. Early in the morning of the day of the operation a pill of five grains of quinine should be taken, and repeated every two hours until fifteen or twenty grains of quinine have been administered, and slight cinchonism produced. After the anæsthetic has been given, and the patient placed upon the table, the parts should again be washed with green soap and hot water, a stiff brush being employed to make the cleansing thorough. The parts should then be bathed with a solution of bichloride of mercury 1 : 2000. The only instruments likely to be required are a scalpel, tenaculum, and a pair of small forceps. These should be placed in a tray containing carbolic acid and hot water, 1 : 40. The next step is to clean the bladder by washing it out with a weak solution of carbolic acid and hot water. A soft-gum catheter is introduced and the bladder washed until the fluid returns free from sediment; in this way the wound about to be made is kept from coming into contact with fœtid alkaline urine, mucus, and pus which the bladder often contains. Before removing the catheter, let all the fluid escape. An empty gum bag which holds about twelve ounces of water should now be well oiled, folded upon itself, and introduced into the rectum above the internal sphincter muscle. A skilful assistant should perform this office, saving the operator loss of time in cleansing and disinfecting his fingers after the bag has been introduced, and inject into it about twelve ounces of warm water. This should be done slowly and gently, and force avoided. The bag, when

filled, pushes the bladder out of the pelvis and above the pubes.

If properly done this lessens the danger and difficulty of the operation. The rectal distention is of great importance; if complete, it removes all danger of encountering the peritoneum. After the operation is completed and the bag is removed the bladder drops back into the pelvis. This makes the track from the bladder to the wound in the skin pass from below upward and forward, and, when the wound is reduced in size to that of the natural urethra, the fistula or artificial urethra has the same relation to the bladder that the spout has to a coffee-pot. If no rectal bag is at hand I would use a pig's bladder, or distend the rectum with sponges; or an assistant with two fingers in the rectum could push the bladder upward and forward. The next step is to fill the bladder with a weak solution of carbolic acid and hot water; probably it will hold six or eight ounces. The use of force should be even more carefully avoided here than in filling the rectal bag. If the capacity of the viscus has been diminished by disease any attempt to enlarge it by forcible dilatation is unjustifiable. As soon as the bladder is seen or felt above the pubes the injection should cease. In some experiments made upon subjects with contracted bladders, I found, when the rectal bag was well filled, that the bladder became prominent above the pubes when only two or three ounces of fluid were used. A catheter may be employed to inject the bladder, but I prefer simply to introduce the small nozzle of a Davidson's syringe into the urethra, say one and a half inches, bend the penis slightly back toward the anterior abdominal wall, making thus a gentle curve of the urethra, and to send the water through this curve from the syringe into the bladder. As soon as any resistance is felt, or as soon as the bladder can be seen or felt like a ball above the pelvic brim, the injection should cease, even if there is little or no resistance. The penis should now be tied near its base with a piece of rubber tubing, or with a gum catheter, to prevent the escape of water, or an assistant may grasp the organ and hold it down between the patient's thighs, out of the way of the operator.

Beginning now with the knife, three inches above the upper border of the symphysis pubes, varying the length according to the amount of fat and thickness of the abdominal wall, a vertical incision should be made down to the pubic bone. This cut should pass through the skin, fat, and cellular tissue down to the linea alba. The linea alba should now be divided, the incision through this structure being from one-half to three-fourths of an inch shorter than the one through the skin, but it should be carried down to the pubic bone, and the shortening be made at the expense of the upper end of the wound. Now, with the handle of the knife separate the recti muscles until the transversalis fascia is reached. There is no necessity for dividing any portion of the attachment of the recti muscles to the pubic bone. Make the dissection vertically, and carefully keep in the median line. The transversalis fascia should now be caught with the forceps, nicked, and divided with the point of the knife; if the operator prefers, he can divide the fascia upon a grooved director. The cut through this structure should not be over two inches long, but division should be made down to the pubic bone. Again, with the handle of the knife, divide the fat and cellular tissue under the transversalis fascia lying between it and the wall of the bladder. Be careful not to disturb this loose cellular structure any further than is absolutely necessary. Careless or rough manipulation here may lead afterward to urinary infiltration. The loose connective tissue just behind the pubes should especially be left undisturbed.

In this space between the transversalis fascia and the bladder sometimes, but not always, may be seen large and engorged veins. They, of course, should be avoided if possible; but, if cut, will cease to bleed when the bladder is emptied and the rectal bag removed. When the bladder is exposed, the tenaculum is passed through its walls, the viscus pulled a little forward and opened with the scalpel. The water will be seen escaping by the side of the tenaculum and the knife. In old cases of prostatic enlargement the bladder walls are thick and tough, and cannot be stretched with the finger, as can the bladders of younger subjects upon whom the high operation for stone is made. So, after the knife has entered the bladder, and is withdrawn, cut, in the median line, an opening large enough to admit the index finger of the left hand.

Let the finger follow the knife quickly, so that it may enter the bladder and thoroughly explore it before all the water has escaped, and do not withdraw the tenaculum until the finger is fairly in the viscus. Make the opening in the wall of the bladder as low down as can be safely done. Let it be opposite the upper border of the pubes, and not higher. A soft-gum catheter should now be introduced into the bladder through the abdominal wound, and the distal end of the catheter dropped into a cup placed at the side of the patient. If the catheter gives rise to vesical tenesmus, or is the source of annoyance to the patient, it may at once be removed. Otherwise it will be better to let it remain some hours, for the sake of cleanliness and to give the wound time to glaze. The wound is now simply covered with absorbent cotton, which should be changed as often as it becomes soiled. The patient can lie in any position he prefers or change his po-

sition as often as he desires. The drainage of the bladder is complete with or without the catheter, no matter what the position of the patient. In the suprapubic cystotomies that I have seen the loss of blood has been slight and the shock of injury has been trifling. In none of my cases have I encountered the peritoneum. After a few weeks it will be necessary to keep in the artificial urethra a silver or a hard-rubber plug, for an hour or so every day, to keep it from closing.

GASTRIC ULCER.[1]

By ANDREW H. SMITH, M.D.,

PROFESSOR OF CLINICAL MEDICINE AND THERAPEUTICS IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL; ATTENDING PHYSICIAN AT THE PRESBYTERIAN HOSPITAL.

What I have to say in opening this discussion will be much compressed, and will relate almost wholly to the clinical aspects of the disease, leaving its pathology to be discussed by others.

I propose to speak only of the simple or round ulcer, described more particularly by Cruveilhier and often designated by his name. This occurs singly, as a rule, but in some cases there are two or more ulcers. Their general characteristics are a circular form, greater diameter at the mucous surface than near the peritoneum, and sharply cut edges, which in recent cases are flat and soft, in chronic cases elevated and indurated.

The ulcers vary in size from one or two inches in diameter to an opening that will barely admit the end of an ordinary probe. They occur usually in the lesser curvature and on the posterior wall of the viscus. Their tendency is to destroy successively the various layers of the stomach and ultimately to result in perforation. This latter event, however, is anticipated in the majority of cases by adhesions to a contiguous organ, as the liver or pancreas, and the floor of the ulcer is then made up of the tissue of the organ involved. When the ulcer is situated on the anterior wall of the stomach such adhesions are not readily formed, and an opening is likely to take place into the peritoneal cavity.

The smaller ulcers more frequently result in perforation than the larger ones, the tendency of the ulcerative process in the former seeming to be to attack the successive layers of the stomach rather than to spread laterally in the superficial coats.

The process is in some cases acute and in others very gradual. Healing may take place at any stage of its progress. Often there is a succession of ulcers at varying intervals of time, and the disease may be protracted in this way for many years.

These ulcers or their cicatrices are sometimes discovered post-mortem when there is no history of any stomach affection during life. Such cases, having no clinical history, are chiefly interesting as curiosities of morbid anatomy.

Gastric ulcer occurs much more frequently in women than in men. The ratio is usually stated as two to one. My own experience would incline me to rate it higher, more nearly in the proportion of three to one. In women it is most common between the ages of eighteen and thirty and after fifty. In men its frequency is about the same in the different periods of life, with a slight preponderance in favor of old age.

The subjects of this disease are generally found among those whose nutrition is in some way faulty. Anæmic and chlorotic girls furnish the greater number. In this country it is of very common occurrence among young female servants. Probably the reason for this is to be found in the unhygienic conditions incident to their habits and mode of life.

The disease is very commonly associated with dyspepsia, and it is often difficult to determine the point at which the symptoms of the one affection merge into those of the other.

The pathology of these ulcers has been the subject of much discussion, and particularly the share which the digestive fluids have in their production. It would not be profitable to follow out the various arguments which have been presented in support of the different theories, but I think that from the facts recorded we may safely deduce the conclusion that in conditions of diminished vitality, either general or local, an abrasion of the mucous membrane, however produced, is liable to be the starting-point of an ulcer. It seems clear that while the healthy epithelium of the stomach is proof against the solvent action of the gastric juice, the underlying structures are subject to erosion when they come in contact with it, and especially if the resistance of the tissues has been impaired by previously existing malnutrition.

Clinically there are four principal ways in which gastric ulcers may behave:

1. There may be perforation without any notable preceding symptoms.

2. There may be hæmorrhage as the first symptom.

3. There may be symptoms of gastric disorder for a variable period, and then hæmorrhage or perforation may take place.

4. There may be a more or less protracted disorder of the stomach without hæmorrhage or perforation, and terminating either in recovery or in death from exhaustion or from intercurrent disease.

In a certain very small proportion of cases a person previously in fairly good, though seldom in robust health, usually while engaged in some kind of muscular effort, suddenly experiences extreme

[1] Read before the Clinical Society of the New York Post-graduate Medical School and Hospital, March 29, 1890.

pain in the region of the stomach, immediately followed by prostration and faintness, or perhaps collapse, and in a very brief period the symptoms of general peritonitis are fully declared. The autopsy discloses a perforation of the stomach the result of a simple ulcer. The progress of the ulcer has not been marked by any symptom sufficiently decided to arrest the attention of the patient, and the appalling result takes him wholly unawares. The ulcer in these cases is usually small and its progress rapid, but as to this latter point the evidence at the autopsy is not always conclusive.

In certain other cases, under precisely similar conditions, a sudden hæmorrhage takes place followed by hæmatemesis. The loss of blood may be so great as to destroy life in a few hours or even minutes. But in the majority of cases the bleeding soon ceases, either permanently or to return after a short interval. There may be a number of these bleedings in quick succession, rapidly exhausting the patient, or the recurrences may be separated by months or years, the patient in the interval enjoying his usual health. When death occurs as the result of this kind of hæmorrhage, an ulcer is found which has opened a vessel of considerable magnitude. As the vessels ramify principally in the submucous coat an ulcer may cause hæmorrhage without endangering perforation.

Such a hæmorrhage may be recovered from, and little or no subsequent inconvenience be experienced, or it may be the beginning of a train of gastric symptoms, including perhaps other hæmorrhages.

Again, a patient may suffer for a variable time with pain, epigastric tenderness, vomiting, and other symptoms of gastric disturbance, which will be dwelt upon at greater length hereafter, and then hæmorrhage takes place or the symptoms of perforation are suddenly developed.

And lastly, the pain, vomiting, etc., referred to above may continue for an indefinite period, constituting the only symptoms of the disease, and leaving the diagnosis perhaps obscure and doubtful. The patient may be worn out at last with suffering and inanition, or may succumb to some intercurrent disease, the autopsy revealing one or more open ulcers and perhaps the cicatrices of others. Or, after a period of suffering, more or less protracted recovery takes place, and we can judge that an ulcerative process has been present only by excluding all other conditions capable of producing the symptoms observed.

Let us now examine the symptoms of gastric ulcer a little more in detail. The first, most prominent, and most constant of these is pain. It occurs in some degree in all cases excepting those in which death results from a single overwhelming hæmorrhage. It exists usually in two forms. The first, which is almost constant, or at least present for considerable periods, is of a comparatively dull, aching character, varying from a mere uneasiness to a heavy, grinding pain. It is similar to that found in chronic gastritis, and probably is due as much to the inflammation which usually accompanies the ulcer as to the ulcer itself. It exists in some degree during the intervals of digestion as well as while food is present in the stomach. At times, however, it assumes an intense neuralgic character, and radiates to the surrounding parts. It may be so severe as to induce syncope. At such times it resembles in character the pain of nervous gastralgia, but unlike this it is usually, though not always, increased by taking food. The other form of pain, and the one which is more distinctive of the disease, is produced by the contact of food with the sensitive surface of the ulcer. It begins shortly after the food is taken, and gradually subsides as the stomach becomes empty. It is much influenced by the quality of the food ingested. Food which contains coarse and irritating particles or is acid or acrid in its nature provokes a more severe reaction than that which is bland and neutral in its properties. Substances which are very hot or very cold when taken into the stomach increase the suffering. The pain is variously described as burning, piercing, grinding, etc. It is very accurately localized in a circumscribed place, usually about the xiphoid cartilage. Sometimes change of posture will give relief by removing the contents of the stomach from the sensitive point, and by this test we may be able to judge of the situation of the ulcer. Very frequently the pain "runs through to the back," as the patient expresses it, and is felt with great intensity at a point directly opposite to the spot in front. At other times it radiates through the dorsal region, or may be felt between or beneath the scapulæ. From my experience I am inclined to attach much diagnostic significance to this dorsal pain. I have very seldom found it wanting in unequivocal cases of gastric ulcer, and I do not remember to have seen it pronounced in any case of gastric disease in which ulcer could be positively excluded.

Epigastric tenderness is very generally present. It is definitely localized, and may be elicited even when pain is not present. Pressure sometimes does not cause pain immediately, but after a brief interval, and the pain so induced may become a severe paroxysm. I have known the examination by the physician, when somewhat energetically carried out, to result in intense and protracted suffering to the patient. Pressure on the epigastrium is often felt more acutely in the back than at the point where it is exercised. As shown by Hilton, the pain is sometimes felt at distant points in the track of communicating nerves.

Next to pain, the most prominent symptom is vomiting. It does not occur in every case, but its entire absence is rare. It does not differ essentially, however, from the vomiting of dyspepsia, unless the vomited material contain blood in considerable quantity. Slight hæmorrhage may occur with the vomiting of chronic gastritis, but it rarely amounts to more than streaks of blood in the vomited matters. The vomiting in ulcer is excited for the most part by the presence of food in the stomach, and seems to be provoked by the pain which the food excites. To this pain it brings at least partial relief. It is of no positive diagnostic value, except when it takes the form of hæmatemesis. The blood is then pure, and if thrown off soon after it is extravasated it is fluid and bright red. If retained in the stomach for a time it comes up more or less clotted and changed to a dark color by the action of the gastric fluids. The quantity may be only a single mouthful or it may amount to pints or quarts. If a large vessel is opened the hæmorrhage may be promptly fatal. The vomiting contributes to this result by interfering with hæmostasis at the bleeding-point. More commonly the loss of blood, assisted, no doubt, by the mental shock, soon reduces the heart's action to a point which permits a coagulum to form in the divided vessel, and the bleeding is arrested, at least for a time. But when the force of the circulation is restored, and particularly if vomiting should again be excited, the coagulum, softened meanwhile by the action of the gastric juice, is likely to be displaced and the hæmorrhage to be renewed. In this way it is common to see a succession of hæmorrhages during several days, which may then prove fatal or may be permanently arrested.

If the blood effused into the stomach be not too great in amount there may be no hæmatemesis, the entire quantity passing off by the intestinal canal. If the peristalsis is active the evacuated blood may be but little changed. But, as a rule, it is retained for several hours in the intestinal tube, and when voided has the color and consistence of tar, having been acted upon by the intestinal secretions and blackened by the sulphurous gases with which it has come into contact.

In all cases of suspected gastric ulcer the patient or nurse should be instructed to observe the evacuations carefully, as otherwise a hæmorrhage not sufficient to cause emesis might escape detection.

Profuse hæmorrhage from the stomach is strongly suggestive of gastric ulcer, but it is by no means pathognomonic. It is often seen in cirrhosis of the liver, and it may occur in gastric cancer. On the other hand, the coffee-grounds vomit, so characteristic of the latter affection, may be occasioned by slow oozing from a gastric ulcer.

Perforation into the free cavity of the peritoneum necessarily entails general peritonitis. But the wall of the stomach may be perforated without communicating with the peritoneal cavity. Adhesion with the abdominal wall, with the liver, pancreas, spleen, or diaphragm may prevent such a result. A gastro-colic fistula may be formed, or the diaphragm may be ulcerated through and a communication established between the stomach and the pleural cavity or the pericardium, giving rise to violent inflammation of the serous membrane. Adventitious cavities are sometimes formed by adhesions between the stomach and adjacent parts, these cavities communicating with the stomach and being filled from its contents. In a case under my observation during the past winter such a cavity formed between the stomach and the diaphragm. It was large enough to hold a pint of fluid. The irritation from it was communicated to the left pleura and to the pericardium, causing inflammation of each. There was also consolidation at the base of the left lung. Two attacks of general peritonitis occurred, induced, probably, by leakage from the cavity into the peritoneal sac. The last of these attacks proved fatal.

The existence of the cavity was not diagnosed during life. Its edge only presenting toward the front, the narrow line of dulness which it occasioned was confounded with that of the liver and heart.

The remaining symptoms which accompany gastric ulcer, if not actually due to the associated gastritis, so closely resemble those of that affection that they have little or no diagnostic significance, and, as to follow them in detail would unduly prolong this paper, I will omit them.

The treatment of gastric ulcer is chiefly dietetic. Our object being to promote the healing of the ulcer or ulcers, our first care must be to remove all avoidable causes of irritation. Solid food is irritating in two ways: first, through the mechanical effect of contact with the denuded surface; and, second, through the peristaltic action which it excites in the stomach. Hence the first requisite of the food is that it be liquid or at least semi-fluid. By universal consent milk is selected as the basis of the diet. But if given in its ordinary form it is likely to produce tough, firm curds, which are as harmful as solid food. This is effectually prevented by peptonizing, and this process has the further advantage that it greatly facilitates digestion and absorption. The single drawback is, that it gives to the milk a bitter taste, which is very objectionable to most patients. This difficulty may be obviated by adding a small quantity of coffee, which entirely masks the bitter taste and is in no wise objectionable. The further addition of a little sugar makes it still more palatable. Milk thus prepared should form the exclusive diet for the first week of treatment. After this, mutton, chicken, or

beef broth may be added. It is better that enough should be given at a time to permit a considerable portion of the gastric mucous membrane to exercise its absorbent function at once, rather than to tease the stomach with frequent small doses which must be taken up by a correspondingly small absorbing surface. But the total quantity should never be more than can be easily disposed of by the stomach. If this amount is not enough for the needs of the system it should be supplemented by nutritive enemata. Indeed, in cases of great gastric irritability it is better to depend entirely upon this method of alimentation and to give the stomach complete rest until its condition improves.

The return to solid food should be very gradual. To the milk and broth may be added, after a time, some of the prepared foods for infants, such as Nestlé's, or Carnrick's, or "Imperial Granum." Raw or soft-boiled eggs may be permitted a little later, then scraped raw beef, boiled sweetbread, boiled breast of chicken, etc. The slightest aggravation of the symptoms, meanwhile, should be the signal for a return to simpler diet.

In the way of medication it is doubtful whether anything which the stomach would retain would be active enough to modify in any degree the condition of the ulcer. I believe, however, that benefit would be derived from one-fourth to one-half grain doses of nitrate of silver, dissolved in an ounce of water and taken while the patient is lying on the right side, supposing the ulcer to be in the usual situation toward the pyloric end of the stomach. If the medicine excited nausea its action could be checked at once by a swallow of a weak solution of sodium chloride.

The Carlsbad salts are found useful to correct the gastric catarrh which is generally present. According to Welch, one or two teaspoonfuls dissolved in a half-pint or a pint of water, at the temperature of 95°, should be given in divided doses before breakfast each morning, with the object of acting upon the bowels.

The presence of acid in the stomach not only interferes with the healing process, but also adds greatly to the pain. Hence antacids are often indicated, and I know of no other so well calculated for this purpose as the precipitated hydrate of magnesia or "milk of magnesia," as it is called. This preparation, which has much the appearance of and tastes somewhat like milk, is perfectly bland and unirritating, and its neutralizing power is very great. Another advantage which it has over sodium bicarbonate is that it does not cause the evolution of carbon dioxide, and thus add to the flatulent distention of the stomach.

Milk of magnesia is prepared by precipitation from a solution of magnesium sulphate by the addition of ammonia. By repeated washings the ammonia is removed, enough water being left at the last washing to keep the flocculent hydrate in suspension.

The pain will generally become bearable under the use of a proper diet, but in some cases it may be necessary to resort to opiates. The danger of contracting the opium-habit must always be borne in mind if this drug is employed.

The vomiting, if not restrained by proper diet, is best controlled by giving bits of ice and by applying ice to the epigastrium. The occasional use of hypodermic injections of morphine for this purpose may be allowable. If these means are ineffectual, all use of the stomach should be suspended for a time and rectal alimentation resorted to.

Hæmorrhage calls for absolute rest, the administration of ice, and cold to the epigastrium. As the gastric artery runs from left to right along the lesser curvature of the stomach, decubitus on the left side gives the advantage of gravitation in the arrest of hæmorrhage, supposing the ulcer to be located toward the pylorus. This position has the further advantage of removing the contents of the stomach from the bleeding point.

The use of astringents and other direct hæmostatics is of doubtful utility. They are very apt to excite vomiting, and diffused, as they must be, over so large a surface their action upon the bleeding point can scarcely be appreciable.

Ergot is generally recommended, but I cannot consider this other than one of the too common abuses of this drug. Its action upon the vessels is confined to the arterioles, and when a vessel of larger size is opened ergot can have no other effect than to obstruct the collateral circulation and thus to increase the tension in the proximal portion of the bleeding vessel. Ergot is of great value in capillary hæmorrhage, for it then acts as a ligature to the smaller vessels. Therefore we might prescribe it (hypodermically of course) in the gastrorrhagia of cirrhosis of the liver; but it is wholly out of place in the hæmorrhage of gastric ulcer.

The rectal alimentation during and after hæmorrhage may be in the form of peptonized milk, with or without the addition of raw eggs; or strong animal broths may be preferred. Digested meat, such as the preparation of Leube or of Rudisch, is a convenient and efficient material. Carnrick's Beef Peptones have been used extensively with good results.

But according to my experience the best possible rectal food is defibrinated blood. It is very readily absorbed, the corpuscles as well as the serum being taken up. This is shown by numerous instances in which the dejections from the bowels during this treatment have been found of a normal color and

absolutely free from all appearance of blood. That blood thus absorbed directly into the circulation requires less elaboration before assimilation by the tissues than any of the usual rectal foods, goes without saying.

It is my habit to order it in all cases of hæmatemesis, and to continue its use in smaller quantities for two or three weeks after the stomach has resumed its functions. I continue its use in order to overcome the profound anæmia usually present, and I know of no other remedy equally efficacious. About three ounces every fourth hour will be sufficient when no food is taken by the stomach. The bowel should be cleansed once a day with a large enema of tepid water.

During the early part of the treatment of gastric ulcer, whether hæmorrhage has taken place or not, the patient should not be permitted to rise from the bed, and later, when the tendency to vomiting has ceased, only the most gentle movement about the room should be allowed. Only after all the symptoms have been absent for some weeks can the patient safely resume his usual occupations.

THE MODERN TREATMENT OF VESICAL CALCULUS IN MALE CHILDREN.[1]

By J. WILLIAM WHITE, M.D.,
PROFESSOR OF CLINICAL SURGERY IN THE UNIVERSITY OF PENNSYLVANIA; SURGEON TO THE UNIVERSITY AND GERMAN HOSPITALS.

Until comparatively recent times the very low mortality of perineal lithotomy in children in the hands of skil ul operators made it seem a work of supererogation to seek for a better method of operation. A safer could scarcely be found. A high rate of mortality after lithotomy was almost always due to deaths among elderly adults. Fergusson long ago said that it would be difficult to name any single operation of magnitude which was more successful on young subjects than lithotomy, quoting a series of 105 cases operated on at the Norwich Hospital with only three deaths, as evidence of the correctness of his statement. Brodie said, "in boys under the age of puberty lithotomy is so simple and so generally successful that we ought to hesitate before we abandon it for any other kind of operation." These opinions were reiterated by surgical teachers almost without exception, from those days until some six or seven years ago. Velpeau enumerated as the objections to lithotomy before puberty "the want of development of the sexual organs, the small diameter of the urethra, the indocility of the patients and the extreme sensibility of the parts." In 1884, Surgeon-Major Freyer, an accomplished lithotritist, and a lithotomist who had cut for stone in boys 132 times consecutively without a single death, repeated Velpeau's assertions almost in the same words, objecting to the crushing of stone in boys on account of the undeveloped condition of the genito-urinary organs, the smallness of the bladder, the narrowness of the urethra, and the liability to laceration of the vesical and urethral mucous membrane. He added that no instruments had been invented by which litholapaxy could be performed with safety in male children.[1]

Other objections have been advanced from time to time, mainly, however, relating to the same anatomical points, and (before the introduction of litholapaxy) to the difficulty of getting rid of the fragments. As late as 1888 Keyes wrote that, on account of the limited proportions of the male urethra before puberty, the excessive sensibility of the child's bladder, and the want of docility and self-control at that time of life, lithotomy is to be preferred in male children under the age of fourteen. He makes exception in favor of very small stones, and quotes in a foot-note the more recent results of litholapaxy in children.

Many similar expressions could be quoted from the writings of surgeons of all degrees of experience, but they emphasize chiefly the same points, the majority of which are now, in the light of the modern improvements in lithotrity, without applicability. Anæsthesia has made the "extreme sensibility" of the parts and the "indocility" of the patients of little moment. Otis has shown that in children, as in adults, the "small diameter of the urethra" may be greatly increased with entire safety;[2] antisepsis during and after the operation has minimized the danger of laceration of the mucous membrane; instruments have been made which are at the same time small enough to permit of their introduction into the urethra and bladder of young infants and strong enough to deal with very large and very hard calculi; Bigelow has overcome the difficulty of getting rid of the fragments: and the argument from statistics is at least neutralized by the records of Keegan and Freyer, the former having performed

[1] Read before the annual meeting of the American Surgical Association, Washington, May 14, 1890.

[1] The difficulty of obtaining suitable instruments for the crushing of stone in children is still very great. I found it quite impossible two years ago to get reliable lithotrites of the proper size. On giving an order to Weiss later (in the summer of 1889) I was told that I could not be supplied for many months, and I finally secured those I now have only through the kindness of a London friend (Mr. Frederick Treves) who brought them to me, having himself had considerable trouble in procuring them. I add this note for the information of American surgeons who may contemplate employing litholapaxy in children in the near future.

[2] He says that the proportionate relation between the circumference of the urethra and that of the penis, which he has already demonstrated in adults, holds good in children. Thus with a circumference of penis of one and a half inches, as in a child from two to three years of age, the size of the urethra would not be less than 16 millimetres in circumference; and this urethral calibre increases or diminishes about two millimetres for every quarter-inch added to or subtracted from the penile circumference.

fifty-nine litholapaxies in children with but one death;[1] the latter, influenced by his colleague's results, having adopted the operation and performed forty-nine consecutive litholapaxies without a death.[2] In the face of these undisputed facts there is but one argument remaining which, to my mind, has any weight as urged against the operation of litholapaxy in children, and that is, the alleged greater probability of recurrence.

As regards the two great classes of operative procedures for the removal of calculus—the cutting and the crushing operations: all forms of lithotomy as compared with all forms of lithotrity, and at all ages—there can be little doubt that the statistical evidence in relation to recurrence is at present in favor of lithotomy. But it should not be accepted without reservation. Many of the tables, notably those of Sir Henry Thompson and of Mr. Cadge, are based on an experience extending over many years, and antedating the introduction of litholapaxy. Those tables make the proportion of recurrence after lithotrity about 1 in 7 or 1 in 8, and after lithotomy about 1 in 20; but, like so much of the statistical matter which our text-books and journals contain, they are useless or misleading at the present day. The two principal causes which lead to recurrence are: *a*. The failure to remove every portion of stone at the first operation; *b*. The new formation of stone in the kidney and its descent into the bladder. In the tables of Mr. Donald Day, based on the records of the Norwich Hospital, the first class includes two-thirds of all the cases of recurrence. But circumstances have altered. The employment of a large-sized evacuating tube, the immediate and thorough emptying of the bladder, the minute pulverization usually possible with completely fenestrated lithotrites, the increased knowledge of the great tolerance of the bladder to prolonged manipulations if they are gentle and skilful, have all combined to place the question of recurrence upon a very different level, and to make the collection of a new set of statistics absolutely necessary before venturing to draw any positive conclusions.

But if, for the sake of argument, we investigate existing statistics on this subject we find that the great majority of cases of relapse or recurrence have taken place in patients past middle life, and especially in very old persons with enlarged prostates and feeble or atonic bladders.[3] It will be recognized at once that these conditions do not prevail in children. The prostate is undeveloped; the bladder is almost an abdominal organ; no pouch exists at the fundus; sacculation is nearly or quite unknown; cystitis is a comparatively manageable complication; the expulsive power is proportionately greater than in the male adult, in whom a "physiological atony" is not at all infrequent. In addition to these reasons for not anticipating the formation of new calculi in children around nuclei of *vesical* origin it may be reasonably expected that the conditions favoring the development of *renal* calculi will be more easily treated and controlled in children than in adults. Certainly among well-to-do people who can carry out a proper system of diet and medication it is fair to suppose that the lithic diathesis, of whatever variety, will be more readily combated in children whose diet and drugs and mode of life can be rigidly administered, than in adults with fixed and often very prejudicial habits.

For these reasons, while admitting that the question of recurrence is still *sub judice*, I am distinctly of the opinion that there is little probability that there will be enough difference between the proportions of relapses in children after lithotomies and after litholapaxies to justify any decided preference on that ground alone.

The position of litholapaxy in children is moreover strengthened by a review of the history of lithotomy which, unlike the operation with which we contrast and compare it, has undergone but little change for many years. The improvements in suprapubic lithotomy have, it is true, rendered it applicable to a much wider range of cases, and it is equally true that its most favorable results have been attained in children; but thus far the statistics of suprapubic lithotomy in children do not compare favorably with those of either litholapaxy or lateral lithotomy. This is probably due to the fact that in a large proportion of cases the operation was selected only after litholapaxy had been attempted and failed, or else was originally chosen on account of the unusual character of the calculus.[1]

It will probably always be employed in preference to lateral or median lithotomy in cases of extremely large or exceptionally hard stones, but when we remember that Freyer has removed by litholapaxy a calculus weighing 808 grains from a boy of nine, and Keegan one of 700 grains (and of uric acid) from a boy of nine and a half, it is evident

[1] Due to laceration of the bladder and urethra during the withdrawal of an unsuspected foreign body two inches in length, introduced through the rectum.

[2] Cadge places the general mortality after perineal lithotomy in children at 5 or 6 per cent.: after litholapaxy, at not more than 2 or 3 per cent. Fenwick has collected 106 cases of litholapaxy in children from one to fifteen years of age with 1 death, a mortality of 0.9 per cent.

[3] Mr. Cadge expressly states that this was true in his own cases, and adds that he has no personal experience of lithotrity in children.

[1] It is true that MacCormac has reported (The British Medical Journal, March 19, 1887) 33 cases of suprapubic lithotomy without a death, but they were from scattered sources, and did not constitute a consecutive series. There is no means of knowing how many unsuccessful, and therefore unreported, cases occurred during the same period.

that neither size nor hardness offers an insuperable bar to the latter operation.

Median lithotomy in children, although advocated by some surgeons, is objectionable on account of the greater danger of wounding the bulb or the rectum, and the difficulty in obtaining space through which to pass the finger into the urethra and the bladder. It is indeed true that the passage of the finger is not absolutely necessary, although it has always been one of the time-honored rules of lithotomy not to withdraw the staff until the finger is in contact with the stone. I have, however, frequently seen Dr. Agnew, when operating on young children introduce a pair of very small lithotomy forceps along the groove of the staff, separate them and seize the stone, and then, after the removal of the staff, extract the calculus the finger never having been in the bladder. I have used the same manœuvre myself with success. I supposed it was original with Dr. Agnew (and believe he was of the same opinion), but I found that Mr. Cadge[1] recommended almost precisely the same method as both safe and efficient, adding, "I dare say it has been adopted by others but I do not find it alluded to in modern text-books." It must be remembered, however, that its adoption places the surgeon in almost the same situation in regard to the possibility of leaving débris or unnoticed stones in the bladder, as he occupies after a litholapaxy. If the stone is soft and breaks down under the forceps, or if there are multiple calculi, he will be dependent on the touch and sound elicited by the vesical explorer just as after the other operation. If then the introduction of the finger be dispensed with in either median or lateral lithotomy in children these operations lose one of their alleged advantages, viz., the assurance of the absolute removal of all calculous fragments. If it be insisted upon it constitutes in a small proportion of cases an unavoidable source of both difficulty and danger. Sir William Fergusson, Keith, Thompson, Cadge, and many others have recorded occasional trouble with this step of the operation. The latter surgeon remarks, *apropos* of Fergusson's case: "He was a master of the art of operative surgery; if the difficulty occurred to him we may conclude that it is not unlikely to occur to any of us."

Lateral lithotomy in children in addition to the special difficulty due to the smallness of the parts, the high position of the bladder above the pelvis, the delicacy and mobility of the deep urethra and the vesical neck, has one possible contra-indication which should not be lost sight of. If the incision be prolonged a little too far backward the left ejaculatory duct can hardly escape division and subsequent obliteration, and although this may not be a serious accident in cases in which the integrity of the opposite half of the genitalia, the testicles, duct, etc., is unimpaired, yet it leaves the patient entirely dependent on that one side for fertility if not for potency. Mr. Teevan has reported four cases of sterile husbands among lithotomized patients. Langenbeck and Sir William MacCormac have called attention to the same danger, and Keegan believes the lateral operation to be frequently followed by emasculation. Dennis quotes Dr. Charles Leale in relation to several cases, coming under his own observation, in which such patients grew up with shrill voices, atrophied testicles, absence of hair upon the face, etc.; in fact with all the characteristics of eunuchs. The evidence as to this point is as yet fragmentary and inconclusive, but is of sufficient importance to deserve careful consideration.

These objections to perineal lithotomy in children are at least as weighty as any that have been urged against litholapaxy. The ease and satisfaction to both patient and surgeon with which the latter operation may be performed, I can best illustrate by a brief abstract of one of my own cases:

C. W., a small boy, aged five and a half, was brought to me by his father in October, 1889, on account of nocturnal incontinence of urine. He had a long, tightly adherent prepuce with pin-point aperture. It "ballooned" at each act of urination. I circumcised him; gave small doses of belladonna and bromide of sodium, and dismissed him, apparently cured, in November.

In January he was brought to me again by his nurse, who told me that his symptoms had returned. I then sounded him for stone, but failed to find it. Insisting (according to my invariable rule in such cases) upon a second examination before giving a positive opinion, I easily found a calculus. I recommended crushing, and after a little delay the parents consented. On February 20th, the child being etherized, I drew off the urine and injected three ounces of warm boric acid solution (fifteen grains to the ounce) into the bladder. I then enlarged the meatus[1] and introduced a Weiss fenestrated lithotrite—No. 16 French. This went in with ease. The stone was readily seized and broken. I spent twenty-five minutes in pulverizing it, paying especial attention to gentleness of movement and to the avoidance of rude or unnecessarily wide separation of the jaws of the instrument. A No. 16 tube was then introduced and a Bigelow evacuator employed. In about eighteen minutes,[2] as no more fragments

[1] Hunterian Lectures, 1886.

[1] Otis recommends performing the meatotomy long enough before the litholapaxy to allow the parts to heal. This is certainly desirable for some reasons, but in nervous children its advantages are counterbalanced by the need for two fixed appointments, two operations, etc. I have never found any harm resulting from the plan I here followed.

[2] The pressure on the rubber bulb during the process of evacuation should be slight and frequent rather than slow and vigorous. Prof. Bigelow, himself, called my attention to the much greater value of the former method, and I have repeatedly verified the correctness of the statement. Not only is the danger of driving back into the bladder sharp fragments of stone, materially lessened,

or dust could be perceived, the tube was withdrawn and the bladder carefully explored with a vesical sound. Nothing was discoverable.

The time of operation was forty-three minutes; weight of dried calculus, 170 grains. The child was sitting up in bed on February 22d, and was out of bed, playing about the room, on February 25th. The nocturnal incontinence persisted for a week or ten days, and then disappeared entirely. There was no fever, bleeding, chill, or other alarming symptoms.

The parents were nervous, consented reluctantly to this operation, and would certainly have postponed a lithotomy for a long time, much to the little patient's detriment.

This is a typical case of litholapaxy in a young boy. It can scarcely be wondered at that after an experience of dozens of such cases Keegan writes that he would as soon think of cutting an old man for the removal of a small stone as of performing lateral lithotomy on a boy whose urethra would readily admit the passage of a No. 8 (No. 15 French) lithotrite and whose stone was neither abnormally large nor hard. Nor is it surprising that Freyer says that lithotomy in the adult having been practically blotted out of his practice, he looks forward confidently to lithotomy in children meeting with a similar fate. Cadge, MacCormac, Jacobson, Kingston, Keyes, Hunt—indeed, most recent writers—press the conviction, though in less sweeping terms, that the field of litholapaxy in children is likely to be considerably enlarged in the near future.

For myself, basing my opinions on the facts mentioned in this paper and on my personal experience, I believe the following conclusions to be justifiable:

1. In every case of calculus in male children[1] litholapaxy, on account of ease of performance, low mortality, speedy recovery, and absence of danger of emasculation, should be the operation of predilection, division of the meatus being freely resorted to if that portion of the urethra offers an obstacle to the introduction of instruments.

2. The lithotrite and evacuating-tube should be of a size which can be inserted into the bladder without much effort or over-distention, and great gentleness should be observed in passing these instruments.

3. They should be withdrawn and reintroduced as seldom as possible, the stone being finely pulverized before the lithotrite is taken out at all. In seeking for or attempting to seize the stone, care should be taken to avoid such wide separation of the blades as will bring the male blade in frequent contact with the vesical neck. The crushing should invariably be done only after rotating the blades into the centre of the bladder. Every particle of the calculous dust should be evacuated.

4. Rest in bed, milk diet, and sterilization of the urine by boric acid or salol given internally both before and after the operation are valuable adjuvants. During the operation every antiseptic precaution should be observed.

5. The exceptional cases of calculi which are both large and hard may be best treated by suprapubic lithotomy, but neither unusual size nor a moderate degree of density should of itself alone be thought positively to contraindicate litholapaxy.

6. Perineal lithotomy has now a very limited field, and should be employed chiefly in those cases of stones thought to be of small or medium size in which no lithotrite, however small, can be introduced with safety.

but the swiftness and effectiveness of the outward current are much increased. I so often see an entirely unnecessary degree of force expended in the working of the bulb during this stage of a litholapaxy, even by expert operators, that it seems worth while to make this note.

[1] These remarks apply almost as well to adults.

THERAPEUTIC OXYGEN.

BY SAMUEL S. WALLIAN, A.M., M.D.,
OF NEW YORK.

THE recent translation of a French work on oxygen, and its publication with American notes and a summary of the experiences of American experimenters, have given fresh interest and impetus to the subject of the therapeutics of oxygen in this country. It is, however, amusing to note that in this somewhat prolix and plethoric volume, as originally published in Paris in 1866, Demarquay refers to the blatant claims of the original "oxygenized air" humbugs who "discovered" this wonderful cure-all (nitrous oxide) in Philadelphia about that time, as evidence of a revival of interest in Priestley's "dephlogisticated air," or oxygen!

There has been a similar confusion in the minds of physicians in this country. They have unthinkingly confounded the recent investigations of oxygen therapeutics with the silly claims of quacks who advertise "compound oxygen." No physician can intelligently study the subject until he has set aside all this specious rubbish. The old prejudice, which arose from the fact that in America the use of this agent, or something which passed for it, was, until quite recently, in the hands of the most arrant charlatans, and by them heralded as a panacea, has gradually given way, and at present some of the most earnest men in the profession are carefully experimenting with, while many others are making extensive clinical use of the agent.

The results of modern research in connection with the physiology of respiration are not yet to be considered as final. The compression chamber, the air-pump, the spectroscope, and more accurate methods of analyzing the circulating fluids, and of collecting and testing the gases of the blood, have

enabled modern physiologists to see a little further and more clearly than their predecessors.

The coloring matter of the blood, hæmoglobin, was first obtained in a crystalline state by Funke, in 1853. Its function seems to be that of an oxygen-carrier, transmitting the free oxygen, absorbed or appropriated from the atmosphere, to the tissues where the vital element chiefly accomplishes its various offices. Formerly oxygen was presumed to effect most, if not all, its work in the lungs themselves, and by direct combination, or so-called combustion. This theory is now practically obsolete, and with it should have gone the very general, but equally erroneous impression, that the direct inhalation of pure or unmixed oxygen is necessarily attended with inflammatory tendencies. It is now conceded that any such results supervening upon the use of this agent are directly traceable to impurities resulting from imperfect methods of preparing the gas.

Furthermore, the study of this gas as a remedial agent will never be entirely satisfactory until a more definite distinction is made between ordinary oxygen, as it exists in the atmosphere, and therapeutic oxygen. The former may be said to be in a comparatively passive condition, while the latter should, doubtless, always be *nascent*, or in a certain degree allotropic oxygen. The difference is marked and wide, but not by any means generally recognized. Modern chemists distinguish at least three states of oxygen: passive or atmospheric oxygen, which they venture to indicate by the symbol O; nascent, or factitious oxygen, designated by O_2; and ozone, or allotropic oxygen, represented by O_3. As the latter condition is extremely unstable, and, on account of its powerful and rapid action as an oxidizer, can be retained only in glass receivers, experimentation with it is both difficult and unsatisfactory. It is only as ozonized oxygen that it can be practically or therapeutically considered. Again, Brereton Baker has shown that the combining activity of oxygen is almost or quite destroyed if the gas be thoroughly desiccated. Charcoal, heated to redness in anhydrous oxygen, showed no signs of ignition. A volume of oxygen was dried for five years in contact with phosphorous pentoxide. In this dried gas sulphur was distilled without emitting the faintest flame; whereas, in moist oxygen sulphur burns at a temperature of 320° C. Even phosphorus could be distilled in similarly dried oxygen, while in moist oxygen it ignites at about 60° C.

Most experimenters have thus far been content to use whatever variety was available in the market—generally passive or stale oxygen; whereas, *therapeutic oxygen*, as it may be properly termed, is a far more active condition of the element. This variety is sometimes called ozonized oxygen, or "ozone oxygen," and probably consists of ordinary oxygen with an added trace of ozone. Failure to recognize these distinctions readily accounts for the varying results reported by different, as well as indifferent, observers. In the parlance of the day, there is oxygen and oxygen; and experimenters ought, first of all, to know what variety or condition of this element they are using.

That oxygen, in the proper or active condition, and intelligently exhibited, has a legitimate province in rational medicine seems now to have been definitely established. It is not, however, in the field of respiratory diseases that its use is followed by the most marked success, as is usually and unthinkingly assumed. Its *forte* unquestionably lies in the direction of inducing and aiding hæmatosis. Nevertheless, most scientific, perhaps because *too* scientific, observers have refused to give it much credit even in this direction, assuming that, in order to prove definite results, they must first demonstrate a definite increment or absorption of the gas, and its increased and excessive presence in the blood immediately after its therapeutic exhibition; whereas, it is rational to suppose that when used in a nascent condition its chemical affinities are so powerful and so prompt that its salutary effects may all be accomplished without leaving evidence of any appreciable excess of the agent, in a free state, in the blood.

Professor McKendrick, in an able and scholarly address delivered before the British Medical Association, announced as a result of his investigations that, once satisfied with oxygen, the hæmoglobin of the blood "becomes indifferent, within limits, to any additional oxygen," even if the latter be forced into it under pressure. The natural inference from this observed fact is also lame and unsatisfactory, for the reason that it really proves nothing to the point, and has no reference to the therapeutic use of oxygen. It is like saying, "Here is an animal which will not eat or drink any more than it wants, and cannot be made to do so, even under the most strenuous urging." It is rational to assume that in health the animal system appropriates exactly the needed and normal supply of oxygen, and then very naturally "becomes indifferent" to any further supply. But in disease, at least in certain diseases, there are numerous obstacles and hindrances to procuring this normal supply: confinement in a vitiated or restricted atmosphere, enforced lack of exercise, diminished breathing capacity, etc. This is the juncture at which therapeutic oxygen becomes invaluable. The starved animal eagerly devours proffered food, and with equal avidity the deprived tissues seek and appropriate the vital element.

Some interesting experiments, conducted recently at Munich, demonstrated that after a day of severe physical exertion the human system has lost about

one ounce of its normal proportion of oxygen. This loss is restored by rest and sleep; but if the rest be incomplete, if respiration be imperfectly performed, or the supply of oxygen be in any manner restricted and insufficient, gradual impairment will follow, and some form of chronic disease is finally established. The use of *therapeutic* oxygen, and it is proper to emphasize the term, is rationally indicated in all conditions in which a normal proportion of the element is presumed to be wanting. This opens to it a wide field, including a large number of chronic and some acute forms of disease. But it must be looked upon as an adjunct, not as a cure-all; at the same time more careful experimentation will doubtless prove its value in many conditions in which its use has not as yet been intelligently invoked.

The diseases in which it has thus far given most marked results are the various forms of anæmia, leukæmia, chlorosis, the indigestions, narcosis from the ill-timed use of anæsthetics or of narcotic drugs, in certain forms of asthma, and in that large class of maladies of which the original cause, whether hereditary or acquired, is found to be a vicious diathesis. Thus in lithiasis and gouty and rheumatic affections with cardiac and renal complications, decidedly favorable results have followed its persistent use.

119 EAST TWENTY-EIGHTH STREET.

THE EFFECT OF MERCURY UPON THE BLOOD OF SYPHILITICS.

BY EDWARD MARTIN, M.D.,
AND
H. M. HILLER,
OF PHILADELPHIA.

IN this country the admirable paper of Keyes[1] upon the influence of small antisyphilitic doses of mercury upon the number of red corpuscles in the blood, first attracted general attention to this most interesting line of research. Wilbouchewitch[2] in an apparently careful series of investigations concluded that small doses of mercury given for a short time increase the number of red blood-corpuscles; if continued, however, this increase is followed by a diminution much more rapid than the increase, and the anæmia thus produced may be more pronounced than it was at the beginning of treatment. On stopping the mercury there is again an increase. Keyes has pointed out the fact that the doses given by Wilbouchewitch were not small, and that in all probability an undue amount of mercury was given, since the patient rapidly lost weight where this condition was observed. Keyes holds that both syphilis and excessive doses of mercury lower the number of red blood-corpuscles below the healthy standard, but that mercury in small doses continued for a short or long time increases the number of these corpuscles both in the syphilitic and non-syphilitic. Ricord and Grassi[1] many years before had advanced as proven that potassium iodide increased the red blood-cells in syphilitics, while mercury had a directly contrary effect. We have not been able to find any detailed account of the amounts of mercury given by these observers, and as it was then the custom to administer the drug with an unsparing hand, we think it probable that doses much larger than necessary were given. These authors, together with the majority who have since written upon the subject, call attention to the great diminution of red blood-cells consequent upon the syphilitic poison. This belief in the direct blood-effect of syphilis is not, however, universal. Hayem[2] states that often there is no material change in the blood of syphilitics, though in females there may be slight anæmia, and that the red blood-corpuscles are never below 3,500,000, while the hæmoglobin ranges from 75 per cent. to 90 per cent. In regard to the action of mercury he states that it is followed by variable results.

In a first series of cases the blood lesion was improved, in another it remained stationary, and in a third it was slightly aggravated. As a conclusion Hayem states: "Therapeutic antisyphilitic doses of mercury do not have any particular effect upon the blood." In Keyes's paper the subject of the hæmoglobin richness of the corpuscles is not considered, and this is we think a matter of great importance, since it is well recognized that there may be a marked deficiency of hæmoglobin even though the corpuscular count be fairly high. Thus the immediate effect of severe hæmorrhage is to decrease both these constituent elements of blood in the same ratio. The corpuscles are subsequently replaced much more rapidly than the hæmoglobin, so that an estimation of the blood taken after a few weeks may show a large count by the hæmocytometer while the hæmometer will give an estimation far below normal. It may be fairly assumed that in normal blood when the Zeiss hæmocytometer gives a count of about 5,000,000 red blood-corpuscles, the Fleischl hæmometer will indicate about 100 per cent. of hæmoglobin. In persons of unusually robust health both corpuscles and hæmoglobin will range considerably higher. This is particularly the case with hæmoglobin. Thus, while a count of 6,000,000 is comparatively rare, we have repeatedly estimated the hæmoglobin as above 125 per cent.

Since it is important, before considering the effect of mercury upon the hæmoglobin, to know, not only what is the normal percentage of this constituent under ordinary circumstances, but also to be cogni-

[1] American Journal of Medical Sciences, p. 17, 1876.
[2] Arch. de Physiol., 1874, p. 509.

[1] Leçons sur Le Chancre. Fournier, Paris, 1860.
[2] Du Sang. Paris, 1889.

zant of the fluctuations to which it is subject in various individuals and under varying conditions in the same individual, we have carefully examined with the hæmometer the blood of five robust men, all athletes and in trained condition, with the following results:

A. Before Exercise.

1. P.,	wt. 165.	Stroke of junior gig.	Hæmoglobin, 115.
2. H ,	wt. 143.	Bow " "	" 120.
3. B.,	wt. 148.	No. 2, Univ'y crew.	" 106.
4. L.,	wt. 172.	Bow " "	" 108.
5. W.,	wt. 165.	Stroke " "	" 120.

These estimates were taken immediately before a hard four-mile pull, the members of the University crew pulling an additional two miles. We had previously determined that the average loss of weight from this amount of exertion and the consequent free diaphoresis was two pounds. Thinking that there might be a marked alteration in the hæmoglobin as a result of the abundant loss of water, both through the lungs and skin, we made another estimate immediately upon the return of the crew to the boat-house:

B. After Exercise.

1. P.	Hæmoglobin, 115.	Unchanged.
2. H.	" 120.	"
3. B.	" 112.	Gain, 6.
4. L.	" 105.	Loss, 4.
5. W.	" 125.	Gain, 5.

It will thus be seen that no marked or constant effect was produced by violent and prolonged exercise.

Penzoldt[1] asserts that food without drink causes an increase in the estimate of hæmoglobin of over 10 per cent., and that the ingestion of liquid (1½ litre of beer) lowers it rapidly 12 per cent. By the free sweating induced by 0.02 gramme pilocarpin, he, in three-quarters of an hour, brought the hæmoglobin estimate from 80 per cent. to 100 per cent. If these statements are reliable, but little dependence can be placed upon any of the comparative hæmoglobin calculations, since a constituent of the blood subject to such marked quantitative changes under comparatively slight causes may vary in amount quite independently of any treatment to which the patient has been subject. For the purpose of determining this point three athletic men were kept without water for some time; their hæmoglobin was then examined; they were allowed to drink freely, and, in twenty minutes, another estimation of hæmoglobin was made. The following table will show the results:

1. M., weight 195 pounds. No liquid for 24 hours. Estimate immediately after dinner. Before taking liquid, hæmoglobin 125; 20 minutes after taking liquid (1 litre), hæmoglobin 112.

2. L., weight 172 pounds. No liquid for 10 hours. Before taking liquid, hæmoglobin 125. Aftertaking liquid (1 litre), 110.

3. H., weight 142 pounds. Did not abstain from liquid. Hæmoglobin 113. After drinking an additional litre of liquid, 113.

4. H., weight 142 pounds. No liquid for 15 hours. Hæmoglobin 120. After taking liquid (1 litre), 120.

In the first two observations there was a marked loss of hæmoglobin—upward of ten per cent. In the last two, both made upon the same individual, there was no change.

These figures show conclusively that when the hæmoglobin is examined such examinations must take place under similar circumstances, and that it is the average of many examinations rather than the results of single ones which will enable us to draw trustworthy conclusions. Thus, L., examined one day before dinner, shows a percentage of 108 for hæmoglobin; three days later, immediately after dinner, his hæmoglobin is 125; an hour and a half later, after copious draughts of liquids, his estimate is 110. In drawing conclusions from the results of blood examination the physique and previous history of the patient must also be borne in mind. Thus one of our observations shows the following:

M., hæmoglobin 120. Red blood-corpuscles 6,500,000. A reduction to the average percentage and count would, in this man, mean a decided blood change.

Again, as another difficulty in the way of rightly interpreting the hæmometer readings, must be considered the fact that many individuals of a most pronounced anæmic appearance in reality show on examination a practically normal blood. Sahli[1] calls attention to this fact, and Oppenheimer[2] confirms his observation, explaining it upon the theory of internal congestion causing reflexly an antagonistic action of the vaso-motors of the skin, as advanced by Dastre and Charcot.

It would seem, then, that while there is a so-called normal percentage of hæmoglobin, this normal is subject to wide variations: that the normal of the young trained athlete is far above that of the average dweller in cities; that even profound pallor is compatible with a full quantity of hæmoglobin; and that there is an almost hourly fluctuation in the percentage of each individual.

It will be seen at once that it is not possible to exclude all of the many sources of error. We eliminated them as far as possible, however, in our examinations of syphilitics, by making the examinations in each case as near the same hour of the day as might be. First, in regard to the anæmia produced by syphilis, we have the following observations:

1. Mrs. G., aged twenty-eight. General lymphatic enlargement; papulo-squamous eruption;

[1] Munchener medicinische Wochenschrift, August 20, 1889.

[1] Correspondenz-Blatt für Schweizer Aerzte, 1886.

[2] Deutsche medicinische Wochenschrift, Oct. 17, 1889.

mucous patches; iritis; periostitis. No chancre or trace of one found. Probable time from inoculation two months. Hæmoglobin 78. Red blood-corpuscles 4,500,000.

2. R. G., aged twenty-four. Healthy, rosy-cheeked young Irishman. Chancre of lip; general glandular enlargement; no skin eruption. Hæmoglobin 110. Red blood-corpuscles 5,600,000.

3. M. S., aged nineteen. Buxom Irish girl. Papulo-squamous eruption; mucous patches. Hæmoglobin 98. Red blood-corpuscles 5,000,000.

4. H. T., aged thirty. Thin and anæmic in appearance. Chancre two months since; periostitis; mucous patches; papular eruption. Hæmoglobin 80. Corpuscles 4,800,000.

5. Mrs. McG., aged forty-five. Rather pale, but apparently strong, Irish woman. Two chancres on cheek; beginning general glandular enlargement. Hæmoglobin 95. Corpuscles 5,500,000.

In three cases, then, all showing the secondary eruption, there was a decided lowering of the hæmoglobin percentage, together with a diminution, though not in the same proportion, of the corpuscular count. In the fifth case the blood was apparently not affected, though, recalling the wide quantitative variations to which the hæmoglobin is subject, it cannot be said positively that there was not also in this case a diminution.

All authors are practically united upon the fact that, coincident with the development of secondaries, syphilitic patients lose weight and become pale and chlorotic in appearance. This is usually much more marked in women than in men. Indeed the term syphilitic chlorosis has been applied to this condition. Wilbouchewitch,[1] Särensen,[2] Keyes,[3] Haffer,[4] and others, have all stated that syphilis diminished the number of red blood-corpuscles. Schulgowski[5] found that not only the red blood-corpuscles, but also the hæmoglobin was diminished in quantity. Laache[6] arrived at similar results, and also stated that the syphilitic chlorosis is in its development closely connected with the roseola. Graeber[7] found both hæmoglobin and corpuscles diminished, and also observed that the red blood-corpuscles were of smaller size.

De Luca[8] objects to the name chlorosis, since he found no diminution in the amount of hæmoglobin, as is the case in true chlorosis. He states that in recent syphilis, in spite of the diminution in the red blood-corpuscles, the coloration remains normal. Stierling[9] found that about the same ratio of red blood-corpuscles to hæmoglobin obtained in syphilitics as in healthy individuals. Lezius,[1] who has perhaps made the most thorough systematic examinations of syphilitic blood, finds both hæmoglobin and corpuscles always reduced below the normal standard, the former to a far greater extent than the latter. He states that the blood of the anæmia of syphilis can only be distinguished from that of true chlorosis by the fact that in the former the diameter of the corpuscle is somewhat greater than normal, while in the latter this measurement is somewhat less. Lezius further states, as the result of repeated examinations, that as a rule, during the early period of secondary incubation (chancre) the hæmoglobin percentage is normal. Later, about the period of exanthematous eruption, a rapid diminution in this element of the blood can be noted. This diminution is observed during the whole course of the specific efflorescence; as with the disappearance of the latter the percentage of hæmoglobin is again increased. In our observations we have been frequently struck with the irregularity in the shape and size of the blood-corpuscles in syphilitics, and Lezius observes that he has noted poikilocytosis in most of his cases.

The effect of small doses of mercury in increasing bodily weight was noted by Hallopeau, Damourette, Basset, and many others, before exact methods of blood examination were known; and Keyes, Liégois, Robin, and Schlesinger have asserted that this drug increases the number of red blood-corpuscles. In regard to its effect upon the hæmoglobin, however, there is not much in evidence. De Luca says mercury has no effect upon the coefficient of the ratio between red blood-cells and hæmoglobin in syphilis. Schlesinger says the hæmoglobin is increased under small doses of mercury. Lezius gave three healthy individuals antisyphilitic doses of mercury by hypodermic injection. In two the percentage of hæmoglobin was slightly increased; in one, slightly diminished. In all the red blood-corpuscles were diminished in number. Blarez states that mercury has a direct oxidizing effect upon the hæmoglobin. Our observations are as follows:

Mr. T., aged thirty. Iritis; periostitis; papular squamous eruption. Chancre three months before.

November 20, 1889. Hæmoglobin 80; corpuscles 4,800,000; weight 106 pounds. Given:

℞.—Blue mass . . . . . 2 grains.
Dried sulphate of iron . . . 1 grain.
Three times daily.

Rapid disappearance of all specific manifestations. Cod-liver oil and beef peptonoids were also given.

December 20. Signs of stomach giving out. Ordered inunction of blue ointment, 2 drachms daily. Hæmoglobin 80; red blood-corpuscles 4,600,000; weight 114 pounds.

[9] Deut. Arch. f. klin. Med., Bd. xlv. p. 75.

[1] Blutverand. bei der Anæmie Syph., Inaug. Diss. Dorpat, 1889.

January 1. Hæmoglobin 90. Inunctions stopped. Protiodide of mercury, ¼ grain three times daily.

11th. Hæmoglobin 105. Diarrhœa for one week past. Reappearance of skin eruption. Ordered inunctions of blue ointment, 2 drachms daily.

23d. Hæmoglobin 95.

30th. Hæmoglobin 100; red blood-corpuscles 5,000,000; weight 121 pounds. Mucous patches on half-arches of both sides. Ordered a potassium chlorate and tincture of myrrh gargle.

February 23. Hæmoglobin 115.

March 23. Hæmoglobin 115; weight 125 pounds.

April 12. Hæmoglobin 115; red blood-corpuscles 5,600,000; weight 126 pounds.

This patient has been continuously taking mercury for five months. His improvement has been progressive; his hæmoglobin has risen from 80 to 115; his red-corpuscle count from 4,800,000 to 5,600,000; his weight from 106 to 126 pounds.

Mrs. McG. Mucous patches on half-arches; general papular eruption two months after chancre.

January 14. Hæmoglobin 95; red blood-corpuscles 5,500,000.

31st. Ordered protiodide of mercury, ¼ grain three times daily. Hæmoglobin 90; red blood-corpuscles 3,800,000.

February 9. Hæmoglobin 90; red blood-corpuscles 4,200,000.

14th. Mercury continued; regular increase of one pill a day since February 3, making fourteen pills to-day. Hæmoglobin 100; red blood-corpuscles 4,280,000. Bowels inclined to looseness; malaise.

26th. Fifteen pills a day since last count. Patient is weak. Hæmoglobin 106; red blood-corpuscles 4,100,000. Stopped mercurial treatment, and gave sulphate of quinine, 2 grains three times daily.

March 11. Eruption much more pronounced. Feels stronger and better. Hæmoglobin 80; red blood-corpuscles 3,660,000. Again put on mercury; ordered her to begin with three pills a day and to increase by one daily.

24th. Since last count has taken thirty-nine pills, each containing ¼ grain of protiodide of mercury. Throat sore; mucous patches. Has slept poorly for a month. Hæmoglobin 108; red blood-cells 4,100,000. Ordered compound tincture of cinchona, 1 drachm three times daily; stopped mercury.

April 7. Hæmoglobin 88; red blood-corpuscles 3,650,000. Ordered potassium iodide, 10 grains, and biniodide of mercury, $\frac{1}{12}$ grain, three times daily. Patient has not returned since.

The observations on this second patient were particularly valuable. Under very large doses of mercury her hæmoglobin percentage increased while the number of corpuscles was slightly diminished. On the mercury being stopped the hæmoglobin percentage dropped from 106 per cent. to 80 per cent., the red blood-cells from 4,100,000 to 3,660,000. A course of mercury, given in moderate doses in two weeks, brought the hæmoglobin up to 108 per cent., the corpuscles to 4,100,000. On the mercury being stopped again the hæmoglobin fell to 88 per cent., the corpuscle count to 3,650,000.

It is to be noted that while the hæmoglobin percentage is higher than when this patient first came under observation, the number of corpuscles is considerably below that which was observed at that time.

We believe that neither the blood condition in syphilis nor the action of mercury upon the blood has yet been formulated. Each observer has seen too few cases for comprehensive conclusions. The previous condition of the patient before contracting syphilis has a modifying influence upon the blood which has not been duly considered. In opposition to Lezius we believe that in the majority of cases the diminution in hæmoglobin is less than the corpuscular count would suggest. Our observations have certainly accorded more with those of De Luca in this respect. We think it must also be granted that both corpuscles and hæmoglobin are reduced in quantity by syphilis, and that mercury prevents the reduction. That the mercury acts as a tonic remains to be proven, since increase in the number of blood-cells and in the body-weight may be the result of retarded oxidation as well as of tonic action.

We believe that the "tonic" dose for each individual must be determined by his susceptibility to the drug. Thus we have given for weeks at a time three grains of protiodide daily with beneficial effect, and again we have produced marked constitutional effects by half a grain of the same drug given three days in succession. An examination of the blood will afford a valuable guide as to the amount of mercury to be given, since an overdose produces a very rapid diminution in the corpuscular count and the amount of hæmoglobin. It must be borne in mind, however, that in the beginning of mercurial treatment there is often a falling-off of the blood condition due to the disease itself and apparently taking place before the mercury has begun to produce any effect.

It is mainly in the hope of suggesting careful examination into the subject on the part of many observers, and consequently the publication of an amount of clinical material sufficient for the establishment of general conclusions that this communication is offered.

THREE CASES OF VARICOSE VEINS IN THE BROAD LIGAMENT.

BY BARTON COOKE HIRST, M.D.,
PROFESSOR OF OBSTETRICS IN THE UNIVERSITY OF PENNSYLVANIA.

Case I.—A woman, who had given birth to two children, one living, the other destroyed by the forceps, was seen by the writer after she had been in labor many hours. The child's head, while still above the pelvic canal, was tightly jammed down upon the brim; the os was well dilated, the lower uterine segment stretched to a dangerous degree.

Forceps had already been tried for several hours without success. Craniotomy was performed with no difficulty, and extraction was easily effected. A careful examination was made for a rupture of the uterus, but no sign of it was discovered. The woman did perfectly well for eighteen hours; then suddenly went into collapse and died shortly afterward. A careful post-mortem examination showed the cause of death to be a ruptured bloodvessel in the outermost portion of the left broad ligament and hæmorrhage into the peritoneal cavity. The bloodvessels of the broad ligament were, of course, enlarged, as they are in every woman who is pregnant or has been recently delivered, but it is impossible to say whether the enlargement was extraordinary, for the region was so thoroughly depleted by the profuse hæmorrhage. This was, however, probably the case, for many thousand broad ligaments are subjected to a great strain during labor without a rupture of bloodvessels within them. It is only natural, therefore, to presume that the veins were much distended and their walls thinned in this case.

CASE II.—M. N., aged thirty-nine, has had four children, the last six years ago. She has been a widow for several years. Menstruation had been regular until six weeks before the patient came under my observation; at that time, during a menstrual period, she attempted to carry a heavy coal-scuttle up a flight of stairs, but on the way was seized with violent pain in the abdomen and faintness. After this there was a constant flow of blood from the uterus associated with pain in the left hypogastric region.

The day on which I first saw the patient, she had taken a long street-car ride to visit her daughter in the Philadelphia Hospital; while walking across one of the court-yards she fell to the ground in a faint and was taken to a bed in the medical ward and from there was transferred to my department. An examination under ether revealed free fluid in Douglas's pouch and an induration in the left broad ligament. Laparotomy was done the following morning in the belief that the case was one of ruptured tubal pregnancy. On incising the peritoneum a large quantity of dark blood welled out; clots were found adherent to the intestines, and in the left broad ligament was a mass of old clotted blood which could be seen and felt through a rent in the posterior layer of the peritoneum covering the ligament. The tube was intact. As there were no traces of fresh hæmorrhage, the clots were picked from the intestines, the fluid blood washed out of the peritoneal cavity, and the abdominal wound closed without drainage. Her recovery was uninterrupted.

Here, no doubt, there had been a large pelvic hæmatoma from rupture of a bloodvessel during menstrual engorgement, followed by rupture of its peritoneal covering six weeks later. The condition found within the abdomen precluded the possibility of tubal pregnancy, and the woman denied, with perfect truth I am convinced, the possibility of impregnation.

CASE III.—L. B., aged thirty years, has had six children, the last two years ago. The day following this delivery she was obliged to arise to do heavy housework. Since this time she has suffered from severe recurrent pelvic pains, which have incapacitated her for work. A week before entrance into the Philadelphia Hospital she had aborted in the early months of pregnancy. On examination, a rather large and exceedingly sensitive tumor, which felt cystic, was discovered in Douglas's pouch. The uterus was anteverted and fixed. The examination, although carefully conducted, lighted up a sharp attack of pelvic peritonitis, which, however, quickly subsided under treatment. A subsequent examination confirmed the result of the first. With the idea that a bad pyosalpinx would be discovered, laparotomy was advised and agreed to.

A tumor was found in the right broad ligament and behind the uterus, to which it was loosely adherent by inflammatory exudate. It was seen to be independent of the tube, which, though slightly enlarged, presented a fairly normal appearance. On bringing the mass in sight, it was startlingly like a loop of intestine; placing intestine and tumor side by side, there was absolutely nothing to distinguish them in appearance. The ligature had already been placed below the tumor, but not tied; an incision was made in it to discover its nature and a great gush of blood told the tale. The thread was quickly and firmly tied, and the mass removed. It was found to consist of many bloodvessels, into some of which I could place the tip of my little finger. The woman made a good recovery, and when I last saw her, some months after the operation, she had been relieved of her former symptoms. There was still some exudate on the right side, but the uterus was in good position, and fairly movable.

The existence of varicose veins in the pelvis as a distinct disease, with distressing symptoms and dangerous possibilities, has not, I think, secured the recognition which its importance deserves. The occurrence of three cases in the experience of a single individual within a year, would indicate that the condition is by no means uncommon. A few other observers have recorded like experiences, and in occasional reported cases, one is inclined to think that enlarged vessels in the broad ligament had been overlooked or mistaken for something else. For instance, in a laparotomy recently described, complicated by rupture of the iliac vein, the vessel more probably was in the broad ligament, but by its size and enormous distention exactly simulated one of the great venous trunks of the body.

CLINICAL MEMORANDA.

MEDICAL.

A Case of Croupous Pneumonia with Pericarditis. Simulating Pneumothorax. — Michael G., aged twenty-eight years; married; born in Hungary; was admitted to the Pennsylvania Hospital April 12, 1890. Patient had been

sent from Phœnixville, and had walked to the railroad station and sat up in the cars on his way to Philadelphia.

Upon admission his respirations were 56; pulse 100, intermittent, and small; temperature 103.5°.

No history of his illness could be obtained, as he knew only a few words of English. Heart was displaced far to the right side, the apex beat being felt beneath the xiphoid cartilage, and over the usual præcordial area a tympanitic percussion note was elicited. A distinct murmur was heard over the heart, which appeared to be exo-cardial. The right chest showed good expansion, that of the left was very defective, and the patient complained of much pain in the left side.

On the left side there was absolute flatness as far as the third rib, below this point the percussion note was high-pitched, but at the same time markedly tympanitic. Breathing was distant and distinctly amphoric in character below the left third rib and over an extended area of the lower two-thirds of the left chest anteriorly. Metallic tinkling was heard over the lower third, and the bell sound could be distinctly elicited. Patient was too weak to enable me to make a very thorough investigation, and I think no examination of the back of the chest was made. From the coincidence of several of the most marked signs of pneumothorax, from the apparently sudden onset, great pains, dyspnœa, and prostration, I was inclined to regard the case as one of pulmonary fistula and resulting pneumothorax, probably following an attack of pneumonia with pulmonary abscess.

He was ordered carbonate of ammonium and whiskey, and sulphate of strychnine one-fortieth of a grain every four hours.

April 13. Condition critical; some yellowing of the scleræ.

14th. Pulse irregular; great dyspnœa.

15th. Failed rapidly, and died at noon markedly jaundiced.

There had been little or no expectoration during the patient's stay in the hospital.

Autopsy, twelve hours after death. Pericardium very much thickened and adherent to sternum, diaphragm, and surrounding parts. Marked diaphragmatic pleurisy. Heart was drawn over to the right by the pericardial adhesions, and the apex was beneath the xiphoid. Flakes of lymph were thickly studded over the whole inner surface of the parietal layer of the pericardium and over the outer surface of the visceral layer and some adhesions between the visceral and parietal layers at the base of the heart. While the pericarditis seemed to be in part recent, the adhesions to the diaphragm were apparently old. Hepatization of nearly the whole left lung. Kidneys normal.

While a more careful examination in this case would undoubtedly have saved me from falling into the error of diagnosis that I made, the diagnosis was, I think, not without its difficulties, and the possibility of such a mistake must be my excuse for reporting the case in detail.

HENRY M. FISHER, M.D.,
Physician to the Episcopal Hospital, etc.
PHILADELPHIA.

TOXICOLOGICAL.

Nitroglycerin Poisoning.—The patient was a married woman twenty-nine years of age; in poor health, and suffering greatly from cardiac asthma. When I first saw her she had been taking a mixture which had produced symptoms of mild belladonna poisoning. The action of the heart was then feeble and irregular, and I prescribed drop doses of a one per cent. solution of nitroglycerin; also a solution of morphine, not only to produce sleep but as an antidote to the belladonna. Early on the following morning she arose to take a dose of the morphine solution, but by mistake swallowed two drachms of nitroglycerin. She soon remarked that the medicine "affected her head like brandy."

I was sent for, and on arrival found her with cold extremities and pale face; pulse strong and regular—eighty beats to the minute. She was semi-conscious, and the asthmatic breathing of the previous evening was still present. She apparently suffered from gastric distress, and subsequently told me that she had a desire to vomit.

A hot mustard foot-bath was given, and an emetic of mustard in coffee was administered, which was quickly followed by vomiting. As her condition was no longer alarming I left, with directions that her chest should be enveloped in a flaxseed poultice and that she remain in bed. On my return, later in the day, the dyspnœa had markedly subsided, and she had nearly recovered from her distressing symptoms.

After recovery she told me that she imperfectly recollected the events following the dose of nitroglycerin, though she remembered that breathing was more difficult than usual and that she was nauseated.

LOUIS KOLIPINSKI, M.D.
WASHINGTON, D. C.

MEDICAL PROGRESS.

Methacetin.—DR. C. SEIDLER reports his results in the treatment of a number of different diseases with methacetin (*Berliner klinische Wochenschrift*, April 14, 1890). In 28 cases of typhoid fever, pneumonia, tuberculosis, and influenza, in adults, a satisfactory antipyretic effect followed the administration of the drug.

In moderately high temperature—100° to 102°—doses of from 4 to 5½ grains are sufficient to reduce the temperature to normal with safety, but in higher grades of fever the dose must be increased to 6 or 7 grains. With a few patients only did the temperature fail to fall more than two degrees. In a patient with severe phthisis with a regular evening temperature of 104°, 5 or 6 grains of the drug about 3 o'clock in the afternoon prevented the temperature from rising above 100½°; but otherwise the patient was apparently not benefited. In most fever cases the fall in temperature was accompanied by a more or less profuse sweat, directly proportionate to the weakness of the patient, which fact unfits the remedy for use in phthisis. Headache, tinnitus aurium, deafness, giddiness, or vomiting were not noticed in any case after the administration of methacetin.

In two cases of acute articular rheumatism the drug acted promptly. The pain diminished on the first day after three doses of 4½ grains each, and on the third day pain, fever, and swelling had disappeared not to return.

As an antineuralgic, methacetin is less useful. For this purpose the author at first employed doses of 1½ to 4 grains, but soon found that to produce any effect larger

doses—5 to 8 grains—were necessary. In two cases of trigeminal neuralgia he prescribed 4½ and 6 grains of methacetin, in the first case with no effect; in the second case three doses of 6 grains each checked the attack. No influence in preventing the return of the disease was observed. The drug was also of little value in the neuralgic pains of locomotor ataxia. In the prodromal headaches of scarlet fever and typhoid fever, and in the headaches of gastric catarrh and nephritis, the effects were good, though in the author's experience antipyrine and antifebrin act more promptly in such conditions.

In conclusion, according to Seidler, methacetin is an efficient antipyretic, free from harmful effects other than the free sweating produced. It is also probably an excellent remedy in the treatment of acute articular rheumatism. As a nervine, and especially as an antineuralgic, it is not very efficient, though possibly it may be used to intensify the effect of other remedies used for this purpose.

Trichloracetic Acid in Diseases of the Nose and Throat.—Ehrmann, of Heidelberg (*Therapeutische Monatshefte*, April, 1890), reports success with trichloracetic acid as a cauterant in diseases of the nose and throat. The crystals were applied by means of a silver applicator. The treatment was employed in 140 cases, including hypertrophy of the turbinated bodies, circumscribed polypoid hypertrophy, hypertrophic tonsillitis, hypertrophied uvula, follicular pharyngitis, and hypertrophy of the lingual glands. In 87 of these cases the cauterization was made but once, in 30 cases twice, and in the remainder from three to five times.

The author believes that trichloracetic is much preferable to chromic acid, in that the cauterant effect is more localized and forms a much thicker eschar.

As an astringent, Ehrmann has employed the acid in the following mixture:

R.—Iodine	2 grains.
Potassium iodide	3 "
Trichloracetic acid	4½ "
Glycerin	7½ drachms.

But as yet he refrains from expressing an opinion upon the value of this application. The acid used was that manufactured by Merck.

Gonorrhœa in a Brother and Sister aged Six and Eight Years.—Dr. F. M. Crandall, of New York, reports the case of a boy six years of age who was brought to the Polyclinic on February 6th with a history of a urethral discharge dating from about Christmas. On examination, the prepuce was found to be swollen and inflamed, and there was a free flow of pus from the urethra. Microscopical examination of the pus revealed numbers of gonococci of typical appearance and grouping.

Under treatment by an alkaline diuretic and an injection, there was a marked decrease in the amount of pus, but a slight gleety discharge still continues. Recent microscopical examinations show but a very small number of gonococci.

On February 11th (five days after the first visit of the boy) his sister, aged eight years, was brought, with a history of a vaginal discharge discovered by the mother about January 28th. Examination showed a profuse purulent discharge from the vagina, with considerable redness and swelling of the vulva. Examination of this pus also revealed gonococci in great abundance.

Vaginal injections of sublimate solution (1 to 5000) were followed by rapid improvement and complete recovery by March 1st.

The author believes that the boy probably acquired the disease from an uncle with whom he slept, and who is known to have had a urethral discharge. The girl then acquired it from her brother, for intercourse is acknowledged by both parties.

Subsequently, however, the boy, following the example of an illustrious ancestor, alleged that the woman had beguiled him and was the author of his woe; that his sister had been infected by a young man who had been in the family, and that his own disease had been acquired from her. It is at least quite certain that the gonococci in the two cases originated from the same source.

The boy, it may be added, is strong, active, and rather large for his age. He is precocious, exceedingly shrewd, and evidently intelligent upon matters which boys of his age should know nothing about. It is a matter of considerable interest in such cases to know how much is due to inherited tendency and how much to vile company and vicious teaching.—*New York Medical Journal*, April 26, 1890.

Transposition of the Abdominal Viscera.—According to the *Lancet*, Mr. Treves, in recently performing an ovariotomy, discovered complete transposition of the abdominal viscera. The liver was upon the left side, the spleen upon the right; the cæcum was in the left iliac fossa, the sigmoid flexure in the right; the aorta ran along the right side of the vertebral column. The stomach was transposed, the pyloric extremity being directed toward the left. It is probable that this condition also existed in the chest, for the apex beat was felt to the right of the sternum.

Antiseptic Management of Vaccination.—To avoid the dangers of vaccination, Dr. Alfred Leach adopts the following precautions (*British Medical Journal*, April 19, 1890):

1. The lymph is obtained on the day it is to be used.
2. The instruments, the patient's arm, and the unopened tube of lymph are washed in a disinfecting solution.
3. In four places small scratches, and valvular punctures are made with a Gräfe's cataract knife charged with the lymph.
4. When the scarifications have become perfectly dry they are dusted with bismuth and a pad of dry lint is applied.
5. After the second day the nurse is directed to wash the part daily with a gentle stream of cold water, no sponge being allowed to come in contact with the wounds.

As a result of this careful treatment the author has seen but one case of inflamed arm during the past six years.

Excision of the Mastoid Cells.—Hessler, of Halle, thinks that in mastoid disease Wilde's incision, which

consists in simply incising the tissues down to the bone, is of use when periostitis alone is present, and that it is insufficient when the cells are involved (*Archiv für Ohrenheilkunde*, Nos. 2 and 3). In doubtful cases he advises raising the periosteum to examine the condition of the bone beneath. If, from the appearance of the bone, disease of the mastoid cells seems probable, he performs so-called excision of the cells. This consists in opening the spaces and removing the carious portions without opening the mastoid antrum. The operation is, of course, inefficient if an abscess of the antrum is present. The author tabulates 66 cases of mastoid operation—89 of opening the antrum, 4 of Wilde's incision, and 23 of excision of the cells. In all of the latter cases there was great improvement, none requiring subsequent opening of the antrum.—*Weekly Medical Review*, April 19, 1890.

Tetanus Treated by Parenchymatous Injections of Carbolic Acid.—BIDDER, of Berlin, reports the following case (*Deutsche medicinische Wochenschrift*, March 6, 1890): A child of three and a half years received a crush entirely removing portions of the phalanges of the third and fourth fingers. Fourteen days after the injury typical symptoms of tetanus developed. The wound was then washed with a 5 per cent. carbolic acid solution, and dressed with a weaker solution. Internally one tablespoonful of a 3½ per cent. solution of chloral was given several times daily. The symptoms then somewhat improved and the jaws could be separated to a distance of three-fourths of an inch, though convulsions recurred when the child attempted to drink. The wound being in an unhealthy condition, the author injected hypodermically, in various places around it, a syringeful of 2 per cent. solution of carbolic acid. On the following day vigorous granulations appeared, the quick pulse became slower, the profuse perspiration disappeared, and the rigidity of the neck slowly relaxed. Three weeks later the wound had cicatrized and the patient was practically well. It is to be noted that during the course of the disease about three drachms of chloral were administered, which doubtless, in a measure, contributed to the result.

Hydrastis Canadensis.—According to *L'Union Médicale*, DR. CABANÉS has published a treatise upon the therapeutics of hydrastis Canadensis, in which he concludes:

1. That preparations of hydrastis Canadensis are useful remedies in the treatment of uterine hæmorrhage, and in the treatment of certain diseases of the stomach.

2. The most efficient preparations are the fluid extract, which may be given in doses of 60 to 80 minims, and the tincture (20 per cent.), which may be given in doses of 20 minims.

3. The drug is a vaso-constrictor, which explains its effect in checking uterine hæmorrhage.

4. In cases of excessive menstruation it should be administered between the periods.

5. The alkaloids of the drug have not yet been sufficiently studied to make their use advisable.

Prescriptions for Gout.—According to the *Internationale klinische Rundschau*, ELOY uses the following in gout:

R.—Iodide of lithium . . 3½ grains.
Extract of gentian . a sufficient quantity.—M.

Divide into 20 pills, of which three or four should be taken daily.

or

R.—Iodide of lithium . . . 1½ drachms.
Syrup of orange . . . 6 ounces.—M.

Two or three tablespoonfuls to be administered daily.

In cases of gout with symptoms of nephritis HUCHARD prescribes the following:

R.—Extract of stigmata of maize . 1½ drachms.
Benzoate of sodium } of each 45 grains.
Carbonate of lithium }
Oil of anise . . . . 3 drops.—M.

Divide into sixty pills.

Two pills to be taken before meals three times daily for twenty days in each month.

Painful Second Dentition.—In the oral pain caused by the eruption of the permanent teeth, DR. LOUIS STARR (*Therapeutic Gazette*, April 15, 1890) recommends painting the gums with the following solution:

R.—Hydrochlorate of cocaine . 4 grains.
Glycerin . . . . 2 drachms.
Water sufficient to make . 1 ounce.—M.

When the pain is caused by molar teeth free lancing with an oblique crucial incision is to be recommended. Dr. Starr considers the following mixture also of much use in softening the gums and lessening pain:

R.—Chloride of zinc . . . 1 grain.
Wine of opium . . . 1 drachm.
Glycerin . . . . 2 drachms.
Rose-water sufficient to make 1 ounce.

Apply to the gums with a brush or soft cloth three times daily.

Formula for Creasote.—The following formula for prescribing creosote is quoted in the *Columbus Medical Journal*:

R.—Creasote . . . . . 20 minims.
Alcohol } of each . . 6 drachms.
Syrup }
Cinnamon water . . . 3 ounces.—M.
Dose.—One tablespoonful.

Constipation in Women.—DR. LUTAUD recommends the following in obstinate constipation occurring in women:

R.—Citrate of iron and ammonium 31 grains.
Fl. extract of cascara sagrada 32 minims.
Saccharin . . . . 8 grains.
Water . . . . 2½ ounces.—M.

A half teaspoonful three times daily before meals.

Depilatory Paste.—The *Pittsburg Medical Review* quotes the following:

R.—Sulphate of barium . . 2 parts.
Pulverized starch } of each 1 part.—M.
Oxide of zinc }

Before using, sufficient water is added to convert into a paste, which is then applied to the skin and washed off when it causes pain.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author.

THE TREATMENT OF HABITUAL CONSTIPATION.

AMONG minor ailments probably none is more annoying to the physician or more disheartening to the patient than habitual constipation. One after another a series of drugs will be prescribed, each affording a measure of relief at first, but soon becoming powerless. Similar results are often experienced with the various articles of diet reputed to have laxative properties, until finally the patient, disgusted with doctors, learns to depend upon proprietary preparations, or, still worse, upon enemata. There are other methods of treatment, however, which are of permanent benefit, but which, unfortunately, are too frequently neglected by the physician in his desire to give immediate relief.

NOTHNAGEL, in a recent lecture on this subject (*Wiener medizinische Presse*, Nos. 10, 11 and 12, 1890), considers massage of the abdomen, electricity, and abundant exercise, the three most important elements in treatment. Abdominal massage cannot be properly peformed by the patient upon himself, the effort required causing contraction of the abdominal muscles, which prevents deep pressure and manipulation. An efficient substitute for a *masseur* is a metal ball, weighing from three to six pounds, and covered with cloth to prevent chilling the skin. Every morning the patient should roll this over the course of the large intestine for five or ten minutes, beginning in the right iliac region. Nothnagel warns us not to expect much from massage for several weeks, or perhaps months, but thinks that in the end it is invariably of benefit. Electricity may be used either in the form of galvanism or faradism, but the faradic current is, perhaps, the most useful. It is entirely unnecessary to place one pole in the rectum, as advised by Leubuscher and others, a strong current over the colon being sufficient. The patient should take considerably more than his accustomed exercise, not only walking and riding, but systematically performing the various calisthenic movements in his room or in a gymnasium. Many cases of slight chronic constipation can be greatly relieved by drinking one or two glasses of cold water on rising in the morning.

Cases of long duration will react to all methods of treatment very slowly, and in the meantime measures must be adopted to prevent them from suffering from the Protean symptoms of fæcal accumulation. For this purpose a resort to laxative mineral springs stands at the head, but as many patients are unable or unwilling to leave their homes for a sufficient length of time, drugs or enemata must be employed. Under such circumstances Nothnagel believes that it is better to avoid drugs, if possible, and to use enemata alone. Enemata, for this indication, may consist of pure water or may contain olive oil, common salt, or castor oil, but glycerin is, as a rule, the most satisfactory enema, from one-half to one drachm being thrown into the rectum, or glycerin suppositories may be used.

The diet should be nutritious and easily digested, and acid fruits should be freely taken.

If, in spite of the patient employment of these measures, an occasional laxative becomes necessary, we have a long list of drugs from which to choose, any one of which may be particularly suited to the case in hand, though it is wiser to avoid calomel, castor oil, and all drastic purgatives, and to employ small doses of the vegetable laxatives, among which Nothnagel holds small doses of tamarind, aloes, and podophyllin in high esteem. A pill which he frequently uses is composed of podophyllin 4½ grains, extract of aloes and extract of rhubarb, of each 45 grains, divided into forty pills, with extract of taraxacum as an excipient. One or two of these may be taken at bedtime. Cascara sagrada, which is undoubtedly the favorite remedy in this country for such conditions, is merely referred to by Noth-

nagel, and seems to have been used but little by him.

Another method, which probably originated in France, and which, though but little known, we have seen act most efficiently, is the daily administration of a tablespoonful of unground flaxseed, which has macerated for a few hours in water. The dose is not disagreeable to most patients, and in some cases it seems to be more than palliative.

Much of this advice may seem trite and timeworn to some, but observation has convinced us that many physicians are unjust to their patients and to themselves in the treatment of constipation; prescribing a laxative pill, giving a few suggestions about diet, and dismissing the case from their minds. To such we would repeat, that the foundation of treatment should be massage of the abdomen, electricity, and exercise, and that every laxative dose prescribed probably prolongs the time required to effect a cure.

THE DIAGNOSIS AND TREATMENT OF SALPINGITIS.

IN obtaining a clear idea of this subject a consideration of the pathology of the affection is necessary. The observations of MARTIN upon 287 cases of salpingitis, and a recent excellent paper by LABADIE-LAGRAVE, in a supplement to *La Médecine Moderne*, April 5, 1890, throw light upon this interesting and disputed point. We may briefly divide salpingitis into catarrhal or vegetating; suppurating salpingitis, whether from septic, puerperal, gonorrhœal, or tuberculous infection; tubal dropsy; and hæmatoma of the tube occurring without inflammation, often the earliest stages of tubal gestation. The anatomical structure of the fimbriated extremity of the tube is such as to favor the retention of secretions and predispose to inflammations. In a very large percentage of cases these affections are the result of endometritis, which often follows puerperal sepsis. It is easy to understand how a specific, tubercular, septic, or cancerous infection in the endometrium should result in salpingitis; but an explanation is not so apparent in the case of virgins, in whom none of these causes has been present; when we consider that the infectious diseases of childhood not infrequently result in inflammation of the vulva and vagina, a rational explanation is found for such cases. Bacteriology confirms these points by demonstrating the presence of the various infectious microörganisms.

Regarding clinical history, the disorder frequently runs an insidious course. With the exception of cases of acute infection, resulting in pelvic peritonitis, the disease may persist as such. Functional troubles are its first evidences, with indefinite pains, soreness, tenderness upon palpation, great discomfort in almost every attitude when prolonged, irritation about the bladder and rectum, and disordered menstruation. The occurrence of salpingitic colic is a very significant feature; it is characterized by sudden lancinating pains, which the patient compares to the pains of labor, referred to the hypogastrium or the location of the tube, ceasing suddenly, followed by the expulsion of several tablespoonfuls of serous or bloody fluid, expelled by the spasmodic contraction of the muscular tissue of the tube. If a tumor has been previously found, upon examination after one of the paroxysms, it has disappeared. A dislocation of the uterus ordinarily becomes reduced after the tube is emptied. A continuance of adhesive inflammation obliterates the fimbriated extremity of the tube, causing sterility. Vaginal examination discloses the tube enlarged, feeling like an irregular nodulated cord, in size and elasticity like the femoral artery, and exquisitely painful upon touch. The best method of examination is that with the patient upon the back, the thighs well flexed upon the abdominal wall, and a mild degree of anæsthesia is frequently necessary.

The subacute varieties of salpingitis develop a tumor, which renders diagnosis more easy. To differentiate this form from conditions resembling it, retroflexion, prolapse of the ovaries, ovarian cyst, phlegmon of the broad ligament, uterine lymphangitis, and tubal gestation, must be considered, though the latter can seldom be recognized with positiveness as more than a tubal hæmatocele.

The prevention and treatment of endometritis are of the greatest importance in the prophylaxis of salpingitis. Such should consist of absolute rest in bed, and disinfection of the genital tract by antiseptics. If this does not promptly reduce an elevated temperature the uterus should be curetted, thoroughly washed out, and disinfected with iodoform. When salpingitis exists it should be treated first by securing free and thorough drainage by dilating the uterus, removing vegetations of the endometrium, which frequently occlude the uterine openings of the tube, and disinfecting the uterine cavity. A tupelo tent furnishes an excellent dilator in these cases, and the curretting should be followed by the application of iodine and carbolic acid, or of car-

bolic acid and glycerin, or creasote and glycerin, to the interior of the uterus. Drainage may be kept up by the insertion of a strip of gauze saturated with iodoform or salol in glycerin, which should be carried to the fundus, and allowed to remain there; the gauze may be renewed every two or three days, and its application continued for several weeks. Uterine suppositories, containing salol or iodoform, may also be used to advantage.

The general treatment of the patient consists in absolute rest, in counter-irritation over the hypogastrium by the thermo-cautery, the application of which leaves a surface healing more rapidly, and less apt to suppurate than that produced by blisters; massage; the administration of tonics addressed to the patient's nutrition; the application of the faradic current, and careful attention to assimilation and excretion.

Laparotomy should be performed only in urgent cases, when the presence of large tubal or pelvic abscesses threatening septic infection is diagnosed. In chronic pelvic peritonitis which resists other treatment, laparotomy, with extirpation of diseased tissue is justifiable. It must be emphasized that these cases belong properly to the field of gynecology, and not to the domain of surgery.

STREET NOISES.

Every practising physician is but too well aware of the hindrances to recovery which often arise from the street noises of a great city. Many of these are inevitable, and recur with such frequency that even the nervous grow accustomed to them. It is the unexpected and, for the most part, preventible noises, like street music, which break in, often with most perilous effect, on the rest of nervous patients, on the first slumber which follows the crisis in some acute disease, or on the sleep either of convalescence, or, more serious still, of the stage which precedes surrender to disease or a successful struggle with its first approaches.

European cities have long since provided protection against street music by giving a householder the right to procure the arrest of any musician who persists in playing when he has been asked to desist. In Philadelphia, and in most American cities, a right of action against a penniless organ-grinder for maintaining a nuisance is the only protection afforded at present by law. Unless an organ-grinder can be bribed to move on, or a street band persuaded by a fee to go elsewhere, both have a full right to remain when every moment of their stay under the window of a sick-room may mean torture, and, perhaps, most serious consequences to the patient.

Mr. Theodore M. Etting has introduced in Councils of Philadelphia an ordinance drawn on the law long in operation in London, which, under suitable restrictions, gives a householder the legal power to protect the sick-room from street music. It deserves the approval of every physician who understands the great difficulty, under the most favorable circumstances, of securing quiet and rest for his patients in a great city, and it supplies an important hygienic lack in the ordinances of this city as they stand.

THE MEETINGS IN WASHINGTON.

In the following columns we present to our readers correspondence relating to the important meetings held in Washington during the last ten days, embracing that for the Pharmacopœia revision, the Association of American Physicians, and American Surgical Association. Many of the most prominent papers read have been obtained for the columns of The Medical News, and will appear as rapidly as space permits. In the issue of next week the full report of the proceedings of these learned bodies will be presented to our readers, it being our endeavor to carry out, as far as possible, the object of The Medical News to be a medical newspaper.

CORRESPONDENCE.

WASHINGTON.

Seventh Decennial Convention for the Revision of the United States Pharmacopœia.

To the Editor of The Medical News,

Sir: The Seventh Decennial Convention for the Revision of the United States Pharmacopœia convened here at twelve o'clock on Wednesday, May 7th, with the President, Robert Amory, M.D., of Boston, in the Chair.

Immediately upon coming to order the President announced the names of those who would form the Committee on Credentials, and this committee was instructed to report at the opening of the afternoon session. Having finished this business the Convention adjourned, and after forming in line, proceeded to the White House, where they were received by President Harrison.

At the opening of the afternoon meeting the delegates from the various medical and pharmaceutical colleges, and from the medical and pharmaceutical associations, were instructed to nominate one member from each delegation, in order that a Nominating Committee for the officers during the coming ten years and for the remainder of the session might be chosen. The rest of the business of this session was of no importance. The Convention adjourned at a little after four o'clock.

In the evening the Nominating Committee, consisting

of nearly one hundred members, met in the committee-room of the Arlington Hotel at 8 o'clock and proceeded at once to the nomination of the proper officers—Dr. Wood, of South Carolina, being chosen Chairman. After a small amount of preliminary business the committee unanimously elected Dr. H. C. Wood, of the University of Pennsylvania, as President of the Convention, and then nominated five Vice-Presidents, rather than two, as has heretofore been the custom. The following gentlemen were nominated: First Vice-President, W. S. Thompson, Washington, D.C.; Second Vice-President, Dr. D. W. Prentiss, Washington, D. C.; Third Vice-President, Dr. J. M. Flint, U. S. N.; Fourth Vice-President, A. E. Ebert, Chicago; Fifth Vice-President, Wm. M. Searby, San Francisco. The result of the ballot for the nomination of Secretary resulted in the election of Dr. H. A. Hare, of Philadelphia, as Secretary, and Mr. G. H. Charles, of St. Louis, as Assistant Secretary. From 10 o'clock until half-past 2 in the morning the time of the Committee was consumed in the nomination of the Committee of Revision, which eventually was made up in the following manner: Dr. Charles Rice, Chairman, New York; Joseph P. Remington, First Vice-Chairman, Philadelphia; Dr. Robert T. Edes, Second Vice-Chairman, Washington; Dr. C. O. Curtman, Third Vice-Chairman, Missouri; Dr. J. M. Flint, U. S. N., Treasurer; Dr. Roberts Bartholow, Philadelphia; P. W. Bedford, New York; Dr. F. A. Castle, New York; Dr. N. S. Davis, Jr., Illinois; C. Lewis Diehl, Kentucky; Dr. R. G. Eccles, New York; Dr. John Godfrey, U. S. M. H. Service; Dr. W. G. Gregory, New York; C. S. N. Hallberg, Illinois; John M. Maisch, Philadelphia; G. F. H. Markoe, Massachusetts; Dr. W. M. Mew, U. S. A.; Dr. Charles Mohr, Alabama; Oscar Oldberg, Illinois; Frank B. Pawer, Wisconsin; Dr. H. H. Rusby, New York; L. E. Sayre, Kansas; A. B. Taylor, Philadelphia; Dr. O. A. Wall, Missouri; Dr. H. C. Wood, Philadelphia; Dr. T. E. Wood, North Carolina.

Immediately upon the opening of the morning session on Thursday the Committee on Nomination made its report and the nominees were elected by the Convention by acclamation, the President and Secretary at once taking their places upon the platform. During the remaining portion of Thursday the time was occupied in the discussion of the thirteen recommendations made by the Committee appointed in 1880, with the result that they were all adopted with almost no changes or amendments, with the exception of three of them which dealt largely with the standardization of drugs and which were referred, after a considerable amount of discussion, to the Revision Committee, which had just been appointed; it being agreed that the entire question of standardization should be left to the judgment of this representative body. One section which dealt with the question of the use of "parts by weight" and the metric system, was laid upon the table and made the special order of business for Friday morning at 10 o'clock, and Professor Mendenhall, of the Coast Geodetic Survey, was requested to address the Convention in regard to the advisability of adopting the metric system in pharmacy. After appointing a committee of seven members to consider the manner in which delegates should be elected to the Convention of 1900 the Convention adjourned.

On Friday morning Professor Mendenhall delivered a very interesting address, partly historical in its character, dealing largely with the importance of the introduction of the metric system and its recognition as the standard of weights and measures by all learned bodies. The interesting statement was made that while certain States of the Union had passed exceedingly stringent laws for the punishment of adulteration, and for the purpose of preventing short weights and measures, they had not yet passed any law stating what the standard weights and measures are, which is rather an anomalous condition of affairs. After a discussion the Convention unanimously agreed to recommend the adoption of the metric system, and referred the question as to the use of parts by weight to the Committee of Revision. At the same time the meeting let it be distinctly understood that the preference of the Convention was for the older method, and favored the abolition of the method in vogue during the past ten years.

In view of the enormous amount of work which had been accomplished by the Committee of Revision of 1880, it was the universal desire of all the delegates that the members of that Committee should at least receive some small amount of money, which would be more in the way of an honorarium than a recompense. Unfortunately the amount of money in the treasury did not permit this; but it was moved, seconded, and unanimously carried by the Convention, that the incoming treasurer should be instructed to pay to the Chairman of the Committee of 1880 the sum of $1000, as an evidence of the recognition of his services. Dr. Rice generously refused to accept the gift, but his refusal was immediately voted down, and the Convention insisted upon his acceptance of the amount, which Dr. Rice immediately announced he would return to the treasurer as soon as it was received.

Two facts of great importance were also decided before adjournment. One was that the Committee should be instructed to publish and copyright the Pharmacopœia themselves, and to sell it at a nominal figure, only a sufficient profit being made to enable the Committee to carry out such scientific investigations as were thought desirable. Several times during the meeting a movement was started looking to the prevention of quotations from the United States Pharmacopœia by commentaries. This movement consisted in one instance in an absolute refusal to permit of such quotation, and in another of taxing the National and United States Dispensatories the sum of $5000 each for the privilege of quoting from the standard book. Both of these movements were defeated, and at no time were popular in their character, the Convention readily recognizing the fact that the Pharmacopœia is published not for the purpose of making money, but of affording a standard to which the medical and pharmaceutical professions may refer when they so desire. It is interesting to note that the number of copies of the revision of 1880 which have been sold during the past ten years amounts to over 17,000, the proceeds from which went toward the enriching of a publishing house rather than the furtherance of scientific research. In view of these facts it is evident that the instructions given to the Revision Committee in regard to publication by the Convention, which has just adjourned, are very much wiser than those of the Convention of 1880.

WASHINGTON.

(From our Special Correspondent.)

Association of American Physicians and the American Surgical Association.

RAPIDLY following upon the adjournment of the convention for the revision of the Pharmacopœia which was held here last week, the Association of American Physicians and the American Surgical Association convened on Tuesday morning May 13th to discuss the papers prepared for their annual gatherings. On the first day the meetings of both associations were rather poorly attended, but upon Wednesday a very full attendance was present, and all through the entire meeting of both bodies the papers read may be considered as above the average, and the discussions resulting therefrom unusually to the point and valuable in their conclusions.

Both societies met in the Army Medical Museum, the physicians meeting in the library room, where sufficient space was provided and surrounded by large flags stretched upon screens, thereby excluding those who were not desirous of participating in the meeting, but who, nevertheless, wished to have access to the bookshelves. The surgeons, on the other hand, occupied a smaller hall on the floor above, which was large enough to suit their wants and sufficiently small to permit of each speaker being clearly heard, an advantage of which the physicians were deprived, unless the speakers made an effort to speak loudly and distinctly.

The session of the Association of Physicians began by the reading of the presidential address of Dr. Busey, of Washington, which dealt largely with the proposed changes in and amendments to the Constitution. Immediately after this, the various changes were taken up *seriatim*, and adopted or defeated as the Association thought best.

After the close of this business, Dr. Reeves, of Chattanooga, Tenn., read a paper of great interest on "Typhoid Fever,"[1] in which he dealt with the course of the disease in all its phases. The second paper of the morning was that of Dr. Norman Bridge, of Chicago, on "Appendicitis," while the third was the "Report of a Case of Varicose Aneurism of the Aorta and Superior Vena Cava." Dr. Lusk, of New York, contributed a paper on "Antisepsis During Labor," which was exceedingly interesting, and which your correspondent was able to obtain for the columns of THE MEDICAL NEWS, as well as the paper of Dr. Bridge already mentioned. The paper of Dr. Danforth, of Chicago, upon the "Diathetic Causes of Renal Inadequancy" was read by title, the author being unable to be present. The last paper which engaged the attention of this Association, on Tuesday, was one by Dr. Israel Dana, of Portland, Maine, upon "Seizures Characterized by Shock and Coma."

The meeting of the American Surgical Association was opened by the presidential address delivered by Dr. D. W. Yandall, of Louisville, upon the "Pioneers of Surgery in Kentucky." This was followed by a paper on the "Surgical Treatment of Tumors of the Bladder," by Dr. P. S. Conner, of Cincinnati, a full abstract of which was obtained from the author specially for THE MEDICAL NEWS.

Dr. Stephen Smith, of New York, then read a paper upon the "Treatment of Fractures of the Shaft of the Femur," and Dr. C. B. Nancrede, of Ann Arbor, closed the afternoon session by an exhibition of photographs and a presentation of the history of a rare form of epithelioma of the upper extremity.

The Wednesday morning session of the Association of Physicians began with an exceedingly interesting and learned paper upon "Disorders of Sleep," by Dr. S. Weir Mitchell, in which his large experience enabled him to make many interesting statements. This was followed by another, read by Dr. Charles F. Folsom, of Boston, upon the same subject—Dr. Folsom being placed on the programme with Dr. Mitchell as co-referee. After some discussion Dr. Charles L. Dana, of New York, read a paper upon a "Study of Sensory Disturbances in Hysteria," and was followed by Dr. Wharton Sinkler, of Philadelphia, with a paper upon "Recent Observations of the Etiology and Treatment of Megrim." Dr. Ward's paper upon "Angio-neurotic Œdema" was not read owing to the absence of its author.

Immediately after luncheon Dr. Harold Ernst, of Boston, made a demonstration of the result of the inoculation of rabbits with five or six drops of milk obtained from a cow afflicted with tuberculosis of the udder. Three out of four of the animals died within eight weeks of the inoculation, and the post-mortem showed the presence of miliary tuberculosis in all the abdominal organs. Dr. Ernst also made a report upon vaccination and the studies of Dr. Martin upon the isolation of the *contagium vivum* of cow-pox, a fuller account of which will be found in the proceedings of the Association, which will be published next week.

The remaining portion of the day was consumed by demonstrations on the part of Dr. Prentiss, of Washington; Dr. Fitz, of Boston; and Dr. Welch, of Baltimore. Dr. Prentiss showed a case of rheumatic purpura, and another of exceedingly slow pulse, while Dr. Fitz and Dr. Welch showed, respectively, microscopical preparations of a case of acute pancreatitis, and another of acute diphtheritic colitis with peri-pancreatic fat necrosis.

On Thursday Dr. Kinnicutt, of New York, and Dr. Shattuck read a paper on "Methods of Diagnosis in Diseases of the Stomach," and Dr. Shakespeare, of Philadelphia, one upon the "Prevention of Tuberculosis." After this Dr. Graham reported two cases of acromegaly. His paper was obtained for publication in THE MEDICAL NEWS.

The Wednesday morning session of the American Surgical Association opened with an address by Dr. Thomas G. Morton, of Philadelphia, upon "Surgical Operations for the Correction of Club-foot, with special reference to Tarsectomy or Excision of Bones." Interesting photographs of the result of surgical procedure were exhibited.

Dr. W. T. Bull, of New York, then read a paper "On the Radical Cure of Hernia," reporting results of over 100 operations.

Dr. Mastin, of Mobile, presented photographs of a case of lumbar hernia, giving an exhaustive *résumé* of the literature upon the subject in an essay entitled "Anomalies of Hernia."

The afternoon session was opened by a paper upon "The Propriety of the Removal of the Appendix Vermiformis During an Interval of Recurring Attacks of Appendicitis," by Dr. Frederick S. Dennis, of New York.

[1] This paper will shortly appear in THE MEDICAL NEWS.

Dr. Theodore F. Prewitt, of St. Louis, was not present to read his article upon "A Successful Case of Splenectomy Complicated with Cyst of Pancreas."

Dr. Joseph Ransohoff, of Cincinnati, reported "A Case of Dural Hæmorrhage, with symptoms appearing one week after traumatism; Trephining; Secondary Hæmorrhage; Ligation of Common Carotid; Pyæmia; Secondary Bleeding from Carotid; Death."

The Nominating Committee then presented their report, which was unanimously adopted, the following officers being elected for the ensuing year:

President—Dr. C. H. Mastin, Mobile, Ala.

First Vice-President—Dr. John Collins Warren, Boston.

Second Vice-President—Dr. Stephen Smith, New York.

Secretary—Dr. John R. Weist, Richmond, Ind.

Treasurer—Dr. Phineas S. Conner, Cincinnati.

Recorder—Dr. J. Ewing Mears, Philadelphia.

Council—Dr. Stephen H. Weeks, Portland.

Committee of Arrangements—Dr. John S. Billings, U. S. Army.

"A WOLF IN SHEEP'S CLOTHING."

To the Editor of The Medical News,

Sir: The following circular came to me in my mail a day or two ago. It seems to me to be a positive insult to the medical profession for these people thus to undertake not only to set them aside, but to solicit their aid in so doing, and you may, perhaps, think it worth while to notice the matter again, for, on a previous occasion, it was dealt with in one of your editorials.

Very respectfully yours,

John H. Packard, M.D.

May 3, 1890.

Philadelphia, April 30, 1890.

Dr. J. H. Packard: We presume you are frequently called upon to require your patients to have an ophthalmic examination.

Fully appreciating the responsibility you are under in referring such patients, both because of the professional skill required, as well as the expense and loss of time to which you are obliged to put your patient, we have endeavored to meet such needs in a thoroughly practical and business-like manner.

We have permanently engaged the services of a number of registered physicians who in addition are ophthalmologists. That we have engaged them for this work is, we hope, a sufficient guarantee to you of their fitness for such a position. We find that all but ten per cent. of persons requiring glasses may be satisfactorily fitted *without* either the use of mydriatics or an examination with the ophthalmoscope. For such cases we charge only for the glasses furnished. When, however, the result of the preliminary examination shows that a more accurate and lengthy analysis must be made, one of our oculists is given charge of the case and the proper formula for the glasses prepared. Of course, any affection which requires other remedy than that of glasses, will be properly cared for. Our charge for such services is ten dollars. You will, we think, at once see that the wants of your patients will be well served if you refer them to us, because: 1st. They will, in most instances, obtain their glasses in *one visit*. 2d. They are not obliged to visit a physician's office in one part of the city, and an optician in another—examination, formula and glasses being all obtained at our office. 3d. As everything in connection with the measurement for the furnishing of glasses is done under our direction, we are able to hold ourselves responsible for a result satisfactory to the patient and yourself, and are ready, in case the glasses are not entirely satisfactory, to take them back and refund the money paid for both examination and glasses. 4th. The cost of the entire transaction is most reasonable, without even considering the saving in time. We, therefore, hope that we may have your esteemed patronage for such work.

Yours truly,

Queen & Co.

NEWS ITEMS.

Tulane University, New Orleans.—It has been announced that Dr. Sterling D. Kennedy has resigned the position of Lecturer on Diseases of the Eye and Ear in the Tulane University, and that Dr. W. C. Ayres has been elected to fill the position. Dr. J. D. Bloom, assistant house surgeon of the Charity Hospital, has been elected Lecturer on Diseases of Children, and Dr. John H. Bemiss Lecturer on Clinical Medicine.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MAY 6 TO MAY 12, 1890.

By direction of the Secretary of War, Henry Johnson, *Captain and Medical Storekeeper*, now on duty at the Medical Purveying Depot, New York City, will take charge of that Depot, and perform the duties of Edward P. Vollum, Colonel, Surgeon and Acting Assistant Medical Purveyor, during the absence of the latter.—Par. 11, *S. O. 109, A. G. O., Washington, D. C.*, May 9, 1890.

By direction of the Secretary of War, leave of absence for two months, to take effect June 1, 1890, with permission to go beyond the sea, is granted Edward P. Vollum, *Colonel, Surgeon, and Acting Assistant Medical Purveyor*.—Par. 10, *S. O. 109, A. G. O., Washington, D. C.*, May 9, 1890.

By direction of the Secretary of War, the following named officers are detailed as Delegates to represent the Medical Department of the Army at the annual meeting of the American Medical Association, to be held at Nashville, Tennessee, May 20, 1890: Jedidiah H. Baxter, *Colonel and Chief Medical Purveyor;* Alfred A. Woodhull, *Major and Surgeon*. The officers named will proceed to Nashville at such time as will enable them to reach there on or before May 20th.—Par. 4, *S. O. 107, A. G. O., Washington, D. C.*, May 7, 1890.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING MAY 10, 1890.

Green, E H., *Passsed Assistant Surgeon*.—Ordered to the Receiving-ship "Dale," Washington Navy Yard.

Whiting, Robert, *Passed Assistant Surgeon*.—Detached from the "Dale," and ordered to the Nautical School-ship "St. Mary's."

Whitaker, H. W., *Passed Assistant Surgeon*.—Detached from the "St. Mary's," and resigned, to take effect November 5, 1890.

Ross, J. W., *Surgeon*.—Ordered to the Navy Yard, Pensacola, Florida.

Flint, J. M., *Surgeon*.—Appointed a Delegate to represent the Medical Department of the Navy at the Pharmacopœia Convention to be held in Washington, May 7th.

Dean, R. C., *Medical Inspector*.—Appointed a Delegate to the American Medical Association Convention, to be held at Nashville, Tennessee, May 20, 1890.

Woolverton, T., *Medical Inspector*.—Appointed a Delegate to the American Medical Association Convention, to be held at Nashville, Tennessee, May 20, 1890.

INFLAMMATIONS OF THE APPENDIX AND CÆCUM, AND THE DUTY OF THE PHYSICIAN REGARDING THEM.[1]

BY NORMAN BRIDGE, A.M., M.D.,

PROFESSOR OF CLINICAL MEDICINE AND PHYSICAL DIAGNOSIS IN RUSH MEDICAL COLLEGE, CHICAGO.

To anyone who reads the recent literature of this subject it will be apparent that it has received its chief study of late, not at the hands of general medical practitioners, who have the greatest opportunities for observing cases of these inflammations, but at the hands of surgeons, men who make surgery a specialty, and who see few cases in their incipiency of inflammation of the abdominal organs. The character and effects of these inflammations have been revealed to a large degree by post-mortem examinations, but it was left for modern surgery with its antiseptic methods to illuminate the subject of the treatment of many of their results as well as their character and tendencies. In proportion to the number of cases falling under the observation and management of surgeons the results in many ways have been profitable and encouraging. The surgeons have reached certain conclusions as to the character of these inflammations and what ought to be done for them, some of which are rather sweeping, and which encounter doubt and opposition on the part of many practitioners who give little or no attention to surgery. If the results attained by surgery were put with the observations of large numbers of cases never requiring surgical interference, and which are never seen by workers in the field of surgery, we should have the safest guide for diagnosis and treatment.

It is certain that these diseases are frequently not recognized and are often mistreated, and that the notions of doctors generally regarding them need to be radically revised. An obstacle to the exact understanding of the whole subject is the reluctance practitioners manifest to reporting their unfortunate results and bad diagnoses.

One prevalent misconception regarding these inflammations is of their actual and relative frequency. Primary inflammation of the cæcum is rare, while that of the appendix is very common. Of all organs of the abdomen in males the appendix is most prone to dangerous inflammation. In females this tendency is exceeded by the pelvic organs only. Of 300 autopsies at random Toft reports that 36 per cent. revealed evidence of disease of the appendix. Such evidence doubtless consisted of adhesions of the organ to adjacent parts, and of various changes in its structure and condition which can be caused only by inflammation of some degree or character. Often these appearances are found in cases not known to have ever had abdominal inflammation. Four-fifths of all cases collected by Fitz were in males, showing a marked predisposition difficult to explain. While of all cases of appendicitis without extension only 20 per cent. were in females, 26 per cent. of cases of perityphlitis were in that sex. This does not prove, perhaps, that women are more prone to perityphlitis from inflammation of the appendix than men, but the increased percentage may be explained by the possibly greater tendency in them to pure cæcitis from foreign bodies—aggravated by constipation—since irritation within the cæcum sometimes leads to perforation and perityphlitis.

Dr. Ludvig Hektoen, of Chicago, a careful observer, has noted the condition of the appendix in 280 post-mortem examinations, and found that in 42 cases (15 per cent.) there were evidences, in adhesions or otherwise, of previous peri-appendicitis from which the patient had recovered. Cases of existing inflammation were not counted. So in Chicago, among people who find their way into the County Hospital, fifteen in every hundred have had inflammation of the peritoneal surface of the appendix or the connective tissues posterior to it or both, and have recovered. These figures are not inconsistent with the records of Toft, since he observed all diseases of the appendix both inside and out, while Hektoen only recorded cases showing inflammation of the outside of the appendix, and which had recovered.

While primary inflammation of the cæcum is unusual, its secondary involvement from appendicitis and resulting perityphlitis or circumscribed peritonitis is doubtless common.

It must be extremely unusual for the cæcum to be primarily attacked, except when irritated by foreign bodies from within. Even in such cases it is rare for perforation to occur, this process usually beginning from without, when a perityphlitic abscess opens into the cæcum.

[1] Read before the Association of American Physicians, May 13, 1890.

The vast majority of cases of so-called typhlitis and perityphlitis begin as appendicitis; the tissues of and about the cæcum become inflamed secondarily and usually as a result of perforation of the appendix. These two pathological conditions are often confounded; probably in most instances perityphlitis is the term to use. It is not the inflammation of the cæcum that is usually a menace to life, but that of the cellular tissue and peritoneum which so often leads to induration and to abscess with its manifold dangers of spontaneous opening in perilous directions.

Probably failure of free evacuation of the appendix is the first step in the causation of its commonest inflammation. The moment its contents are unduly retained harmful decomposition begins, deposits of lime salts occur upon retained fæcal matter, if such is present, and enteroliths are formed which press too hard on the swollen and tense mucous membrane, which finally yields in the weakest spot, and an ulcer is present. Only occasionally are similar consequences produced by foreign bodies in the appendix. In a considerable proportion of cases the ulcer occurs without the irritation of a hard body of any kind. The ulcer deepens by a persistence of its causes till it touches the internal surface of the covering peritoneum, or the cellular tissue if within the mesentery; then trifling peritonitis or cellulitis or both occur, ending in a few days if the causative process stops. If, however, the ulcer deepens it perforates the appendix, a particle of its contents is extruded, when peritonitis or perityphlitis promptly ensues. In some instances the peritonitis is sharply localized and plastic exudation bars the irritating material from the general peritoneal cavity, and intraperitoneal abscess forms; in others a general peritonitis occurs, and usually death in a few days.

If the perforation is within the mesentery a cellular inflammation results, and we have the common perityphlitis—usually not wholly independent of more or less peritonitis—and in a large proportion of cases such induration as may be easily demonstrated, and within this pus.

Most cases in males of so-called "inflammation of the bowels" are simply instances of inflammation of the appendix or cæcum, with or without the involvement of the connective tissue about them, or the peritoneum, or both. It is equally true that most cases of peritonitis in men and boys, and not a few in females also, are due solely to perforation and infection consecutive to these diseases. Until discovered after death this cause is generally not suspected. I venture the assertion that most autopsies after peritonitis in the male sex reveal this etiology—and sections are made in only a meagre minority of such cases.

A case in point came under my observation in consultation about two years ago:

Mr. S., a large, robust man, forty-five years of age, had enjoyed apparent perfect health for many years. After attending a banquet he stood for half an hour, dressed in thin clothes and without an overcoat, in a cold and windy doorway waiting for his carriage. The next day he felt uncomfortable; later, had some pain and slight tenderness in the abdomen; the next day, fever and some vomiting. A consultation a day or two later discovered simply the evidences of mild general peritonitis; there was neither much fever, pain, tenderness, nor prostration, and the tenderness was localized in the lower zone of the abdomen, and to the same degree on either side. There was moderate tympanites, but no dulness on percussion. He was somewhat under the influence of opiates. He continued in much the same condition for nearly a week, when the symptoms suddenly became worse, collapse soon appeared, and death in a few hours. The autopsy revealed a fresh general peritonitis, a peritonitis of longer standing localized about the appendix, the intestines glued together by thick plastic deposits, a pocket of pus, with fæcal matter, by the side of the appendix, and the latter perforated at its junction with the cæcum. The steps in the case were appendicitis, ulceration, perforation, extrusion of fæcal particles, localized peritonitis and abscess, extension of the poison and the process to the general peritoneal cavity, general peritonitis and death.

Many cases of supposed intestinal obstruction, such as intussusception and volvulus, with some evidence of inflammation, are instances of peritonitis from perforation of the appendix, or of abscess due to previous inflammation of the appendix and its results. The fallacious theory that is often held is that an obstruction has occurred, which in a few hours has developed inflammation.

A case in my own hospital service well illustrates this error:

A youth of less than twenty years walked into the hospital from a cab at the curbstone, complaining of pain in the abdomen. He said he had been sick for several days with this pain to such a degree that he could not lie down, but must sit in bed bent forward. His friends said it had been impossible at times to keep him in bed, his suffering was so great. The sickness had, it was declared, come on suddenly, and he had repeatedly vomited. After his arrival he vomited yellowish fluid having a stercoraceous odor. He had considerable fever, a pulse of 130, a tense abdomen, and a look of desperate sickness. A consultation with my surgical colleague, Dr. Graham, resulted in the conclusion that the case was probably one of obstruction followed by peritonitis. Certain to die speedily without surgical relief, he was given the chance of laparotomy. Nothing but peritonitis was discovered. This was afterward found to have resulted from a perforation of the appendix.

It is probable that abscess rarely occurs until after perforation, which may be regarded as the direct cause of it. Inflammation of small surfaces of the peritoneum with adhesions, however, often supervene, as well as probably some degree of cellular inflammation, without perforation.

The mortality from appendicitis, considering the frequency of the disease, cannot be regarded as great. The mortality from those cases eventuating in perforation of the appendix, however, is great, since this is the condition that leads to induration and extraperitoneal abscess, and to acute severe local peritonitis and intraperitoneal abscess, or to general peritonitis. The general peritonitis means almost sure death, and the abscess, wherever it is and however well it may appear to be surrounded by protecting plastic deposits, is a constant menace to life, as abundantly shown by its spontaneous opening into the abdominal cavity, the venous canals, the bladder, and the chest cavity, as well as externally and into the intestinal canal.

In view of these considerations it is of the highest moment that we should be able, if possible, to distinguish the mild from the grave cases. One-fourth at least of all post-mortems show recoveries from previously existing inflammation, or other diseases of the appendix, and probably 15 per cent. show recoveries from peri-appendicitis. The duty and aim of the doctor must be to determine clinically, if possible, the cases that form this vast class and commit them strictly to medical treatment, while he insists on surgery for those that lead to death directly, or to the hazardous results of abscess. Can this determination be made with certainty?

The diagnosis of perityphlitis is usually easy. Localized pain, sometimes masked early by pain elsewhere, often in the epigastrium, and by vomiting; more especially, localized tenderness; soon some evidence, both by palpation and percussion, of tumefaction in the cæcal region; possibly pain in this region on flexing the thigh, and with some fever —all perhaps following or attending diarrhœa—are ordinarily sufficient. Percussion dulness is often present over the tumor, though tympanites sometimes masks it completely, but palpation discovers an induration even of small size if it is done carefully and in comparison with the opposite side. The diagnosis of acute appendicitis before the advent of perityphlitis is more difficult, from the absence of any tumor and the deep location in the abdomen of the tenderness. The appendix sometimes hangs down into the true pelvis and far from the anterior wall of the abdomen. An appendicitis may be ushered in by vomiting and pain in the epigastrium, which may evoke such complaint as to mask the pain in the cæcal region. In only a little over one-half of all cases of acute inflammation in the cæcal region is the pain mostly in that locality, while in nearly one-third the pain is attributed to the abdomen generally.[1] Sometimes there is a misleading sensation of induration to touch due to the tension of the abdominal muscles over the tender point, a condition that wholly disappears under anæsthesia. For purposes of diagnosis the hypodermic needle is permissible only when it is absolutely certain that it may be passed into the centre of the induration without entering the general peritoneal cavity. It is unsafe to use it in a supposed intraperitoneal abscess. The absence of fluctuation over an induration is no proof of the absence of pus; pus is present in all large and in most small indurations of a few days' standing. In a few cases (it must be very few) digital exploration of the rectum will discover indurated tissue below the cæcal region.

A large proportion of first attacks, and probably many subsequent attacks, of acute appendicitis will doubtless recover without abscess, and with slight cellulitis or local peritonitis and adhesions, under proper treatment; namely, quiescence in bed, hot applications, anodynes, light diet, and a rigid avoidance of all influences that can provoke general intestinal peristalsis. It can hardly be questioned that a majority of such cases recover even without these wholesomely safe measures of treatment and hygiene. Many cases of chronic appendicitis utterly fail to improve much under any treatment, albeit treatment doubtless often prevents such from passing on to ulceration.

When to go beyond medical treatment of these diseases and insist on operation probably cannot be determined by any absolute rule. Each case must be dealt with by itself to some degree, since cases differ widely; but there are certain general principles that ought to guide us, in view of which we cannot shirk our full responsibility.

Reliance on medical treatment is justifiable in acute inflammation in the cæcal region (*i. e.*, appendicitis, perityphlitis, or typhlitis) of moderate severity, in the absence of strong evidence of perforation, abscess, peritonitis, or marked tender induration lasting two or three days without some sign of decrease, and of high temperature either continuous or recurring, rapid weak pulse, or rapid anxious respiration. But we can never know when a catastrophe is to occur, even in an apparently mild case such as is here characterized. A few cases falling in this category will suffer sudden perforation, general peritonitis, and death; but nearly all of them, failing of prompt recovery, will, if perforation occurs, have sharply localized peritonitis or perityphlitis, and probably abscess that will be easily discovered, and will demand surgical treatment. That, in a

[1] Fitz.

high percentage of a large number of post-mortem examinations made on all sorts of cases, there should have been found evidence of previous, recovered appendicitis would seem to justify the position here taken.

Reliance on medical treatment is also justifiable in subacute and chronic inflammation where the constitutional symptoms are mild, pain and tenderness slight, and the induration small and not increasing. Such cases frequently suffer occasional slight exacerbations of short duration, which do not positively indicate the need of an operation, unless each recurrence increases the size of the tumor or its sensitiveness to pressure, or develops other proof that it is an abscess. To say that every perceptible induration at the site of the cæcum should receive the ministrations of surgery is not justifiable; and probably numerous cases might be reported of operation on small indurations without discovering pus. One such is here presented:

Mr. A. B. entered my hospital service complaining of slight pain and tenderness in the right iliac region, and giving a history of several attacks of acute inflammation within a year. In each attack there was moderate fever, and in the beginning frequent diarrhœa. A small induration over the lower part of the cæcum was distinctly made out; it was slightly tender to pressure, and forward movement of the right thigh was embarrassed. This case was transferred to my surgical colleague, Dr. Parkes, in the belief that an operation should be made. He performed laparotomy, and found some thickened omentum, numerous adhesions, some of which he separated, but neither abscess nor appendicitis. The wound healed promptly.

The two outlines given above include the vast majority of all cases, and if the premises are correct, then these cases are most properly committed to strictly medical treatment, and the only proper treatment is the conservative course already described.

But surgical interference is demanded in certain cases of inflammation in the region under consideration, whether they happen to be called typhlitis, appendicitis, perityphlitis, or by some other name, and the weight of first responsibility is on the physician more than the surgeon.

1. Surgery is imperative in cases of acute inflammation in the cæcal region, with rather protracted high temperature, and with distinct induration, sensitive to pressure, that does not show positive evidence of subsidence within two days, or three or four days from the beginning. This rule becomes more urgent if the induration continues to increase in size and sensitiveness after two days, or if symptoms of general peritonitis occur, or rapid, weak pulse, or rapid respiration. The vast majority of such cases if left to themselves eventuate in abscess in less than a week, and many before that time lead to mortal peritonitis. Some require operation in less than two days from the beginning of the attack, and most of them have perforation of the appendix as early as the beginning of the symptoms.

I am aware that a few cases here characterized do not require operation and would recover without it, but the number is so small compared to those in the greatest peril to which it is a crime not to offer the benefit of surgery, and the danger of an antiseptic operation is so slight, that they constitute no impeachment of the rule.

2. Operation is required in cases of undoubted severe acute inflammation in the region of the appendix, even though no particular induration is demonstrable, and in cases of acute localized peritonitis having its origin certainly at the appendix, and causing marked constitutional symptoms. In the one situation there is almost certainly such violent inflammation of the appendix as seriously to threaten perforation, with all its dire possibilities; in the other, perforation has occurred and an abscess is probably forming. In the one case there should be laparotomy and extirpation of the appendix; in the other, laparotomy, extirpation of the appendix, if possible, and treatment of the abscess. Probably these two classes cannot be distinguished from each other; many of the symptoms of the one belong to the other. Practically, it is hardly important that they should be distinguished, as both abundantly justify surgical interference; the patients are in vastly less jeopardy with the operation, when carefully made, than without it.

3. Surgery is especially promptly required in that small class of acute cases in which a large, sensitive induration develops rapidly, with high fever and general evidence of severe constitutional disturbance. Here extensive deposit and large abscess are almost certain to be present, and the danger of early rupture into the peritoneal cavity is considerable, hence the necessity of prompt action.

4. Surgical aid is demanded in all cases which have advanced to the subacute or chronic stage with distinct induration of considerable size, or with any induration that steadily increases in size for many days, since in most such cases pus is present. These are the cases where sometimes weeks and months after the acute stage a tumor of variable size is found in the iliac region, slightly tender, dull on percussion, and attended by a slight stiffness in walking dependent on pain in flexing the right thigh. Usually in such cases there are frequent exacerbations of moderate suffering in the affected region, often with slight fever, and disabling the patient for a day or two. Unless the tumor is very small pus is almost invariably found in its midst, the quantity varying from a few drachms to many

ounces. The patient cannot be safe so long as an abscess is present in the neighborhood of the cæcum, but the danger is in proportion to the size of the abscess. Some portion of the cæcum must generally form a part of the abscess wall, hence the liability of rupture into this canal and into the peritoneal cavity. In a case seen by the writer in consultation with Dr. J. B. Murphy, a perityphlitic abscess had undoubtedly existed for a year, since the date of a previous illness in which there were dull pain and fever for several weeks. The abscess ruptured into the abdominal cavity while the patient was scrubbing a floor: peritonitis rapidly supervened; a circumscribed large peritoneal abscess formed, which was opened by Dr. Murphy, and a quart of pus evacuated. This case also exemplifies the large induration developing rapidly already referred to. The apparently small difference between cases sure to die without operation and those likely to recover without it, as well as the difficulty in finding the line of duty in management, is shown in the two cases that follow:

D. F. G., aged fourteen years, robust and active, went hunting on April 30, 1881, and became very tired. The whole of the next day he felt fatigued.

May 2. Felt a little better, but had a mild diarrhœa; next day more diarrhœa, pain, and slight tenderness on pressure in the cæcal region.

4th. I was called and found the diarrhœa better, but still some pain and tenderness at the point mentioned: pulse was 100, and temperature 101° F.

5th. Patient was improved; slight tumefaction in the cæcal region; pulse 100, temperature 101.7° F.

6th. No pain; tenderness less; pulse 100, temperature 99° F.

7th. Temperature 99° F. There had been no increase in respiration rate, and the patient felt convalescent. The next day at 11 P. M. a piercing pain was felt in the lower abdomen, at the right side, lasting only a few minutes. Some tenderness was found soon afterward, but no tympanites; the pulse was 100 and small, temperature 98.5° F.; respiration 20. Collapse came on in six hours, pulse was 150, temperature 98.5° F., and death in four hours more. It was found, post-mortem, that perforation of the appendix had led to an intraperitoneal abscess containing an ounce of pus; that the plastic wall of this abscess had given way at its superior point, a fulminating general peritonitis being instantly lighted up. The rupture was at the distal end of the appendix, which was gangrenous.

G. B., aged thirty, salesman, strong and active, had had occasional attacks of pain in the abdomen lasting for a few hours. He was seized last February, in the morning, with severe pain in the lower abdomen, and went home and to bed. By evening his temperature was 104.5° F.; then he discovered that the pain, which had continued to some degree all through the day, was most intense in the right iliac region. His bowels were moved by an enema. I saw him first at this time and found tumefaction and dulness in the cæcal region with the slightest possible tenderness; next day, and the day after, the evidence of tumor was greater than at this time, the tenderness being reduced. The second day of attendance the temperature was over 103° F., the third day 102°, and the day following 99°, from which time convalescence was rapid, and he was out in a week from the onset. The pulse was at no time much above 100, and the respiration was not accelerated; there was no diarrhœa and the patient was tranquil in mind.

It will be seen that the temperature rapidly fell after the third day of the sickness; with its fall the evidence of tumor rapidly disappeared. In this case tumefaction and dulness on percussion were marked in the cæcal region, and entirely disappeared with recovery and there was never any notable tenderness. In the case of D. F. G. clinical evidence of tumor was slight, but during the first week there was constantly more or less tenderness, a symptom we now know as some indication for surgical relief.

5. Surgery is justifiable in all cases of undoubted chronic appendicitis with occasional exacerbations even if no induration is present. In all such cases we cannot doubt that the patient is in constant danger of perforation of the appendix, and mortal peritonitis or perityphlitis—a danger greater than that involved in an antiseptically done laparotomy and extirpation of the little organ entire.

If the diagnosis was positive in every case there could be no objection to this proposition, for it covers only cases with some persistent cause of the inflammation, and not those with a temporary cause, and a single seizure with no special tendency to a recurrence. The persistent cause is usually something within the appendix that makes pressure and irritation, and back of that some constriction of the appendicular opening or some fault of its valve; the cases of one mild attack and quiescence afterward are those in which there is no incarceration of irritating matter of any sort, and where the exit from the canal is free.

Fitz says catarrhal appendicitis is probably not recognizable. The diagnosis of such cases is beset with difficulties and probably many of them cannot be diagnosed, but some may be, and these should not fail to receive the benefit of surgery simply because they may not appear for the moment to be formidable. The diagnosis must often be made by exclusion and is easier in males than females, since in the latter the pelvic organs are apt to produce symptoms resembling those of appendicitis. The following case is illustrative:

A lady of twenty-eight years, vigorous and robust, had experienced from time to time since girlhood slight pain in the right groin and thigh, often aggravated by exercise. Occasionally there was accom-

panying but less pain in the left groin and thigh. Last summer she had what appeared to be a dysenteric attack, passed bloody stools, had much pain in the abdomen, especially on the right side, and fever. She recovered and resumed her active life, which required her to be much upon her feet. Soon pain in the abdomen recurred, then came slight fever, anorexia, occasional vomiting and constipation, tenderness over the hypogastrium and pain in the thighs. At the end of six weeks she entered my hospital service and was carefully examined, my gynecological colleague, Dr. Merriman, assisting. Then she was in bed, unable to move without pain in the abdomen, and suffering considerably in the thighs, hypogastrium, and right inguinal region. The abdomen was tender over its right side, from the border of the ribs to Poupart's ligament, but no tumefaction or dulness was discoverable. An examination of the pelvic organs revealed nothing pathological, nor could any induration be felt through the vagina or rectum. She had a daily rise of temperature to 100° or 101° F. The thighs were kept flexed much of the time, and pain in the psoas region occurred on flexing the right thigh against resistance; a daily enema was required; the appetite was poor, and the sleep much disturbed by pain. She soon began to improve, and in a month or six weeks could turn in bed with only slight discomfort; her appetite was better, the pain less, and the temperature much of the time normal. The tenderness in the abdomen, however, persisted and became more marked over the cæcal region; and one or two tentative efforts at sitting up were followed by rise of temperature and return of pain lasting two days or more. It now seemed that the history and course of the case had excluded every other pathological condition but some chronic inflammation at the location of the cæcum and appendix, and that the time for surgical exploration had arrived, and my colleagues, Drs. Parkes and Merriman, examined her at my request and agreed that an operation was justifiable. Laparotomy was made by Dr. Parkes, and the appendix was found enlarged in its diameter, hard and tense, projecting forward in an erect position, and deeply congested. No other pathological condition was discovered in the abdomen. The appendix was extirpated and found to contain three small enteroliths, and a quantity of thick, tenacious mucus; its walls were thickened. On laying it open longitudinally it assumed instantly a rolled form in the reverse direction—apparently the peritoneum contracted and the thickened mucous membrane and muscular tissue became extended. The patient made a good recovery from the operation and her symptoms have disappeared.

There was in this case no evidence of beginning ulceration of the appendix, and so no immediate danger of a perforation, but the tension of the organ was so great as to prove the existence of an almost complete closure of its opening, and must have led to ulceration sooner or later. Moreover, the patient apparently would have been a permanent invalid without the operation.

THE IDEAL OPERATION FOR CATARACT.[1]

By W. C. PIPINO, M.D.,
OF DES MOINES, IOWA.

AFTER holding sway for nearly thirty years it now seems probable that Gräfe's operation for cataract is to be supplanted by one performed nearly a century and a half ago—a "survival of the fittest" it would seem. After all these years of faithful trial by the most expert and skilled ophthalmologists of the various methods and modifications that have been introduced for the extraction of cataract, we are about to return and give preference to the simple flap extraction.

History informs us that it was Daviel, a French surgeon of Marseilles, who performed the first operation for cataract extraction in the year 1747, by making a long corneal section, using a lance for puncturing, a two-edged knife for enlarging the puncture, and scissors for finishing the flap. We are informed that the first modifications made by his successors were in the instruments used; the knife of Richter appearing in 1773, twenty-six years later. In 1813 Beer's triangular knife was introduced. The next step in the line of improvement was to bring the base of the flap nearer the horizontal diameter. In 1862 Thoreau performed iridectomy with flap extraction. In 1865 von Gräfe introduced what is known as Gräfe's peripheral linear extraction. This is the operation that has held undisputed possession or preference in the hands of the majority of operators until quite recently, when its superiority began to be questioned. At present there is a strong tendency to return to the original flap operation, and indeed there are good and sufficient reasons, as I will endeavor to show. One would naturally come to the conclusion that better vision would be secured from a round movable pupil, than from an irregular one. And such is the fact. The coloboma caused by the mutilation of the iris has always been an annoyance to the fastidious operator, the unnatural and enlarged pupil causing more or less loss of acuity of vision; moreover, the unsightliness is a constant reminder of the surgeon's knife.

Schweigger, of Berlin, says that one of the interesting changes in the ophthalmology of the present day is the return to the old method of cataract operation. The restoration of sight with the preservation of a round and movable pupil is undoubtedly one of the greatest operative achievements. How was it possible that we could have renounced the attainment of this ideal from the beginning?

In order to answer this question we must go back thirty years. Ophthalmology at that time was

[1] Read before the Iowa State Medical Society, April 16th, at Des Moines.

dominated by the overpowering impression of the cure of glaucoma by iridectomy, which, of course, was just as inexplicable then as it is now; then somebody or other invented the magic word "antiphlogistic" iridectomy, and that operation became the cure, not only for existing but also for anticipated inflammation. Since then reason is being restored, and the time is not far distant when iridectomy will be performed in complicated cases only. In a recent article on the subject Dr. Ayres says:

"To extract the lens and preserve the shape, size, and activity of the pupil, and at the same time improve the vision, must certainly be the aim of the operator and must constitute the ideal operation."

Thus it is seen that this movement is bound to command attention here, as it is engaging the minds of some of the most eminent ophthalmologists both in Europe and America. The question naturally suggests itself, If the simple extraction is the best operation, why was it ever discarded? To answer this question properly requires much time and reading. I offer the suggestion, however, might it not be due to our increased knowledge obtained from the experience of our most eminent ophthalmologists, who are becoming more expert operators as their experience increases? Or might it not be due to the fact that we look to men of great opportunities for guidance, and, sheep-like, follow in their tracks? Again, the dangers of iritis, prolapse, and imperfect coaptation of the flap, I think, are greatly exaggerated. It cannot be denied that the advances made in antiseptic measures have diminished the danger of these operations as of others. I am a firm believer that the less we disturb the iris (as by iridectomy), the less is the risk of iritis. I have yet to see the escape of the vitreous in the simple extraction, which is more than I can say for the linear extraction with iridectomy, and I have had some experience in both. To remove a lens successfully without iridectomy and thus obtain a round movable pupil is the final purpose which every conscientious ophthalmologist hopes to attain. It must be remembered that simple extraction is not possible in all cases. There are complications where the Gräfe extraction would do better.

Dr. Knapp, whom we all recognize as in the front rank, says:

"If I review my cases the opinion is forced upon me that the simple extraction is not only the best but the safest method of removing cataract. The iris, spread out as a *velum interpositum* between the corneal section and ciliary body, protects this, the most susceptible part of the eye, from the deleterious substances that may enter through the wound."

He gives a record of 1000 cases operated upon by him, the first eight hundred by the linear or Gräfe operation, and the last two hundred by the simple extraction. In the first three hundred he had 91 per cent. of good results, 3 per cent. of imperfect results, and 6 per cent. of loss.

In the fourth and fifth hundred 82 per cent. of good results, 6.5 per cent. of moderate results, and 11.5 per cent. of total loss.

In the sixth hundred 89 per cent. of good results, 1 per cent. of moderate results, and 10 per cent. total loss.

In the seventh hundred 88 per cent. good results, 7 per cent. moderate results, and 5 per cent. total loss.

In the eighth hundred 90 per cent. good results, 8 per cent. moderate results, and 2 per cent. total loss.

The ninth hundred cases were operated upon by the flap method without iridectomy, and the good results are apparent at a glance. Of these there were 96 per cent. of good results, 3 per cent. moderate results, and 1 per cent. total loss, while in the last hundred cases, operated upon by the same method, the results are still better, 97 per cent. good results, 2 per cent. moderate results, and 1 per cent. total loss.

These results speak for themselves, especially when we remember how rare it is to obtain vision of $\frac{20}{20}$, after Gräfe's method, and how frequently vision of $\frac{20}{20}$ is obtained after simple extraction without iridectomy, showing without a doubt the superiority of the one over the other.

De Wecker, Panas, Galezowski, Schweigger, and others claim equally good results. During the last winter I have operated upon eleven cases by the flap extraction without iridectomy. The results obtained are sufficiently encouraging to warrant a continuance of the method.

Case I.—Mr. E., aged seventy-four; senile cataract in both eyes; unable to distinguish fingers. Both eyes were operated upon at the same sitting. Operation satisfactory. Perfect recovery, with round, movable pupil; with + 11 D vision $\frac{20}{20}$. Has since written me letters expressing his gratitude in once more being able to shoot squirrels.

Case II.—E. H., aged thirty-four; semi-hard cataract in both eyes. Cannot count fingers with right eye, but can with left. Right eye operated upon without iridectomy. Operation was smooth and quick; spontaneous reduction of iris; pupil round and movable. Six weeks after operation with + 11 D sph. ⌒ + 1 D cyl. 110°, vision = $\frac{20}{30}$.

Case III.—W. H, aged sixty-four; senile cataract of both eyes. Unable to count fingers. Left eye operated upon; flap extraction; round movable pupil; with + 10 D vision = $\frac{20}{50}$.

Case IV.—Mrs. J., aged sixty-nine; senile cataract; both eyes operated upon by flap extraction, without iridectomy. Corneal incisions smooth, and pupils black. Immediately after operation could count fingers; recovery uninterrupted, with + 11 D vision = $\frac{20}{20}$.

Case V.—P. E., aged thirty; zonular cataract in

both eyes; flap extraction under cocaine; pupil round and black. Second day after operation plaster was removed, and the anterior chamber was found to contain pus; corneal wound united. Eye was kept bathed with a solution of bichloride, 1 to 4000, and a few drops of the same were instilled between the lids every third hour. In three days the pus was absorbed and cornea clear. At present with + 11 D ⌒ + 1 D ⌒ 90°, vision = $\frac{20}{25}$.

To economize time, and a useless repetition of reporting the other cases, I will simply state that nothing occurred during the after-treatment worthy of mention, and the results were good.

It will be noticed, however, in the case last reported, had the plaster not been removed and the eye inspected there is no doubt that the eye would have been lost, the timely application of the bichloride preventing the destructive process. Had the old plan of dark room, eye bandage, and let-alone treatment been practised, the patient would now be mourning the loss of an eye. In marked contrast to the cases just reported as having been operated upon, and to the good results obtained, I will mention the case of an old gentleman upon whom the modified linear operation was performed on account of posterior synechia. It would have been impossible to remove the lens by the flap operation, so iridectomy was made. Six weeks after the operation, in trying to correct the aphakial condition with lenses, he was found to have an astigmatism of 4 D, so with a + 11 D sph. ⌒ + 4 D cyl. 180° his vision was brought up to $\frac{20}{40}$. In connection with this I might here remark that I have met less astigmatism after the flap extraction without iridectomy than after the peripheral extraction with iridectomy.

A 4 per cent. solution of cocaine is dropped upon the cornea at intervals of two or three minutes. It rarely requires more than three drops to anæsthetize the cornea completely and render the operation painless.

All of these cases were operated upon at the hospital, nursed by skilled attendants, and all antiseptic precautions were taken. In none were the patients confined to their beds, with heavy bandages, and darkened rooms. Indeed, all needless and annoying restraints were removed. The patients were allowed to walk from the operating table immediately after the operation to their rooms. On the second or third day they were permitted to walk around on the outside of the building. I have yet to regret the privilege allowed these unfortunates. In one case in particular that was operated upon at the institute, when a conjunctivitis developed on the third day after the operation, the patient was restricted to his room as a precautionary measure. Although no bad results followed the conjunctivitis, the patient lost his appetite and about fifteen pounds in weight. Being an individual accustomed to outdoor life from youth, the confinement told rapidly upon his general health. Notwithstanding Schweigger's advice to the contrary, I invariably remove the dressing, viz., a strip of isinglass plaster, on the second day, and inspect the eye to see if all goes well. On two occasions I have thus been able to save the eye operated upon by the timely instillation of "eye-drops." It might be urged that it is meddlesome curiosity to inspect an eye so soon after an operation, and, consequently, bad practice. It has been my experience to see eyes cut through the cornea by foreign substances, inspected daily lest iritic inflammation or other trouble should occur unobserved, get well. If such eyes do not suffer from inspection, why should an eye operated upon for cataract under strict antiseptic precautions suffer? The truth of the matter is, we have been needlessly cautious in the past, and unnecessarily confined our patients in a dungeon cell, causing them to do just what we wish to avoid, viz., to put themselves into a nervous state, which is anything but conducive to perfect healing of the corneal wound.

THE CONDITIONS OF THE NASO-PHARYNX AS AN INDEX OF DISEASE.

By WOODS HUTCHINSON, A.M., M.D.,
of Des Moines, Iowa.

What connection or correspondence, if any, exists between the condition of the mucous membrane of the naso-pharynx and the state of the general system in health? The first thing that strikes us in a glance at the region is its double relationship, on the one hand with the alimentary, and on the other with the respiratory system, while nowhere else in the body, except upon the retina, are the meshes of the circulatory system more nearly laid bare to our view. Nor is this relationship merely the passive one of simple continuity of tissue. It is the active one of guardianship, with sentinel nerves and cilia supported by a system of distensible elastic cushions, effective in barring out respiratory intruders, and highly trained muscles capable of promptly expelling any alimentary trespasser.

For an intelligent performance of these functions constant communication with headquarters is indispensable; and when we further consider the remarkable vicarious excretory action which the tonsils and fauces are capable of assuming, and the active sympathy which clinical experience has shown them to manifest with many disturbances, I think we are safe in concluding that an inspection of this region furnishes a valuable guide to, if not an absolutely reliable index of the condition of at least the receptive portion of the animal processes. The popular impression that "put out your tongue, sir," is the indispensable preliminary to the medical investiga-

tion of almost every case is not wholly without a rational basis.

The *rôle* played by the fauces and nares in the exanthemata is a most interesting one, and far from being thoroughly understood. They seem to be pitched upon as the amphitheatre of fierce combat between the marauding germs or their deadly virus, and the peaceably disposed but sturdy and indignant fixed cells of the body.

The mere fact that both gastric and respiratory disturbances are here represented, each disturbing the cell equilibrium from a different standpoint, is hardly sufficient to account for the remarkable intensity of the process. It would almost seem as if those lightly esteemed and much-persecuted bodies, the tonsils, were bravely fighting the battle of the whole organism single-handed. The only theory which seems to throw any fresh light upon the subject is one advanced some months ago—suggested by the fact that the tonsils are by their structure more closely allied to lymphatic glands than to any other tissue—that they are actually breeders of leucocytes, not for replenishing the blood, but for acting as scavengers and sanitary police for the upper part of the alimentary canal. Supposing this to be the case, can we not then largely account for the intense activity of these glands in most of the exanthemata, notably, scarlet fever, syphilis, and diphtheria, as well as in poisoning from sewer gas, or contaminated drinking-water? In response to the demand for phagocytes the normal secretion is first rapidly increased, then, in the struggle to keep up the quantity, quality deteriorates, imperfectly developed cells are poured out, and we say suppuration is established; finally the vitality of the secreting cells themselves is reduced by the strain of their desperate efforts, they perish bodily, and ulceration occurs.

Diphtheria would seem to bear out this explanation even more strongly, for the microscope shows the "membrane" to be composed almost entirely of leucocytes and their débris, the scavenger-corpuscles having hurled themselves upon the attacking bacilli in such myriads as literally to smother them with their dead bodies; also, because of the rapid and serious systemic symptoms which almost invariably occur whenever any considerable surface of the fauces is deprived of its protective covering, or when a region less amply supplied with these corpuscles, such as the nares or stomach, is attacked. In fact, the diphtheritic membrane would seem to have not a few points of analogy to the secretion poured out by the tissues of the oyster around an intruding foreign body, forming the smooth and unirritating pearl, or to the cluster of angry leucocytes around a bacillus tuberculosis which forms the essential basis of the anatomical tubercle.

May not a similar action underlie the production of the typical lesion of typhoid? Peyer's patches may almost be called the "tonsils of the intestines." They are even more typically lymphatic in character than the faucial tonsils. They go through the same stages of hypersecretion, enlargement from excessive cell-multiplication, loss of vitality and ulceration: while the albumin, corpuscle-salts, and débris of leucocytes generally, which form such a prominent element of the "pea-soup" stools, strongly suggest the existence of some such process of scavenger production. That the cells do exercise some sort of restraining influence upon these disease germs is made highly probable by the fact reported by several observers that the fresh stools are almost wholly innocuous, and do not develop infectious properties until ample time has elapsed for all the phagocytes to have perished from exposure to the lower temperature of the external air, a temperature which unfortunately has no unfavorable effect upon the bacilli.

The part played by the lining membrane of the naso-pharynx in a "a bad cold" is alone of great interest and importance: whether the "cold" be the result of wet feet, cold hands, or a draught on the back of the neck, in nine cases out of ten the nares and fauces become the seat of intense morbid activity. The compensatory vascular congestion which affects the entire internal surface of the body, whenever marked contraction of the superficial vessels of the external surface occurs, would partly account for this, but only partly. It is no mere mechanical congestion, but genuine inflammation, accompanied by excessive secretion, and going on to ulceration if the irritation is sufficiently intense. I think we can hardly look upon the intensely irritating properties of the nasal discharge in acute coryza, the promptness with which it excoriates nostril and lip, and its yellow color, without being inclined to regard it as, to some extent at least, an excrementitious product, which supposition is supported by the discovery in it of urea and other nitrogenous extractives, and by its reputed infective properties. Further, when we consider the almost invariable occurrence of digestive disturbances, and the not infrequent appearance of diarrhœa, or those uric-acid storms popularly known as "bilious attacks," as symptoms or complications of a "severe cold," does it not seem probable that an attempt at vicarious excretory action on the part of the whole internal surface of the body is present as a factor in the process?

Such, then, being the close interdependence and important relations existing between the functions of the naso-pharynx and the general system, would it not be reasonable to investigate carefully how far each morbid condition of these parts is symptomatic

of a general disturbance of equilibrium or nutrition before proceeding to dub it any form of "catarrh," or many-syllabled "-itis," or to attack it by special or local treatment? And yet how little attention do we find paid to this view of the subject in our special text-books? I think it would be safe to say that three-fourths of the cases of pharyngitis which present themselves to a specialist are dependent upon some derangement of either the first or second digestion, and the same proportion of nasal troubles upon a general lowering of the vital tone in all the tissues, the neurasthenia of Beard, yet scarcely more than a page or two, and a scattered paragraph here and there, are devoted to this most important factor.

Instead of being looked upon as a page in the book of general symptoms of diseases, the nose and throat are, I think, far too exclusively ticketed and discussed as distinct separate entities with an existence and pathology almost apart from that of the general system. If we were to look upon the pharynx as we now look upon the tongue we should find it an almost equally reliable and even more delicate index of the condition of the alimentary canal, and if we based our treatment of the morbid conditions presenting themselves upon the same principle, our results would be far more satisfactory and permanent. No one has so far suggested searing a coated tongue with the galvano-cautery or invented a curette for removing the coating, and yet the much-enduring pharynx is cauterized and swabbed and sprayed with a sublime disregard of the fact that it is in nine cases out of ten merely an index of the state of the organs. Viewing them from this standpoint the eye soon learns to distinguish the brick-red congestion of acid dyspepsia ("alcohol throat," "coffee throat"), the dull, purplish crimson of chronic constipation or hepatic torpor, the deep garnet of the lithæmic diathesis, whether "gouty" or "rheumatic;" the flabby "raw-ham" color and frothy mucus of anæmia, and the blanched palate and palely "granular" pharynx of phthisis, and to refer them to their underlying causes, and when this has been done it is surprising how few cases of "idiopathic" pharyngitis are left. If I were obliged to give up either local applications or systemic treatment in the management of pharyngitis, I would unhesitatingly drop local applications.

The connection between morbid conditions of the nasal mucous membrane and states of the general system is less constant and much more obscure, yet I have been greatly struck with the frequency with which our favorite national disease and popular pathological luxury, catarrh (congestive or obstructive rhinitis) is associated with what I scarcely know how to describe other than as a general loss or lowering of tone on the part of all the tissues, as evidenced by a faded complexion, spare form and features, flabby muscles, a digestion which is either openly rebellious or must be treated with respectful consideration, atonic bowels, frequent neuralgic attacks, and abnormal susceptibility to fatigue and worry. I believe I have never seen a case of hypertrophic rhinitis in which some or all of these symptoms were not present. In fact I should be strongly inclined to regard a large proportion of our cases of nasal catarrh as simply a local expression of a general lack of tone on the part of the mucous membrane and erectile tissue covering the turbinated bones with their consequent engorgement, hypersecretion, and swelling. The frequency with which these troubles are encountered in this country may be partially explained by the fact that the American race is undergoing marked and rapid changes in adapting itself to a new and trying environment and that our tissues are consequently in a highly unstable and irritable condition. The most potent influence in the new environment is probably that of climate, and hence the parts of the body most directly exposed to and affected by climatic changes might naturally be expected to suffer most intensely. But that this is not the only influence at work is shown by the fact familiar to all of us, that the classes presenting the largest proportion of nasal troubles are not those most exposed by occupation to climatic changes, such as farmers and day-laborers, but, on the contrary, those least exposed to out-door influences, such as merchants, clerks and their families, and town-dwellers generally. What, then, is the additional predisposing influence rendering the organism thus vulnerable? I answer, lack of sunlight and exercise and consequent imperfect oxidation and defective nutrition, and appeal to the personal experience of the reader for support. Do we not find our largest proportion and most aggravated cases among those who are most closely confined and least energetic in their habits, especially among women and children? If nasal catarrh were treated as merely a prominent symptom of "sunshine hunger," the popular belief in its incurability would be considerably shaken. In fact, I am strongly inclined to regard catarrh as really a valuable danger-signal which will attract the attention of the most indifferent patient. Many of our patients will submit with almost apathetic resignation to any or all of the other symptoms of lowered vitality, but let them once discover the fact that they have "catarrh," and they will move heaven and earth to get rid of it and thus give us an opportunity to build up the entire system by a vigorous course of out-door exercise, sun-baths, cold sponging, rubbing, and rational diet. People can be literally led to live more vigorous and rational lives when they can be neither driven nor frightened in any other way.

Those of us who have tried forcing our catarrhal,

neuralgic, and dyspeptic patients into the open air for at least two sunshiny hours daily, insisting with Spartan firmness upon their sponging the upper part of the body with cold water every morning, followed by a vigorous rubbing with the hand or a rough towel, at the same time helping nature to get rid of the results of past indiscretion by digestives and appropriate local applications, which latter serve the useful purpose of keeping up the patient's interest, will, I think, have but little doubt of the correctness of the symptomatic theory.

The greatest value of the specialty of rhinology is as a handmaid to general medicine and an aid to diagnosis, especially in that it furnishes our promptest and most delicate means of appreciating an almost indefinable departure from the normal vigor and diminished resisting power of the human body, which is the invariable negative precedent of all positive morbid action.

A CASE OF ABSCESS IN THE ABDOMINAL WALL COMPLICATING FIBROID TUMORS OF THE UTERUS.

BY EDWARD P. DAVIS, M.D.,
DEMONSTRATOR OF OBSTETRICS IN THE JEFFERSON MEDICAL COLLEGE, ETC.

THE following case recently came into the gynecological department of the Jefferson Medical College Hospital, in the service of Professor Parvin; it exhibited an unusual complication of uterine fibroids, which led to an error in diagnosis, and finally to a fatal issue. The case is as follows:

The patient was aged about forty years, and had been married ten years; no children; no miscarriages. Menstruation began at the age of thirteen, and was always regular. Five years ago she had much pain and a small swelling in the abdomen, which increased in size, the pain being always present except during menstruation. A second swelling on the left side developed within three weeks of her admittance to hospital; since then she had been unable to work, and generally confined to her bed; leucorrhœa was always present; she suffered from sharp pains, shooting posteriorly from the uterus, except during menstruation; she had headache occasionally, but had a good appetite. For the past six months she had lost flesh. Shortly after her admission an abscess formed at the swelling, described by the patient as occupying one side of the abdomen, and ruptured spontaneously. The cavity was washed out, and packed with iodoform gauze.

The examination of the patient disclosed the presence of multiple uterine fibroids of large size. The introduction of a probe or of the finger in the abscess cavity gave the impression that the cavity was in one of the fibroids, a portion of which had suppurated through the abdominal wall.[1] Following the rupture of the abscess and its washing out the patient suffered but little, and it was proposed to allow the abscess cavity to close by drainage, and then, if practicable, to perform hysterectomy. About ten days after admission the patient was brought before the class a second time, the abscess cavity was washed out and tamponed with iodoform gauze, without occasioning especial pain or giving rise to collapse; the patient was kept carefully recumbent, but, while being taken to the ward, she complained of sudden faintness, collapsed, and death followed. The most rational cause for death seemed to be embolism, probably septic in origin, from the abscess cavity. A few hours after death a post-mortem examination was made by Dr. Coplin, and his notes are as follows:

Autopsy (one and one-half hour after death).—Rigor mortis slight in flexors of fingers, not marked in the larger muscular structures. The body was fairly well nourished, and still slightly warm. On a line drawn from the anterior-superior spinous process of the ilium to the umbilicus, and about two and one-half inches from the first-named landmark was a circular opening in the skin, about one-half inch in diameter, with irregular jagged and infiltrated edges. This opening communicated with a circular cavity about one inch deep at its centre, and having a capacity of two to three ounces.

The external covering consisted of skin and superficial and deep fascia, and the base was lined with the muscular wall of the abdomen. In the upper portion of the cavity was a small opening which barely transmitted a grooved director, and which communicated with a deeper abscess cavity; this was not examined further.

An incision was made, extending from the suprasternal notch to the symphysis pubis, the abdominal cavity laid open from the ensiform cartilage downward, and the tissues dissected from the ribs on either side. The cavity was further opened by a lateral incision at right angles to the first, extending from one inch above the umbilicus to the axillary line laterally on the left side, in which the superficial abscess cavity was seated. A topographical examination of the organs was made, and the general condition of the cavity noted as normal, except as will be hereafter stated. The thoracic cavity was then opened; immediately upon puncture the lungs entirely collapsed, a condition often noted after sudden death. The pleuræ were normal; there was a small quantity of serum, no adhesions, no ecchymotic petechial spots on their surfaces. The pericardium was next opened and found normal. The right side of the heart was enormously distended with blood, while the left was firmly contracted and empty. Thinking that here lay the cause of sudden death, the venæ cavæ were ligatured, the entire cavity eviscerated, and its contents put aside for more careful examination.

The abdominal cavity was then examined more fully. The pelvis was found completely filled with a tumor lying in what had been the posterior *cul-de-sac*. The anterior surface had pushed the vagina, urethra, and bladder upward and forward, so that the anterior vaginal wall was shaped like an inverted

[1] This diagnosis was made by Dr. Parvin, and also by several others who examined the patient.

italic *S*, the upper end of the *S* being at the os uteri and the lower at the vulvar outlet. The bladder was entirely raised out of the pelvis, and pushed forward over the pubic bone. This tumor had for its origin or pedicle the posterior lip of the uterus, and was attached as far up as the middle third of the lower uterine segment. It was firmly adherent to the surrounding soft parts and viscera; it was hard and inelastic, and its surface was smooth, although somewhat irregular. Rising from its upper extremity was what seemed to be the uterus itself, more than trebled in its longitudinal axis and with a diameter from before backward of four and one-half inches, and from side to side of five and one-eighth inches, and extending upward to the umbilicus; its surface was irregular but smooth, and had three subserous fibroids, one of which was sessile, and two having distinct beginning pedicles. The right ovary was normal; the left, only partially to be made out, was the seat of a cyst about the size of a goose-egg.

The omentum was firmly adherent to the cyst, and, by bridges, to the wall of the cavity and to the transverse colon, which was pulled down and adherent to the abdominal wall at a point corresponding to the external opening. The adhesion, more properly speaking, was to the parietal peritoneum, just external to which was an abscess cavity lying between the muscular wall and the parietal peritoneum. The capacity and measurements were the same as those already described, and, as noted, it communicated by a small opening with the external abscess cavity. The transverse colon was diminished in its lumen, due largely to the longitudinal extension or traction which was made by the adhesion to the wall. No direct communication could be demonstrated macroscopically as existing between the cavity of the bowel and the abscess cavity, but there is reason to infer that such was the case.[1] The other viscera were normal, except some dilatation of the uterus, which, however, was not marked; the kidneys were normal.

Upon careful dissection of the thoracic viscera, the following points were noted:

The cardiac valves were competent, and showed no evidences of recent marked inflammatory process. The tricuspid valves were slightly thickened, but in no way was their ability to close the opening altered. The other valves were perfectly normal, and there were no intra-cardiac clots, either ante- or post-mortem; the lungs were well aërated; at the base on the left side was a small wedge-shaped area of infarction, the base of which was probably about one-half inch across. In the right middle lobe was a similar but smaller lesion; these were all that could be found upon the external aspect. On dissection, both pulmonary arteries were found completely occluded by a recent thrombus, continuous in both vessels; the process of formation may be briefly described as follows: Thrombosis had occurred in some of the large veins coursing over and through one of the pelvic tumors, and an embolus had been swept into the right side of the heart; there it gained in size by the addition of new elements, and there, too, it probably sent off its forerunners, which formed the two areas of infarct already alluded to; it was then forced into the pulmonary artery, and so completely and instantly occluded its lumen that death was immediate.

As stated by Dr. Coplin, the abscess was entirely independent of the fibroids of the uterus, and probably arose from infection through the intestine; it was impossible, however, by examination of the sac of the abscess before death to satisfy one's self that no communication existed between the fibroid and the abscess; no history of violence or injury to the parts existed to account for suppuration in the fibroid, and no adequate explanation of the presence of pus could be given before the post-mortem examination.

Recent studies in ectopic gestation have shown that it is quite possible for suppuration to occur in the sac of an ectopic fœtus by infection from neighboring intestines.

Jerzykowski[1] reports a case in which the sac of an ectopic gestation was mistaken for an ovarian cyst, until it ruptured by suppuration into the rectum. Morisani's case[2] was similar to the foregoing.

Hecker's collection of 132 cases of ectopic gestation embraces 28 which ulcerated into the intestine.

Barsony's case,[3] in which the fœtal sac was directly accessible through the recto-vaginal septum, illustrates the formation of abscess by proximity to the intestine; it is quite possible that a similar illustration is furnished by many cases of perityphlitic abscess.

Regarding treatment, hysterectomy with thorough examination of the abdominal contents probably furnished the only satisfactory method; nevertheless, the autopsy clearly proved that this operation would have been impossible, or could only have been partial, for one of the chief tumors originating in the posterior uterine wall was too firmly attached in the pelvic cavity to permit its safe removal.

From the standpoint of pathology the sudden and complete embolism which occurred was especially interesting. So, too, the case suggests the possibility of a similar error in the diagnosis of a

[1] In order to prove that a given abscess is due to infection from the bowel, it is not necessary that an absolute perforation should be demonstrated. It is only necessary to prove that the visceral layer of the peritoneum and parietal layer have been brought together and held while the inflammatory process has converted the two points in juxtaposition into embryonic tissue, and then made the lymphatics of the parietal and visceral layers continuous, and at the same time obliterated the communication between the centre of the area of adhesion and the lymphatics of the mesentery; the lymph-spaces are then occluded, and infection of the wall is almost a certainty, unless very rapid cicatrization takes place.

fibroid of the uterus undergoing suppuration, the abscess opening through the abdominal wall—an event exceedingly rare; had neither autopsy nor abdominal section in life been made, this case would have been regarded as typical of such suppuration.

CLINICAL MEMORANDA.

THERAPEUTICAL.

Eucalyptus in Catarrh of the Respiratory Tract and Obstinate Cough in Children.—For several years I have been in the habit of using preparations of eucalyptus, both internally and by inhalation, in the treatment of certain cases of acute and subacute bronchial and laryngo-tracheal catarrh, more especially in children. Some three years ago, in a case of peculiarly obstinate cough in a child, not the cough of pertussis, for which all physical basis, so far as examination could show, seemed to have been removed, I was advised by Professor J. M. Da Costa to use fluid extract of eucalyptus, which had not been employed in the acute bronchitis from which the cough apparently held over. Previous to this, also with Dr. Da Costa's advice, a reliable preparation of belladonna had been used and had failed. Recovery was so prompt as to be striking. Since that time I have repeatedly resorted to the same expedient in similar cases, with equally satisfactory, though not always equally rapid, result. While the use of eucaylptus in the treatment of inflammatory conditions of the respiratory tract is familiar, I do not remember to have seen mention, in print, of this particular phase of its usefulness. It has seemed to me worthy of report, and I have mentioned the circumstances under which I began its use, in order not to claim credit for originality not mine. The value of eucalyptus in relieving headaches and facial neuralgias not of malarial origin, its undoubted value as an inhalation in pertussis, and the property of relieving semi-spasmodic coughs here reported, seem to indicate a nervine quality in some of its constituents. For inhalation in diphtheria, croup, laryngitis, whooping-cough, and phthisis, I prefer eucalyptol; but for internal use in bronchial and laryngo-tracheal inflammations the fluid extract seems to serve a better purpose.

In acute cases my usual custom is to administer it in connection with ammonium salts; in subacute cases a little paregoric may be advantageously added. In the obstinate irritative coughs following inflammatory affections which have apparently subsided, the fluid extract of eucalyptus is best given without other drug, in syrups of tolu and acacia or in an emulsion of oil (castor oil, olive oil, cod-liver oil, almond oil), as necessary, to disguise its taste or modify its action. The dose is about five drops for a child of two years. The following are specimen formulæ:

℞.—Ammonium carbonate . 8 to 16 grains.
Ammonium chloride . 22 to 48 "
Fluid extract of eucalyptus 1½ fluid-drachms.
Syrup of acacia . . ½ fluid-ounce.
Syrup of wild cherry, *or* Glycerin, *or* Syrup of tolu ½ "
Water, sufficient to make 2 fluid-ounces.

For a child two years of age, with acute bronchial or laryngo-tracheal catarrh, one fluid-drachm in milk or water every two, three, or four hours.

℞.—Aromatic spt. of ammonia, Camph. tincture of opium, of each 2 fluid-drachms.
Fluid extract of eucalyptus 1½ fluid-drachms.
Syrup of acacia, Syrup of wild cherry, of each ½ fluid-ounce.
Water, sufficient to make 2 fluid-ounces.

For a child with subacute bronchial catarrh, one fluid-drachm in water every two, three, or four hours.

219 South Seventeenth St., Philadelphia.

OBSTETRICAL.

A Substitute for Post-mortem Cæsarean Section.—Passing through the wards of the Philadelphia Hospital about a year ago, when not on duty, my attention was called to a dying woman in the last month of gestation, lying in the laparotomy-room, surrounded by a group of resident-physicians who were waiting for the moment of death, that one of their number might do a post-mortem Cæsarean section. The woman evidently had but a short time to live; there was no pulse at the wrist, the death-rattle sounded in the throat, the eyes were opened, insensible and glazed. The fœtal heart-sounds, curiously enough, were still quite distinct and regular, and active fœtal movements could be seen and felt. In view of the child's good condition, and of the possibility that in the woman's lingering death the fœtus might die before its mother, I advised the resident-physician in charge of the case to dilate the cervical canal with his fingers, insert his hand and do a version followed by immediate extraction; surmising, as it proved, correctly, that the tissues of the dying woman could offer no resistance to these manœuvres. Although there was not the slightest dilatation of the os when the operation was begun, Dr. Sharpless, the physician-in-charge, extracted the child in less than five minutes. It was born alive, and soon cried lustily. It lived a week, I believe, and died of some condition independent of the manner of its birth. The woman's death, a short time after delivery, was certainly not hastened by the operation; in fact, she seemed a trifle better after it. At the post-mortem examination meningitis was found to be the cause of death.

Where the procedure just described is at all possible, I believe it should always be preferred for post-mortem Cæsarean section. By waiting for the mother's death one may lose the infant as well; the post-mortem section is a disfiguring and bloody operation which would horrify the friends of the patient, and for which their consent could not always be obtained; and, finally, there is the alarming suspicion entertained by the by-standers, if not by the physician, that the woman might not have been dead, but was killed by the operation. On the other hand, version and extraction are as quickly done as section, if one can judge by this single experience; the child is rescued while it is still in good condition; there is nothing repulsive about the operation to the bystanders, and death is not hastened by it.

Barton Cooke Hirst, M.D.,
Professor of Obstetrics in the University of Pennsylvania

MEDICAL PROGRESS.

The Excision of Hæmorrhoids.—DR. LEWIS S. PILCHER, who approves of Whitehead's method of removing extensive hæmorrhoids *en masse*, mentions several cautions which he thinks should be observed in performing the operation (*Annals of Surgery*, May, 1890):

1. It is possible to injure the sphincter so that permanent fæcal incontinence may result. It is by no means easy to recognize the muscular fibres in the first stage of the dissection, particularly if the tumors are large and the sphincter is flabby and has been relaxed by preliminary stretching. Hence, the first step in the operation should be identification of the muscle, after which it may be drawn aside and the enucleation proceeded with.

2. The surface of the sphincter should be closely hugged, thus keeping outside of the muscular tissue of the tumor. This facilitates the operation and causes much less hæmorrhage than if the dissection is through the diseased tissue. For the latter reason the dissection should be carried well up beyond the hæmorrhoidal tissue before making the final transverse section of the bowel.

3. In the aggravated cases there is always relaxation of the rectum with a tendency to prolapse, and considerable retrenchment of the bowel is important in order to secure the most satisfactory results. On the other hand, none of the skin at the anal margin should be removed, however redundant it may seem at the time. When suturing of the intestine and skin has been completed the line of sutures will be some distance outside of the anus, but in time the rectal walls regain tonicity and retract, the sphincter contracts and, finally, the line of union will be within the anus.

4. The retrenchment of the rectum should be exactly equal on each side, or partial ectropion of the mucous membrane may result where the mucous membrane is the longest.

Clamp and Cautery Operation for Hæmorrhoids.—DR. TRZEBICKY reports a series of 120 cases of hæmorrhoids operated upon by the clamp and cautery, in every case with good results. In but two cases was there return of the hæmorrhoids after a period of four years. Trzebicky concludes that the cautery operation is the best of all methods for the radical cure of hæmorrhoids; that there is no danger of hæmorrhage or subsequent stricture; that it is suitable to all varieties of the disease, and that the only contraindication is suppuration within the hæmorrhoids or in the surrounding tissue.—*Schmidt's Jahrbücher*, April 15, 1890.

Oubaïn in Whooping-cough.—DR. GEMMELL, of Glasgow, publishes his results in the treatment of whooping-cough with oubaïn (*British Medical Journal*, April 26, 1890), an alkaloid derived from an African plant used by the natives as an arrow poison. The alkaloid is exceedingly powerful, $\frac{1}{2600}$ grain causing death by cardiac paralysis in frogs.

When he began to use the drug in whooping-cough the author gave doses of $\frac{1}{3200}$ grain, but soon increased the amount and has now adopted $\frac{1}{1000}$ grain every three hours as the proper dose for a child of five years. With these amounts the paroxysms were quickly reduced in number and severity, though in two exceptionally severe cases the dose was gradually increased to $\frac{1}{250}$ grain every three hours. He has treated 49 cases with the drug, of which number 25 recovered, 4 died, and the remainder are still under observation. The fatal cases died from diphtheria, tubercular meningitis, capillary bronchitis, and progressive emaciation. Gemmell thinks his observations prove that oubaïn is of marked benefit during all stages of the disease; that given in the first stage it cuts short the attack; given in the second stage it diminishes the severity of the disease, and in the third stage it hastens convalescence remarkably.

The best form in which to administer it is in a solution, of which one drop represents $\frac{1}{1000}$ grain of oubaïn.

The Treatment of Dropsy.—At the recent Congress for Internal Medicine, held at Berlin (*Münchener medicinische Wochenschrift*, March 18, 1890), FÜRBRINGER deprecated the use of the newer diuretics and cardiac tonics and stated that digitalis remains the sovereign remedy in the treatment of all varieties of cardiac and renal dropsy, even when due to acute glomerulo-nephritis. He believes that there is no anatomical change of the heart which is a contraindication to the use of digitalis, and that it can be safely given for long periods. Strophanthus and caffeine he evidently thinks are only useful as adjuncts to digitalis when, as is sometimes observed, the latter fails to increase the urinary secretion.

Excision of Local Pulmonary Tuberculosis.—At the recent Congress of the German Society for Surgery PROFESSOR TILLMANNS exhibited a man of about thirty years from whom he had removed a tubercular deposit involving a portion of the left lung, pleura, and thorax. After the operation the lung contracted in such a manner that by a second operation the remaining tubercular area was completely removed. The wound was covered with cutaneous flaps and healed completely, and the patient is now able to work. As the operation was performed about two years ago the cure may be regarded as permanent.

Tillmanns thinks that the surgical treatment of pulmonary tuberculosis is proper if the disease is localized, but that in most cases two operations will be required—the first to expose the affected part in order to bring about atrophy and contraction; the second to remove the disease.—*Lancet*, April 19, 1890.

The Treatment of Dysentery with Salicylic Acid.—CIMBALI advocates the use of salicylic acid combined with opium in the treatment of dysentery (*Internationale klinische Rundschau*, April 20, 1890). He administers seven grains of salicylic acid with one-sixth or one-fourth grain of powdered opium every four hours, and finds that the number of stools is rapidly reduced, the pain and tenesmus become less, and complete cure follows in four or five days, though it is safer to continue the medicine a day or two longer.

The author's opinions are founded on fifty cases treated by this method, in none of which were untoward effects produced.

He has also had good results in the treatment of chronic intestinal catarrh with salicylic acid.

SATURDAY, MAY 24, 1890.

THE TREATMENT OF ANAL FISTULA COMPLICATING PHTHISIS.

THE propriety of surgical interference in cases of anal fistula complicating phthisis is a question on which many and widely divergent opinions have been held. At the present time the majority of practitioners undoubtedly recognize the fact that in many cases recourse to the knife is demanded, but that in others surgical treatment would aggravate the pulmonary disease. Just how to distinguish cases suitable for operation is often puzzling, and appreciating this difficulty, MR. HERBERT W. ALLINGHAM formulates a series of rules for the guidance of the surgeon (*British Medical Journal*, April 12, 1890).

Allingham considers, first, fistula occurring in the course of acute phthisis. In such cases the fistula usually begins as a tuberculous ulcer of the rectum, and has a large internal, but no external, opening. Here no attempt should be made to close the sinus, but the patient must be relieved of the distress incident to the accumulation of fæces and disintegrated tissue in the peri-rectal pocket by an incision converting the blind internal fistula into a complete fistula.

Fistulæ developing in the course of slowly advancing chronic phthisis are next considered by the author. This variety usually begins just within the verge of the anus, and has a large external opening. The adjacent skin is much undermined, and the edges of the orifice are infiltrated and unhealthy. In these cases radical cure should be sought, as the system cannot afford the constant suppuration, the checking of which will certainly prolong life and possibly assist in arresting the pulmonary disease. The main sinus should be freely opened, avoiding the external sphincter as far as possible, the entire cavity curetted, and unhealthy skin removed. A dry, iodoform-gauze dressing should be applied, perhaps dusting the cavity with pure iodoform, though Allingham seems to regard the materials of the dressing as of little importance so long as they are dry.

A "strumous fistula" which, the author thinks, occurs in persons with an inherited tubercular diathesis is also described in this paper. Such fistulæ should be promptly treated, as they not infrequently become tubercular, or, at least, open the way to general tubercular infection. Indeed, fistula, even in a robust individual, seems to be a peculiarly accessible port for the entrance of the bacillus tuberculosis, and it should be the invariable rule to operate on such cases without delay.

Regarding the choice of anæsthetics for operations on phthisical patients, Allingham distinctly prefers chloroform, as it is less likely than ether to increase cough. But from this opinion most American surgeons will dissent, as the heart is invariably weakened in phthisis and less able than in health to withstand the depressing effects of chloroform. The condition of the heart and the character and amount of cough should be the guides to the anæsthetic suitable to each case. If cough is severe and spasmodic and the heart not markedly weak, chloroform is probably safer, while if cough is not a prominent symptom ether should be used.

After such operations it is desirable that the patient should sit up, if possible, on the following day, for if the recumbent position is maintained longer hypostatic congestion and aggravation of the pulmonary disease is likely to occur. Moreover, the operation should be performed under the best sanitary conditions available, Allingham advising that the patient be previously removed to the seashore.

THE TREATMENT OF VARICES OF THE VULVA.

THE practical importance of the extravasation of blood about the vulva becomes apparent when we consider the occurrence and course of hæmatomata

of this region, varices, or the rupture of a vessel during labor. Not only may sudden acute hæmorrhage bring the patient into a condition of collapse, but also thrombosis and embolism may result, with exceedingly serious consequences.

A recent case of pulmonary embolism following hæmatoma of the vulva, in which a dangerous pneumonia resulted, emphasizes these remarks. In the *Revue Médico-chirurgicale des Maladies des Femmes*, March 25, 1890, BATUAUD writes upon varices of the vulva and their importance in obstetric practice, basing his remarks upon a recent thesis by Moussard, of Paris.

So far as diagnosis is concerned, there can be but little difficulty in recognizing this condition. The prognosis is favorable in ordinary cases, but depends upon the possibility of rupture and embolism. If they occur during pregnancy excessive exertion should be avoided—violent respiratory movements are especially injurious; and should rupture be threatened, pressure should be made by a T-bandage; when local irritation and discomfort are present, cocaine and starch-powder, or starch-water, will be found useful. When hæmorrhage occurs, compression should be promptly made, either by a small *pincette* of some sort or by hæmostatic forceps if the point of rupture is discernible; if not, an antiseptic compress and T-bandage are indicated.

In cases of syncope after labor, depending upon severe hæmorrhage from whatever cause, good results have followed the hypodermic injection of dilute solution of chloride of sodium (6 to 1000).

During labor the bladder and rectum should be promptly emptied to relieve pressure, the pelvis should be elevated, and precautions taken that the head is not born too soon, or with violence. Chloroform is found a most useful adjunct in modifying the forces of labor.

The forceps is occasionally indicated to restrain the head and control its exit.

Pressure may be made upon the varices during labor by the fingers of the obstetrician, or by an antiseptic pad should rupture threaten.

THE MEETINGS AT WASHINGTON AND NASHVILLE.

As a medical newspaper, the current issue of THE MEDICAL NEWS presents, in an interesting narrative form, the proceedings of the meetings of the American Association of Physicians and the American Surgical Association, held at Washington, and of the American Medical Association, which has been in session at Nashville during the week.

Long reports, detailing tedious discussions and matters of limited interest, should find no place in the columns of a weekly periodical such as THE NEWS. Their proper sphere is in the volumes of Transactions issued by the societies themselves; and with this in view the correspondents of THE NEWS have been restricted to presenting only such material as possesses general attractiveness.

In the coming issues will appear at length the more valuable original papers read at these meetings.

SOCIETY PROCEEDINGS.

THE ANNUAL MEETING OF THE ASSOCIATION OF AMERICAN PHYSICIANS.

Held at Washington, D. C., May 13, 14, and 15, 1890.

THE proceedings of the Association, so far as its scientific work was concerned, opened with a paper by DR. JAMES E. REEVES, of Chattanooga, Tenn., upon "Some Points in the Natural History of Typhoid Fever," in which he considered the character, course, and complications of the disease from its inception through convalescence. (See THE MEDICAL NEWS, May 31st.)

In discussion, Dr. J. C. Wilson, of Philadelphia, spoke of his belief in the great value of Brandt's method of using the cold bath whenever the temperature rises to a point over 101.5°, and briefly detailed the favorable results obtained by him in the treatment of thirty cases of the disease in the wards of the German Hospital in Philadelphia. In the majority of these no medicine was given, in a few a little calomel being occasionally used to evacuate the bowels at the beginning of the attack, and in every instance the results were extraordinarily good.

Following Dr. Wilson, Dr. Alfred L. Loomis, of New York, stated that he failed to recognize the distinct forms of typhoid fever characterized by Dr. Reeves as mild, intermediate, and malignant, and expressed surprise at the statement of the author that he had seen five recoveries in typhoid fever after perforation of the bowel had occurred. He himself had never seen a recovery where perforation really took place; although he had observed cases in which peritonitis of a localized or diffuse character had complicated typhoid fever, not due to perforation, and resulting in recovery. Dr. Loomis believed that cardiac softening is a very common complication of typhoid fever, and asserted that if a loud systolic murmur is heard at the apex the prognosis is unfavorable, as it shows that softening has occurred, and that thrombosis or sudden dilatation has taken place, the latter resulting from some sudden movement straining the softened viscus. He thought that getting up too soon probably caused the symptoms of a weak, dilated heart following typhoid fever. Dr. Loomis then proceeded to state that he had recently seen in New York a form of nervous trouble consequent upon typhoid fever which, as far as he was aware, had been described nowhere except in a paper by Dr. V. P. Gibney, in

which the author had detailed several instances of what he was pleased to call "typhoid spine." This condition is marked by great pain and tenderness over the spinous processes of the vertebræ, and has been confused by some physicians with lumbago and other similar conditions. Eventually the cases which had consulted Dr. Loomis were cured by the use of the hot iron and a particular jacket devised by Dr. Gibney.

Drs. S. Weir Mitchell and Abraham Jacobi objected very strongly to the idea that typhoid spine was in any way a new or distinct sequelæ of typhoid fever, both agreeing that it was simply a spondylitis.

Dr. Hosmer A. Johnson, of Chicago, stated that he had seen a case of what he believed to be recovery after perforation of the intestine in typhoid fever, and detailed the symptoms which gave rise to this belief.

Dr. William Pepper, of Philadelphia, agreed with the opinions of Dr. Mitchell and Dr. Jacobi, and expressed the thought that the immunity from typhoid fever in Chattanooga, as stated by Dr. Reeves, was very extraordinary, and must be largely dependent upon some peculiar condition of the soil. He also insisted upon the great value of the use of nitrate of silver internally in typhoid fever throughout the attack as a means of avoiding complications and lessening its severity.

The paper of DR. NORMAN BRIDGES, of Chicago, on "Appendicitis" (see page 549) was discussed by several of the physicians present, and Dr. Atkinson, of Baltimore, stated that in his opinion the surgeon is often called too late, and yet, on the other hand, a large proportion of the cases get well if left alone; leaving us in a position of indecision as to what course is to be pursued.

Dr. R. Fitz, of Boston, believed that there were many cases of mild catarrh of the appendix that never come to the care of the physician, and gave the conclusions derived by him from seventy-two cases which he had personally seen. He thought that the five hundred cases previously collected by him and reported some four years ago had been somewhat misleading in respect to the results derived from them. His opinion at present is that there are half as many females affected as males, and he added that while 11 per cent. in his statistics had recurring attacks, 44 per cent. in his personal experience had recurring attacks. Dr. Fitz also made the interesting statement that recurring attacks take place with equal frequency, whether the cases be treated medically or surgically, unless the appendix be removed, the general average of recovery being 74 per cent. He believed that the mortality of medical treatment is only 11 per cent., while that of surgical treatment is 40 per cent., but it is to be remembered that the high percentage of surgical treatment rests largely upon the serious and advanced condition of the disease before the surgeon is called in or given the opportunity to operate. He also thought that two simple rules could readily be formulated — namely, that where the symptoms were very urgent, or where a tumor was present the surgeon should operate, but that in cases of slow recurrence without urgent symptoms medical treatment is to be resorted to, as surgical treatment is difficult owing to the changes produced in the relative positions of the parts caused by previous attacks.

Dr. Jacobi, of New York, objected to the term "turn the case over to the surgeon," saying that in his opinion physicians should be able to perform four surgical operations—namely, intubation, tracheotomy, herniotomy, and abdominal section for appendicitis. He did not think that localized peritonitis in the right groin should be operated upon during its stage of activity, but punctured if necessary and operated upon in the course of a week or two, after the severity of the inflammation had passed, provided that it was considered necessary to use the knife. Dr. Pepper, on the other hand, did not believe that any physician should operate upon such a case and thought it required all the skill of the thoroughly trained surgeon to undertake such a procedure, the physician always sharing his responsibility with a surgeon. Dr. John H. Musser spoke of tuberculosis as a cause of appendicitis, having seen three such cases.

The paper of DR. LUSK on "Antisepsis during Labor" (which will appear in THE MEDICAL NEWS, May 31st) was discussed by Drs. Welch, Pepper, and Roosevelt, who all expressed their interest in the conclusions reached by the essayist, and agreed with him as to the inadvisability of the vaginal touch in most cases. The fact that the hands of the accoucheur could not be considered sterile, although they might be aseptic, even if a very strong solution of bichloride of mercury was used, was pointed out by Dr. Welch.

DR. DANA read a very able paper upon "Seizures Accompanied by Shock and Coma," which was discussed by Drs. Lyman, Loomis, and Edes. Dr. Loomis spoke of the difficulty of differentiating embolism, apoplexy, and thrombosis in diagnosis. In many cases he has found supposed apoplexy to be in reality cerebral thrombosis with softening. The patient in embolism, however, generally does not lose consciousness, and he thought that before fifty years of age such attacks are always due to extravasation and after fifty to thrombosis and softening. In his opinion, too, uræmic coma cannot be diagnosed by the condition of the pupil. Dr. Jacobi stated that in his experience the œdema of uræmic coma is often unilateral, not bilateral, and that its diagnosis cannot rest upon any such diffusion of the puffiness.

The paper of DR. S. WEIR MITCHELL, as referee, upon "Disorders of Sleep," was unusually interesting, and dealt with the psychical motor and sensory disturbances of the præ-dormitium and post-dormitium, including sensory, motor, and emotional overflows or explosions, as well as the condition of the subjects of waking numbness, and post-somnic paresis and paralysis. Dr. Mitchell also dwelt on the curious nervous disorders known as night neuralgias, night choreas, and failures of respiration in sleep.

Dr. Folsom, the co-referee, considered the physiology of sleep, the causes and conditions of insomnia, the influence of habit and the various diseases and poisons which produce it. He also spoke of the vaso-motor conditions associated with disorders of sleep, and discussed quite fully the treatment of these by measures directed to the improvement of hygienic surroundings of the patient and by the use of certain drugs. He believes that drugs are to be generally avoided as far as possible, but that chloral, hyoscin, methylal, and sulphonal are the best remedies to be resorted to if drugs are necessary. Dr. Pepper added that a person might train himself to sleep and to put aside all

mental effort, arranging the body in such a manner as to let it rest entirely upon the skeleton, thereby affording the muscular system total relaxation and rest. As the superior oblique and external rectus muscles of the eye are generally severely strained by prolonged eye-work, and ache, he advised rotation of the eyeballs upward during the endeavor to obtain sleep, in such a way as to relieve these muscles from all exertion. Dr. H. M. Lyman, of Chicago, said that he believed that many cases of insomnia were due to rheumatism, and recommended the use of milk of sulphur and bitartrate of potassium in the proportion of one to five parts. Dr. G. L. Peabody, of New York, related a case where full doses of soda and rhubarb cured insomnia which had resisted all other remedies. Dr. M. Allen Starr, of New York, expressed great confidence in sulphonal as a hypnotic, and believed it to be valuable, particularly if food is taken just before instead of just after its administration.

In closing the discussion, Dr. Mitchell remarked that many cases of insomnia, though depending upon gastric or other trouble, failed to recover from the disease causing the insomnia unless sleep was induced by the use of drugs. He also recommended the administration of sufficiently large doses of hypnotics to make the production of sleep sure of occurrence, as the use of smaller doses if they fail, produces a condition of doubt in the patient's mind as to his ability to sleep, or the power of remedies to make him sleep, which is unfortunate and interferes with successful results. He advocated the administration of thirty or more grains of bromide at once, or that one-hundredth of a grain of hyoscin should take its place. Finally, if these both fail, he depended upon sulphonal.

DR. CHARLES L. DANA, of New York, followed with a paper upon a study of the "Sensory Disturbances in Hysteria," which showed careful study of the entire subject, and was received with great interest.

The paper of DR. WHARTON SINKLER, of Philadelphia, upon migraine, dealt very largely with its causes, its unusual visual phenomena, and particularly with its treatment. He recommended phenacetin, antipyrine, eucalyptus, and caffein in large doses as the best means of treatment.

A very interesting demonstration was that of DR. HAROLD ERNST, of Boston, who showed to the Society the body of a rabbit, which was one of three to which he had given, by means of a hypodermic needle, in the abdominal region, five or six drops of milk derived from the udder of a tuberculous cow. All the abdominal viscera were thickly studded with miliary tubercles, but the lungs were not affected. Dr. Ernst naturally believed this to be a very strong evidence of the communicability of tuberculosis by means of milk to human beings, and asserted that he was sure that the rabbit which had died after its inoculation was not affected by tuberculosis arising independently of his injection of the milk, as rabbits which did not receive the milk were healthy at this date. He then proceeded to discuss briefly and to place on record certain studies carried out by Dr. Stephen Martin, of Boston, concerning the *contagium vivum* of cow-pox and vaccine material. Dr. Martin had been able to make cultures through five generations of this material, and had inoculated children with matter derived from the fifth generation with success, since these children, when vaccinated with lymph which had been found active in other children, failed to develop the typical vesicles. He stated that Dr. Martin was continuing his investigations and would report further upon them at future meetings of the Association.

DR. D. W. PRENTISS, of Washington, showed a man with an extraordinarily slow pulse, the pulse-beat at the time of the exhibition being but 30 per minute, but had been as low as 11, the respirations being 32. He also presented a boy suffering from rheumatic purpura, in whom so large an amount of blood had been poured out beneath the skin on the anterior belly wall as to produce a slough. In the discussion of this last case Dr. Atkinson, of Baltimore, stated that he had seen somewhat similar cases, and knew of instances where similar sloughs had occurred. Dr. Tyson, of Philadelphia, also mentioned one such occurrence in his experience. Dr. Jacobi expressed the belief that all these cases were dependent upon changes in the bloodvessel walls, and that in those instances where the blood had undergone a change the leakage which resulted was due to alterations in the bloodvessels resulting from the hæmic alterations.

DR. W. H. WELCH, of Baltimore, then reported a case of "Acute Diphtheritic Colitis with Peri-pancreatic Fat-necrosis." The patient, fifty-three years old, had been a hard drinker. Three days before death he became delirious and was admitted to the hospital. Temperature elevated—when first observed, 101.5° F.; on day of death, 105.4° F. Pulse 120 to 132, compressible. Spleen not enlarged. Abdomen tympanitic, tender on pressure, especially in epigastrium. Urine slightly albuminous. Tongue clean and moist. No diarrhœa until a few hours before death, when he had an offensive liquid stool. Urine and fæces passed involuntarily. Patient became unconscious and died two days after admission to hospital.

At the autopsy, which was made a short time after death, were found numerous foci of so-called fat-necroses in the transverse meso-colon, and in the adipose tissue around the pancreas, with beginning sequestration of the pancreas. Liver intensely fatty. Contents of bile-ducts and of gall-bladder viscid, clear, with only slight yellowish tint. Renal epithelium fatty. Ecchymoses, small ulcers, superficial necroses and diphtheritic exudation in large intestine. The foci of fat-necroses, as well as the liver, bile, and spleen, contained in large number a single species of bacteria, which was isolated and studied in pure culture. The organisms are bacilli, belonging to the group of colon bacilli, and probably identical with the bacterium coli commune. Cultures and microscopical specimens from this case were exhibited.

He also reported a case in which symptoms suggesting intestinal obstruction existed. Exploratory laparotomy was performed. Numerous foci of fat-necrosis were found in the omentum and mesentery and a swelling in the region of the pancreas, but no intestinal obstruction existed. Portions of the omentum containing necrotic foci were excised and were examined microscopically by the writer. The patient recovered.

Following this report DR. REGINALD FITZ, of Boston, described a "Case of Acute Pancreatitis," which illustrated the suppurative in contrast with the hæmorrhagic and gangrenous varieties of the disease. Microscopical

preparations were shown and the recent literature on the subject was reviewed.

DR. E. O. SHAKESPEARE, of Philadelphia, then read a paper entitled "What Can and Should be Done to Limit the Prevalence of Tuberculosis in Man?" In this essay the speaker advanced the following propositions:

1. The bacillus tuberculosis is the sole active or exciting cause of the disease, which is infectious or contagious and non-hereditary.

2. Whilst on the one hand the discovery of the bacillus has advanced our methods of treatment but little, on the other hand it has revealed most important principles upon which to base efficient means of preventing the spread of the disease.

3. In view of the admitted inefficiency of all present modes of treatment of actual cases of tuberculosis, effective prophylactic measures are infinitely more important to the general public, and should also be to the physician, than the most skilful therapeutic measures.

4. Since analysis of the fullest records bearing upon the relation of family history to the causation of tuberculosis can possibly account, through hereditary predisposition, for little more than one-fourth of the cases, the most perfect measures conceivable for the lessening of that influence cannot be rationally compared in importance to those which are essentially based upon the destruction of an infective poison, which is virulent enough to produce the disease, not alone in the comparatively few who may be born with hereditary predisposition, but also to cause tuberculosis in the majority who succumb, notwithstanding the absence of an hereditary weakness.

The following general principles underlie an efficient system of prevention of tuberculosis:

1. From the standpoint of the already diseased, effective and preventive measures should look to the rapid destruction of the tubercle bacilli in the excretions and secretions, and by as little association of the well with the sick as possible.

2. From the standpoint of those liable to become infected, nothing which may contain the living tubercle bacillus should be permitted to enter the digestive apparatus. Rigid inspection of meat and milk is a necessity.

3. Tuberculous subjects should not be admitted to hospital wards in which those with other diseases, especially of the lungs, are confined. In general hospitals, consumptives should be assigned to special consumptive wards.

4. Special hospitals for the treatment of consumption should be established.

Dr. F. P. Kinnicutt followed with a paper upon "Methods of Diagnosis in Diseases of the Stomach."

Dr. F. C. Shattuck also read a paper upon the same subject.

The meeting closed with "A Report of Two Cases of Acromegaly," by Dr. J. E. Graham, of Montreal, which will be published in the columns of this journal.

ANNUAL MEETING OF THE AMERICAN SURGICAL ASSOCIATION.

Held at Washington, D. C., May 13, 14, and 15, 1890.

THE meeting of the American Surgical Association was opened by DR. P. S. CONNER, of Cincinnati, who read a short but forcible paper upon "The Surgical Treatment of Tumors of the Bladder." The essayist stated that the ultimate prognosis in all cases of cystic neoplasm was bad, even though the tumor was, in itself, not malignant. In all, he was able to collect the statistics of 176 cases upon which operation had been performed and the result noted. The general resultant mortality was 22.7 per cent. In males 26.6 per cent., in females 13.46 per cent.

In only 13 per cent. of the general mortality could death be attributed directly to operation, and even in this proportion previous conditions played an important causative *rôle*. In nearly all there was decided relief from distressing symptoms.

As to operative technique the dilatability of the urethra in women suggests in them the advisability of using this passage for the removal of new-growths. Even though incontinence occasionally follow, it is generally temporary. In males the choice between the high and the perineal incision is still *sub judice*.

A study of statistics gives no solution of the problem, as the mortality is practically the same in each. Since the graver cases are usually relegated to the suprapubic operation, however, the fact that this procedure gives about as slight a mortality as the perineal cut is distinctly favorable to the high operation. From the perineum a clean exsection of the growth with subsequent suture of the divided tissues is not possible. Even diagnosis at times cannot be made, since there are many cases where the bladder is so displaced that the finger cannot reach it from the perineum. By the suprapubic cut the whole operative field is open to inspection and palpation, and can be subject to every detail required by modern surgery. Excepting perfect drainage, it has every point in its favor.

The author concluded his paper with the following statements:

1. Only after operation is there much chance of recovery from any kind of vesical tumor.

2. Operations should be done in all except the least and most severe cases.

3. As a rule, in males, the bladder should be opened above the pubes.

4. The removal should be as complete as the situation and extent of the growth will permit.

In the discussion which followed the reading of this paper it was generally conceded that the perineal operation was frequently insufficient, even for exploration, especially when the prostate was enlarged. There was a practically unanimous expression of opinion as to the ease and safety of the high operation.

Dr. W. W. Keen, however, stated that in one case upon which he operated, even though both bladder and rectum were fully distended, it was only after putting the patient in Trendelenberg's position that the interior of the bladder could be explored.

Dr. C. B. Nancrede stated that even with a suprapubic incision, and though the finger could be carried over every portion of the cystic mucous membrane, he, on one occasion, was unable to determine whether or not a tumor was present. To his finger none was perceptible, while two of his colleagues distinctly located a neoplasm. The subsequent history of this patient clearly indicated that in reality there had been no bladder tumor.

In cases where the condition of the bladder or urethra is such that it is advisable to maintain a suprapubic out-

let for the urine, both Drs. Hunter McGuire and A. Vander Veer stated that this artificial outlet could be so managed by the patient that the urine could be retained for several hours.

Dr. D. Hayes Agnew alluded to the importance of diagnosis in these cases, and said that he had been materially aided by passing into the bladder a small instrument especially designed for this purpose and snipping off a portion of the growth for microscopical examination.

Several of the members spoke of the aid afforded, in examination of the base of the bladder, by two fingers passed into the rectum, by means of which the *bas fonde* could be made accessible to search from above.

Dr. L. McL. Tiffany stated that unilateral surgical kidney was peculiarly liable to occur in connection with bladder tumors.

DR. STEPHEN SMITH, of New York, then read a paper in which he carefully discussed, from the standpoint of a general practitioner, the treatment of fractures of the femur. He explicitly stated that his purpose was to advocate the treatment which would give the best results in the hands of men not especially trained in surgical work. After carefully considering the mechanics of displacement, Dr. Smith stated that in his opinion all fractures of the femur are best treated in the extended position. When the break is just above the condyles this position, of course, increases the tendency to backward displacement of the latter; extension of the foot will, however, relieve the tension upon the gastrocnemius, thus enabling the fragments to be accurately apposed. Extension should be exerted by the ordinary method of adhesive straps applied to the leg and a weight attached to them passing over a pulley at the foot of the bed. By means of the straight position and extension the muscles are drawn taut and the fragments are strapped in proper position. The number of pounds employed to exert tension should be about twenty, except in the case of children, when this would exceed the weight of the patient. Finally, four short splints of light wood are applied about the thigh and secured in place by tapes.

Dr. Agnew agreed with Dr. Smith in the main, but was in the habit of placing all fractures just below the trochanters upon a double inclined plane and making extension from the knee. He objected to the primary plaster dressing, on the ground that it caused much disturbance in adjustment and removal, prevented inspection of the parts, and was liable to exert an injurious amount of pressure, or, on the subsidence of swelling, become so loose that motion at the seat of fracture was possible only after consolidation of the bone should the plaster dressing be applied. Under no form of treatment was union without shortening possible.

Dr. J. H. Packard believed that any result which enabled a patient to walk without limping was satisfactory. He used, in addition to extension in the straight position, an anterior coaptation splint. He agreed with Dr. Agnew in regard to plaster dressings, and under some circumstances would recommend the Nathan R. Smith wire suspension-splint.

Dr. S. H. Weeks had always followed the treatment advocated by Dr. Smith. The forward tilting of the upper fragment he combated by a sand- or shot-bag, and added to the apparatus described a long Liston splint.

Dr. J. A. Comingor stated that he applied immediately to all fractures of the thigh a plaster dressing. The patient was drawn to the foot of the bed, the buttocks being supported by a suitable stand, the fracture was reduced, and while the bone was retained in normal position by manual extension, a plaster dressing was applied enveloping the injured leg and thigh, and ending in a case enclosing the pelvis and waist. At times the sound thigh was taken in. By this dressing swelling was prevented, the fragments were fixed in normal position, the patient could turn in any position in bed, and in two weeks could walk about on crutches. The results were good. Congestion or atrophy never followed, and in case it were desirable to inspect the seat of injury, this could be readily accomplished by slitting up the plaster bandage and springing it open. This has given better results in the speaker's hands than the method of sand-bags and extension. Dr. J. R. Weist and Dr. D. W. Yandell warmly seconded Dr. Comingor's laudation of the plaster dressing.

The afternoon session was closed by a very careful and scholarly paper upon "A Rare Form of Epithelioma of the Upper Extremity," by DR. CHARLES B. NANCREDE, of Ann Arbor. The case described was one in which a long-standing ulceration of the hand underwent epitheliomatous change, requiring amputation. Professor Gibbes made a minute microscopical examination and contributed his report to Dr. Nancrede's paper. The essayist thought that this case went far toward proving the fallacy of Mr. Hutchinson's interesting, but still unproven, theory of arsenical keratosis.

The Wednesday morning session was opened by a paper upon "Surgical Operations for the Correction of Club-foot," by DR. THOMAS G. MORTON, of Philadelphia. He stated that the cause of club-foot is probably dependent upon the same nerve-changes that characterize other forms of infantile palsy. When both extremities are affected the prognosis is unfavorable, since centric changes are so great that complete reduction is often impossible. The amount of deformity depends not only on the extent of nerve lesion, but also upon the period of intra-uterine life in which the lesion occurs. Subsequently the deformity is much increased if the foot is used in walking and if it has been subjected to improper or careless surgical procedures.

The simple cases of congenital varus are amenable to non-operative treatment with possibly section of the tendo-Achillis in some, though this should not be performed until the child is ready to walk. In the complicated cases the difficulty is commonly a displacement of the astragalus forward and of the tibia and fibula backward, owing to the unopposed pull of the calf muscles before the bones have been fully formed. As a result, the astragalus becomes so deformed that no amount of force can replace it, nor will tarsotomy or tarsectomy suffice. When this condition has been still further aggravated by the patient walking upon the displaced foot, complete excision of the astragalus, combined, if necessary, with free section of the soft parts, is the only method which will allow the foot to be unfolded and placed in its normal relation to the leg. At times others of the tarsal bones will have to be removed. The deformity should be over-corrected, then the wound drained with catgut and the foot bound to a right-angled tin splint and not dis-

turbed for several weeks. Dr. De Forest Willard agreed that excision of the astragalus was safe, easy, and efficacious; its popularity would, however, depend upon ultimate results. The great point is to put a child's foot flat on the ground; this accomplished, the weight of the body with the action of the muscles will insure cure. He believed that this could nearly always be accomplished by the exertion of force without having recourse to the knife; when the latter is used it should be employed subcutaneously as far as possible, to avoid the secondary deformities dependent upon cicatricial contraction.

Dr. C. T. Parkes, of Chicago, stated that he did not think tarsectomy, or any of the cutting operations were necessary. He followed König's method of forcible rupture. Great force was at times necessary, but he had always been successful. After over-correction he immediately applied a plaster dressing, and allowed it to remain for several weeks. At times the treatment had to be repeated. No padding or cotton should be placed beneath the plaster; simply two pairs of stockings, the pair next to the skin of silk. In this way the elasticity of the foot was preserved, while cutting often gave a result but little better than that following a Symes amputation.

DR. W. T. BULL of New York, then read what is probably the most valuable paper yet written upon the results of the radical treatment of hernia. In all, he had operated upon 134 cases, 16 of them being children under fourteen years of age. In this whole series there were but three deaths. In one of the fatal cases strangulation existed at the time of operation.

In four cases the gut was wounded in separating adhesions; no bad results followed this complication. Once the vas deferens was injured and suppurative orchitis followed; the patient, however, ultimately recovered. In about half the cases primary union took place. Where silk was used in the deep sutures, stitch abscesses developed without exception.

He operated on one series of cases by applying a ligature to the neck of the sac, dissecting the latter free and excising it, or if it was very large and adherent draining it. In another series of cases he ligatured and excised the sac and sutured the columns of the rings in close apposition. In still another series, he ligatured and excised the sac, and by a double set of sutures closed the entire inguinal canal. The results show that relapse is as prone to follow the more difficult and tedious methods as is the case in simple ligation and excision of the sac; hence the latter operation should always be preferred. The essayist stated that no operation had yet been devised which satisfactorily stood the test of time. In the large majority of cases relapse was assured. Whether or not the wearing of a truss following operation exerted a favorable influence could not be determined. In the cases where this point had been observed no such influence was noticed. Although there was no prospect of obtaining a radical cure by operation, the surgeon should not hesitate to use the knife under certain circumstances; since the risk to life is very slight and there is nearly always an improvement in local conditions. The circumstances under which operation should be advised are:

1. In children who cannot wear a truss, or in whom no improvement follows after prolonged trial of a truss.

2. In adults who cannot wear a truss, or in whom the hernia is either irreducible or strangulated.

With the ideas of the author of this paper there was practically a unanimous concurrence on the part of the Fellows of the Society.

Following Dr. Bull, a very careful and exhaustive discussion of "Lumbar Hernia" was presented by Dr. C. H. Mastin. The fact, as noted by Mr. Owens, that this form of rupture was not dependent upon the existence of Petit's triangle, was very clearly demonstrated, and interesting photographs of a child suffering from lumbar hernia were exhibited.

The next subject on the programme was "The Propriety of the Removal of the Appendix Vermiformis during an Interval of Recurring Attacks of Appendicitis," by DR. FREDERICK S. DENNIS, of New York. The essayist stated that the objections to this procedure were: 1, the danger to the patient; 2, the difficulty of diagnosis; 3, the liability to subsequent development of abdominal hernia; 4, the lack of evidence that the operation gives permanent relief; 5, the fact that as a result of a relapse immunity may be afforded in the future. As to operation after the first attack, the fact that only eleven per cent. of these cases relapse sufficiently answers that proposition. Even of the eleven per cent. a very small proportion terminate in perforation; and though this most serious and grave of all complications occur, recovery is still possible. Frequently an operator has failed to find the appendix; Dr. Dennis enumerated about twenty different pathological inter-abdominal conditions which had led eminent men into a false diagnosis of appendicitis, as a proof of the difficulty of diagnosis. When the cæcum is the seat of trouble, and a differential diagnosis cannot always be made, an operation on the appendix would, of course, be futile.

Finally, statistics prove that operation upon the second or third day of an acute attack gives a lower mortality than the incision in the interval; hence, save in very exceptional cases, this latter procedure should not be practised.

This paper was carefully discussed by Drs. Joseph Ransohoff, Keen, Parkes, Bull, and M. H. Richardson, the latter reading for Dr. Porter an account of two successful operations performed in the interval between attacks. The feeling was generally expressed that the operation should be recommended only when the attacks were so frequently repeated as completely to cripple a patient, preventing him from pursuing his ordinary calling. The fact that this operation is at times extremely difficult was strongly brought out, and it was agreed that the ultimate results were not always satisfactory.

Following this paper DR. J. RANSOHOFF, of Cincinnati, reported a case of head injury, in which there were no symptoms of intra-cranial bleeding for eight days. Then coma and general muscular twitchings appeared rather suddenly, with dilatation of the left pupil, though the right side of the head was the one upon which external signs of trauma were marked. Guided by the dilated pupil a trephine opening was made over the middle meningeal artery of the left side. A huge firm clot was found, which was only removed by means of the curette. Following the operation consecutive hæmorrhage appeared, which required ligation of the common carotid artery for its control. This was followed by pyæmic

symptoms and embolic pneumonia. In fifteen days from the carotid ligation recovery seemed fairly inaugurated, when secondary hæmorrhage occurred at this point and the patient perished.

Drs. F. S. Dennis, Keen, and James McCann considered ligation of the carotid an uncertain means of controlling hæmorrhage from vessels of the head, on account of the very free anastomosis. The ligation of the main trunk of the middle meningeal, enlarging the bone opening if necessary, and either passing a tenaculum under the artery and ligating or passing a thread by means of a curved needle was suggested.

Dr. Ransohoff stated, however, that the artery could not be found, that plugging failed to check the bleeding, and that ligation of either the common or the external carotid was the only surgical resource left him.

After an executive session, on Thursday morning DR. W. W. KEEN read his paper upon "Nephrorrhaphy." The subject was handled with even more than the usual clearness which characterizes this author's writings, and formed decidedly one of the best essays of the meeting. The extreme rarity of floating kidney as found in autopsy records was explained on the ground that the pathologist rarely looked for this condition or noticed it unless it existed in an aggravated form. The result of an elaborate statistical search was called in evidence of the fact that looseness of attachment was very generally found in the right kidney of women. Among the evil consequences of non-interference were mentioned hydronephrosis, albuminuria, and uræmia. The diagnosis was usually easy, though little reliance could be placed on the signs afforded by percussion. As to treatment, the first effort of the surgeon should be to retain the kidney in position by means of a band and pad. This failing, nephrorrhaphy or nephrectomy could be considered. Against a mortality of two per cent. for the former stands the formidable death-rate of thirty per cent. for the latter. Then, in case of advanced disease, or when the kidney cannot be replaced, this organ may at times properly be excised. The oblique incision should be practised, excision of a rib not being necessary, and the operator should come upon the perinephritic fat at the outer edge of the quadratus lumborum muscle. When the kidney is not in its normal position the operator may have much trouble in finding it, the liver more than once having been mistaken for this organ. The colon should be carefully observed, then the finger should be carried over the upper border. The assistant should not press the kidney back into its place till after the perinephritic fat is torn through. At times the kidney will have to be drawn into its normal position by means of a vulsellum or tenaculum, or both. The kidney should be secured in its lowest normal position to avoid as much as possible the respiratory movements. It may be anchored by sutures passed through the fatty capsule, through the fibrous capsule, or through the parenchyma, including, of course, both capsules. Finally, the capsule may be stripped off, thus allowing a broad surface for firm adhesion. As far as stitches go, the parenchymatous suture seemed to give the best results. Six stitches were usually made by the operator, and sterile silk, the finest compatible with the requisite strength, was used in preference to catgut, and was left buried in the wound; the latter was left open, and dressed with bichloride or double cyanide gauze. The great after-pain referred to the hip was probably due to disturbance with the ileo-hypogastric nerve. This, if seen, could be resected, and thus an unpleasant complication could be avoided. The patient should not sit up for four weeks. Subsequently an elastic support should be worn, and occupations or amusements calculated to reproduce the condition should be avoided.

There was a general expression of opinion following the reading of Dr. Keen's paper upon the desirability of operating when the symptoms referable to the kidney incapacitated the patient for his ordinary vocations. Dr. Richardson stated that a movable gall-bladder might lead the surgeon to a false diagnosis. He preferred the silk sutures, but usually removed them before complete closure of the wound. Dr. Dennis thought the stitches should include the parenchyma. Dr. L S. Pilcher believed that the removal of a portion of the kidney capsule would afford the highest percentage of cures. Dr. Parkes stated that he did not consider the operation a desirable one. The majority of these operations had been done in times so recent that it was impossible to determine what the ultimate results would be. The kidney substance was so friable that he saw no advantage from including it in the sutures. Dr. Tiffany thought that in some of the reported cases the symptoms were dependent upon a tight capsule, and that relief followed from this condition being relieved rather than from the anchoring of the kidney. Dr. Willard called attention to the importance of producing a broad, deep scar, since it was by this, and not by the stitches, that cure was effected. Dr. McCann preferred silkworm-gut as a suture material. It was never absorbed, and gave no subsequent trouble. The great majority of cases of movable kidney suffered very slight inconvenience from this condition, hence operation would be required rarely. Dr. Keen appended to his paper a table of 134 operative cases, the most complete yet published.

EXECUTIVE SESSION.

On Thursday morning there was an executive session of the American Surgical Association, when Dr. Oscar H. Allis, of Philadelphia; Dr. Arpad G. Gerster, of New York, and Dr. Henry W. Bradford, of Boston, were elected Fellows.

(*By Telegraph.*)

THE AMERICAN MEDICAL ASSOCIATION.

Forty-first Annual Meeting, held at Nashville, Tenn., May 20, 21, 22, 23, 1890.

The forty-first annual meeting of the American Medical Association opened its session in the Vendome Theatre at 11 o'clock Tuesday morning.

The number of delegates registered was about 950—a smaller attendance than was expected.

The exhibition of drugs, books, etc, was excellent and well arranged, but the exhibition hall was so distant from the chief centres of interest as to limit its visitors to a smaller number than usual.

The hospitality of the citizens is most marked, more personal invitations being extended than can possibly be accepted, but, notwithstanding, desertions from the meetings are rare.

As might be expected, the hotel accommodations are entirely inadequate, three or four persons being frequently forced to room together, and the service is, naturally, not what it should be.

In the absence of Governor Taylor, Senator T. D. Craighead welcomed the delegates in behalf of the State of Tennessee. He was followed by Mayor McCarven and by Dr. Briggs, the Chairman of the Entertainment Committee.

The President, Dr. E. M. Moore, of Rochester, New York, then delivered his address, dwelling upon the Acts of Congress regarding the subjects of Quarantine, Marine Hospital Service, and Inter-state Quarantine.

The delegates then proceeded to elect the Nominating Committee, Dr. William H. Daly, of Pittsburg, being chosen to represent Pennsylvania.

At 3 o'clock the various sections met in their respective halls, that of Practice of Medicine in the Vendome Theatre, that of Obstetrics and Diseases of Women in separate rooms in the building of the Y. M. C. A.; the other Sections finding accommodation in the various churches and schoolrooms.

Section of Practice of Medicine, Materia Medica, and Physiology.

Dr. J. H. Musser, of Philadelphia, *Chairman.*

The Secretary being absent, Dr. Sawyer moved that Dr. George Dock, of Texas, be elected to fill the vacancy; carried.

The Chairman then called attention to the rules governing the proceedings of the Sections, and delivered his Annual Address, which was of much interest and received great applause. He dwelt upon the effect on the profession of the recent epidemic of influenza, which had so greatly increased the labors of many already overworked men, and had demanded their best judgment and ability. The recent advances made in all branches of medicine were briefly commented upon, and reference made to the increased time and knowledge which modern methods demand of the physician, and which should be recompensed with a proportionate increase of remuneration. The great advantage of trained nurses in the treatment of serious disease was referred to, and the suggestion of the elder Dr. Gross, that training schools for nurses should be established in small towns, was approvingly mentioned. In closing, he urged that a more thorough and exhaustive study of the effect of the older and more familiar drugs should be made, and deprecated the aimless experimentation with the newer remedies that is so characteristic of the day

Dr. de Saussure, of Charleston, S. C., followed with a valuable paper embodying the results of the clinical study of "Twenty-two Cases of Filaria Sanguinis Hominis."[1] In discussion, Dr. Levering, of Ohio, spoke of the similarity between the symptoms described by Dr. de Saussure and those seen by himself in cases of trichinosis. Dr. Kelly, of Baltimore, described cases of the disease which he had seen in the Johns Hopkins Hospital under the care of Dr. Osler. In closing the discussion, Dr. de Saussure stated that he thought all cases found in the Northern States had a Southern origin, and that but two of his patients had been anæmic. As to treatment, the remedies which check the chyluria he found did not affect the filaria.

Dr. C. H. Shepard, of Brooklyn, followed with a paper on "Rheumatism and its Treatment by the Turkish Bath," in which the author attributed much of the good effects of this form of medication to the high temperature, which not only increased sweating but had a powerful effect on the germs circulating in the blood. Drs. Ulrich, Didama, Cronin, and Bailey disagreed with the arguments of the speaker, and questioned the advantages of the form of treatment he advocated over those in general use.

Dr. J. W. Davis, of Tennessee, in answer to a call for volunteer papers, read one on "The Use of Calomel in some Varieties of Dysentery," describing a case of chronic dysentery in which 10 grains of calomel with 2 grains of ipecac effected a cure. This he thought was due to the action of the calomel on the liver. Dr. Dawson said that he thought much of the benefit observed in this case was due to the ipecac, and that one of the most important indications in dysentery was rest. Dr. Ulrich thought that calomel in the case cited would have produced better results if administered *per rectum*. Dr. Woodhull, U. S. Army, mentioned a case in which improvement followed the administration of ipecac in large doses, and Dr. Sloan said that he had obtained admirable results from the injection of a 10-grain silver nitrate solution. Dr. Didama thought that the discussion had wandered from the subject, and with some remarks from the Chairman and Dr. Davis the discussion closed.

The Section adjourned until 2.30 P.M. on Wednesday, leaving several papers unread owing to the absence of the authors.

Section of Obstetrics and Diseases of Women.

Dr. William W. Potter, of Buffalo, *Chairman.*

In his annual address, the Chairman called attention to the advances which have marked the progress of obstetrics and gynecology during the past year. In the former much had been gained through antisepsis and its effects upon the mother, the child, and upon the puerperal state. In gynecology also the advancement has been great and substantial. Vaginal hysterectomy was deemed the best operation for removal of the cancerous uterus when an operation is indicated. The treatment of uterine diseases and ectopic gestation by electricity, though much lauded, has not accomplished all that is claimed for it, since abdominal section has revealed unchanged conditions in cases which were supposed to have been cured. The subject, however, was considered well worthy of further investigation.

Dr. William H. Wathen, of Louisville, read a paper upon "Intraligamentary Cysts," explaining their possible pathological formation and describing their more usual seats. The author advocated enucleation by median abdominal section with complete or partial excision of sac.

Dr. Henry O. Marcy, of Boston, followed with a paper on "The Surgical Treatment of Non-pedunculated Abdominal Tumors," advising removal of as much of the cyst-walls as possible, and suturing the remainder to the abdominal wound, thus closing the general peritoneal cavity. Solid tumors should be treated by ligature or clamp. Complete enucleation has the advantage of

[1] Will shortly appear in The Medical News.

leaving no pedicle at the lower angle of the wound. In forming a stump, Dr. Marcy advised separation of the peritoneum for one or two inches from the cyst-wall with division of the pedicle and inversion of the edges by means of double, continuous, tendon sutures. Freshly cut edges are thus inverted, and held away from all possible infection. Then flush the peritoneal cavity and close without drainage. In three or four hours lymph covers the stump, and healing by first intention takes place. Dr. T. A. Reamy, of Cincinnati, discussed Dr. Wathen's paper and approved of the surgical methods advocated by Dr. Marcy.

DR. F. H. MARTIN, of Chicago, then followed with a paper entitled "A Plea for Early Vaginal Hysterectomy for Cancer," in which he advocated vaginal rather than abdominal hysterectomy, because the entire cervix can then be removed, as is not always possible in the latter operation. Drainage is also more perfect, and the operation is not complicated by an abdominal wound. He stated that the mortality of this operation is now less than 15 per cent.

DR. CHARLES A. L. REED, of Cincinnati, next read a paper upon "Primary and Ultimate Results of Vaginal Hysterectomy for Cancer," in which he reported his clinical observations of a series of eleven operative cases, with one death. In two of these cases cancer recurred. Absence of pain in the early history of the case renders diagnosis difficult, but much better results follow if the operation be not delayed. Uterine hæmorrhage depletes the patient and reduces her nervous system so that she cannot bear well the shock of the operation. In such cases the author uses douches of vinegar and the curette for two or three weeks before operating. The wound is packed, not sutured, and the after-treatment consists in rest, warmth, and hypodermic administration of stimulants. The packing is removed in twenty-four hours, and the vagina is washed out with a mild antiseptic solution.

Dr. Dunning, in discussing the foregoing papers, disagreed with Drs. Reed and Martin, maintaining that the operation was too fatal, and that amputation of the cervix should be substituted. Dr. Reamy quoted Dr. August Martin's statistics and those of Schroeder and Leopold, which show a lower mortality in Europe than in America.

The following papers, on account of the unavoidable absence of the authors, were read by title only: "She Supposed it was Her Change of Life," by Dr. A. Vander Veer, of Albany; "Psychical Results of Gynecological Operations," by Dr. J. S. Stone, of Virginia; "Stricture of the Urethra in Women," by Dr. Ely Van de Warker, of Syracuse; "A New Operation for Relief of Prolapse of Anterior Vaginal Wall," by Dr. A. F. Currier, of New York; "Colocystotomy," by Dr. R. B. Hall, of Cincinnati; "Electrical Treatment of Salpingitis and Allied Conditions," by Dr. G. B. Massey, of Philadelphia.

SECTION OF SURGERY.

DR. B. A. WATSON, of Jersey City, *Chairman*.

The Section of Surgery and Anatomy was opened by an address on "Concussion of the Spinal Cord," by Dr. B. A. Watson, of Jersey City. As a result of special study and elaborate experimentation on this subject, Dr. Watson concluded that in nearly all cases of injury to the spinal cord there would be concomitant grave lesions of other parts of the body; a serious injury to the cord is possible, even though there be no demonstrable lesion of the enclosing bones and ligaments, and finally, that unless there were demonstrable lesions of the cord itself, no sequelæ of grave import should be feared. He further stated that no amount of force applied to the anterior part of the body could possibly affect the cord, and that pathological changes were never produced in this portion of the nervous system by the application of moderate force. The importance of these conclusions from a medico-legal point of view was fully discussed. Dr. W. P. King, of Kansas City, stated that Erichsen had done the profession great harm in advancing his theory of spinal concussion, and that in his experience patients, with an object to gain, when complaining of this form of injury, detailed the classical symptoms of Erichsen with great accuracy. Dr. J. H. Murphy, of St. Paul, and Dr. S. F. Carpenter, of St. Joseph, Mo., agreed in the main with the essayist, Dr. Carpenter stating that though injuries to the column were not rare, those of the cord were most exceptional. In closing the discussion, Dr. Watson expressed his entire scepticism of a condition of concussion of either the brain or the cord without recognizable lesions.

The succeeding paper was that of DR. RICKETTS, of Cincinnati, in which some cases of Rhinoplasty were described. The author advised that flaps should be taken preferably from the cheeks; if not from that portion, the arms should be chosen, and finally, that if neither of these regions could supply the new tissue, they should be taken from the forehead. Silk should always be used to suture the soft parts. Wire is preferable for uniting bone. Where resection of bone is required, the deficiency should be made up by sawing from the superior maxilla rather than having recourse to the forehead or hand. In all doubtful cases, an exploratory excision should be made, and the operator should bear in mind the effect that developing teeth sometimes produce on the bone.

Following this paper, DR. C. L. LEWIS, of New York, warmly advocated the use of continuous silk sutures in enterorrhaphy. The method of Ghely, except that the suture was continuous rather than interrupted, was then demonstrated. Increased strength of the suturing and saving of time are the advantages over the ordinary interrupted Lembert suture. In the discussion which followed, Dr. Shimwell, of Philadelphia, stated that the interrupted suture was safer, and more quickly applied than the continued suture, and that increased strength was not required since the bowels were always paralyzed at the seat of operation. Dr. McCoomis, of Maryland, stated that he had used a suture similar to that described by Dr. Lewis more than twenty-five years ago, when an ignorant midwife tied a portion of the small intestine in a congenital umbilical hernia, while ligating what she supposed to be a thick cord. With an ordinary thumb lancet and a needle and thread, which he happened to have with him, Dr. McCoomis opened the belly, resected the gut, did a circular enterorrhaphy and closed the wound. Some years afterward, this child died from an attack of acute intestinal obstruction. An autopsy showed that death was due to strangulation of the colon by a mesenteric rent. The seat of suture was found somewhat contracted, but not sufficiently to produce the slightest obstruction.

The last paper of the day was read by DR. THOMAS MANLEY, of New York, who reported seven cases of radical operation for hernia performed on children in early infancy. The author expressed the opinion that recommending a truss was a humiliating confession of inability to cope with the disorder, and that in early infancy a truss could rarely be endured, or, if endured, did not efficiently accomplish its object. In discussion, Dr. J. B. Deaver, of Philadelphia, alluded to the fact that a truss in children was not merely palliative, but was often curative; that after all operations a return of the hernia was probable, and that indications for the knife were irreducibility, strangulation, or inability to bear a truss. Of all operations he prefers that advised by Dr. McBurney.

SECTION OF OPHTHALMOLOGY.

DR. S. C. AYRES, of Cincinnati, *Chairman*.

The address of the Chairman called attention to the value of a classified register of the cases encountered in private practice, and advocated the topical use of sublimate solutions.

DR. WM. CHEATHAM discussed the use of jequirity. He preferred it in the form of an impalpable powder, which is more manageable than a solution. Dr. T. E. Murrel, of Little Rock, described a danger in the use of jequirity heretofore unmentioned, viz., the spreading of the inflammation to the lachrymal passages, causing stricture of the duct.

DR. A. R. BAKER, of Cleveland, read a paper on "Functional Nervous Diseases." He found the neurotic tendency to be the real cause of nervous diseases of so-called reflex origin.

DR. GEORGE H. GOODE, of Cincinnati, reported a case of sympathetic inflammation two weeks after enucleation of the injured eye. The case ended in partial recovery.

DR. F. C. HOTZ presented a simple and reliable astigmatometer, based on the apparent shape of a point of light.

The Committee on the Improvement of Census Statistics with regard to Blindness, reported that measures had been adopted by the authorities which, with the aid of the profession, would add much to the value of the returns of this year's census.

SECOND DAY.

The General Session of the American Medical Association met at 10 A. M. The call for the names of the members of the Nominating Committee was made by the Secretary, and the Committee, as completed, was requested to meet in the Watkins Building immediately after the morning session.

The members of the Committee were granted leave of absence during the morning hour. A communication was then read extending an invitation to the Association to hold its next annual meeting at Manitou, Colorado. A discussion touching the workings of the sectional meetings followed, and a resolution was offered to authorize the President to appoint a committee of nine to consider the revision of the working methods of the Association, but the discussion was passed over as not pertinent to the order of business.

DR. N. S. DAVIS, of Chicago, followed with an address on "The Practice of Medicine," the conclusions of which were: If we would reach the highest degree of success in the treatment of acute general diseases, we should keep distinctly in mind the following propositions:

1. As early as practicable the patient should be separated from the further action of both the specific and predisposing causes of his disease by surrounding him with pure air, and as perfect sanitary conditions as possible. As the system uniformly tends either to destroy or eliminate the specific morbific causes by its own metabolic changes, we should carefully avoid the use of such remedies as either directly or indirectly retard or prevent the normal metabolic processes, even for the object of repressing one or more prominent symptoms. On the other hand, we must use such general alterative and antiseptic remedies as are known to sustain and correct such processes, and thereby aid in hastening the destruction or elimination of the disturbing *materies morbi*, whether they consist of living germs, ptomaines or leucomaines, or only excretory matters abnormally retained in the system.

2. As the pyrexia or high temperature results mostly from interference with the processes of heat-dissipation, we must further aid in restoring these processes by gently promoting elimination and the direct abstraction of heat by sponge-baths and, in severe cases, by wrapping in the cold wet sheet. All of these measures exert a restorative influence on the vaso-motor, cardiac, and respiratory nerve-centres. With equal care we must avoid administering such internal antipyretics as diminish heat-production by retarding both blood- and tissue-metabolism, and which also depress nerve sensibility and force.

3. Again, as every specific cause capable of producing the complex assemblage of morbid phenomena that constitutes a general fever has displayed a tendency to induce special local changes in one or more of the important organs during the progress of the general disease, we must early and accurately use remedies that palliate or modify the local developments wherever they may be manifested, and thereby prevent such structural changes as might otherwise end in fatal exhaustion.

4. Finally, as all acute morbid processes, when established, are progressive through the successive stages of increase, culmination, and decline or destruction of the patient, we must carefully adjust our remedial agents and nourishment to the stage of the disease, and to the capacity of the patient to receive and appropriate them. But we must remember that remedies which might be of great value in the first stage, might be injurious or even destructive if used in the stage of culmination, or still more injurious in that of decline. Hence, specific remedies for acute general diseases can be rationally and successfully used only when aimed at the destruction or elimination of the specific causes, and in the first stage of the morbid processes. Indeed, the chief benefits thus far derived from the use of antiseptics and germicides have been as preventives in the incubative and prodromic stages, rather than as curatives after active morbid processes have become manifest.

Dr. Davis said that it required much careful clinical observation, aided by some analytical and experimental work, during the first thirteen years of his professional

life, to gain a clear comprehension of the foregoing general indications for the management of acute diseases, but since then they have served as a general guide during his forty years of constant practice; and with results that have neither diminished his faith in the efficacy of remedial agents nor the confidence of the community in which he had practised. He did not wish to be understood as persistently using the same remedial agents during the last forty years; but that the correct principles or indications for the treatment of the different stages of any given disease have remained, and always will remain, the same. Our choice of individual remedial agents for fulfilling those indications may be influenced by every addition to our knowledge of etiology, materia medica, and therapeutics.

Dr. Brodie, of Detroit, moved a vote of thanks to Dr. Davis for his very able paper, and the motion was carried.

Dr. Patterson, the Treasurer, in the absence of the Chairman, Surgeon A. L. Gihon, U. S. N., read the report of the Rush Monument Committee. He eulogized Dr. Rush, exhorted the profession to take a more active interest in the work of the Committee by a generous response to the call for funds, and suggested Washington as the most fitting site for erecting the monument.

The Treasurer made the following report:

Received from Dr. J. M. Toner, $1195.69. Contributed since Newport meeting, $310. Total, $1505.69.

Disbursements during year, $17.50. Balance on hand, $1488.19.

Dr. Jones, of Washington, moved that both reports be accepted and printed in the *Journal of the American Medical Association*.

The President announced that Dr. Patterson would receive, upon the stage, contributions toward the Rush Monument Fund.

Dr. J. M. Toner, of Washington, submitted the report of the Board of Trustees of the *Journal* of the Association, which he announced was in a flourishing condition and showed a steady growth in circulation.

Dr. Carl Seiler, of Philadelphia, asked to be informed as to who is responsible for publications appearing in the *Journal*. The Chairman informed him that the *Journal* was an irresponsible publication, and that for many reasons it was impossible to give satisfaction to every one. Dr. Seiler then asked why papers read before the Association at their annual meeting do not always gain admission to the *Journal*, and why articles and papers from other sources enjoyed prior publication.

Dr. N. S. Davis answered that he could not speak officially, being no longer a member of the Board, but that he would try to explain. The *Journal* is limited to eighteen pages for original articles, and the remainder is devoted to reports of societies, etc. If a gentleman read a paper of interest at a local society meeting, the paper and the discussion which followed should be published, in order to make the report complete. It is the endeavor of the Board to raise the standard of the *Journal* as high as possible, and to make it of interest to the contributors. Fifteen or twenty pages a week are as many as a busy practitioner cares to read.

Dr. C. E. Comegys, of Cincinnati, moved that the President appoint a committee of one from each State to further the publication of the *Journal* of the Association.

Dr. J. V. Shoemaker, of Philadelphia, said that he hoped that the meeting would not pass a motion that would virtually be an unkind and unjust criticism upon the work of the honored president and members of the Publication Committee. He said that union and harmony meant the success of the *Journal of the American Medical Association*, and begged of the members to uphold their editors.

Dr. J. M. Keller, of Arkansas, moved that the motion be laid upon the table. The motion was carried.

The consideration of several proposed amendments to the constitution then came up. Dr. Keller moved to repeal the amendment to the constitution which was made two years ago, and that the old rule be reëstablished. This amendment took away from the Nominating Committee the right to elect officers of the Sections, and referred it to the Sections themselves.

Dr. Bell, speaking for the Section of State Medicine, opposed this motion.

Dr. Taylor, of Louisville, said that the great difficulty in the past was the fact that gentlemen often went from one Section to another and frequently voted in more than one. He proposed that every one should register in which Section he proposed to vote.

Dr. Moyer, of Illinois, moved that Dr. Keller's motion be laid on the table. Motion lost.

The question of repeal was then put to vote, and carried by 72 to 61.

The President announced that the motion was carried, but upon an appeal from Dr. Edward Jackson, of Philadelphia, calling attention to the fact that it required a three-fourths vote to amend the constitution, the Chair ruled that the motion was lost.

The morning meeting then adjourned.

SECTION OF SURGERY AND ANATOMY.

The opening paper of the second day's proceedings of this Section was by DR. NICHOLAS SENN, of Milwaukee, upon "Two Cases of Resection of the Cæcum for Carcinoma," with general remarks upon ileo-colostomy for pathological conditions involving this portion of the alimentary canal. Two cases were detailed, in each of which the diagnosis of malignant disease was made only after the abdomen had been opened. In both there was a history of chronic obstruction with intercurrent subacute attacks. In one the cæcum, together with the mesenteric and retro-peritoneal glands, was found involved. Not only the cæcum, but eighteen inches of small intestine were resected. The two ends of the divided gut were then invaginated each within itself, and were occluded by a continuous Lembert suture. Then the continuity of the intestinal canal was restored by means of lateral apposition secured by two moist, decalcified bone-plates. The peritoneal surfaces to be apposed were scarified by means of needle scratches; the threads attached to the plates were tied each to its fellow of the opposite side, and the operation completed by Lembert sutures applied about the periphery of the plates. The patient left the hospital in three weeks entirely well, and has had no recurrence since.

The second case was diagnosed as cancer of the pylorus. A median operation showed that the cæcum was involved, and that, in addition to cancerous degeneration, there was an ileo-cæcal invagination, which was reduced after the application of considerable force.

The cancer was discovered only after reducing the invagination. The whole involved region was resected, and the continuity of the bowel was restored as in the first case. Peritonitis developed on the third day, and was quickly fatal.

Autopsy showed that the parts were firmly united, and that peritonitis was due to a small ulcer a short distance from the anastomosis. The ulcer had infected the peritoneum. The rings were gone, but the threads still remained at the seat of anastomosis. The union was firm and complete.

Dr. Senn stated that it was a mistake to suppose that a great many sutures were needed to prevent the escape of gas and fæces in such operations. Broad peritoneal surfaces held in apposition for a short time, especially if inflammation and organization were hastened by previous irritation of these surfaces, provided the best protection against infection of the general peritoneal cavity. As a result of experimental work and of his clinical experience, Dr. Senn arrived at the following conclusions:

1. Resection of the cæcum for carcinoma can be done with a fair prospect of permanent cure if the operation is performed before infiltration of the mesenteric or post-peritoneal gland takes place.

2. Ileo-colostomy, with moist decalcified aseptic bone-plates, affords the best method of restoring the continuity of the intestinal tract after excision of the cæcum.

3. Hygroscopic or unabsorbable materials should not be used in the preparation of approximation plates or rings, since the former may cause pressure-gangrene, and the latter may prove a source of danger by remaining as foreign bodies.

4. Ileo-colostomy, without resection of the cæcum, may be performed in cases of obstruction from inoperable carcinoma of the cæcum, irreducible invagination without perforation or evidence of gangrene, and in cicatricial stenosis in the ileo-cæcal region which is not amenable to plastic operation.

5. Scarification of the serous surfaces interposed between the bone plates is the most reliable means of hastening the formation of adhesion and of shortening the process of healing.

6. Resection of the cæcum and ileo-colostomy with or without enterectomy should be performed through an incision extending from the middle of Poupart's ligament to a line drawn from the anterior superior spinous process of the ilium to the umbilicus.

7. Suturing serous surfaces just beyond the margins of the bone-plates renders material service in maintaining apposition between serous surfaces which it is intended to unite, and furnishes additional safeguards against fæcal extravasation.

8. Anchoring the approximated parts in the cæcal region with a mesenteric peritoneal suture should be done in ileo-colostomy after resection of the cæcum.

Before the reading of the next paper, DR. W. T. BRIGGS, of Nashville, asked permission to exhibit a case of persistent erection of the penis, in the hope that some suggestions as to treatment might be elicited. The patient was a lusty young man, and the father of several children. Without known cause he awakened one morning, about a year ago, with an erection which has persisted until now. Absolutely no other nervous symptoms could be elicited. It was suggested that the condition might depend upon clots in the corpora cavernosa, which could be removed by an incision.

DR. HOWARD KELLY, of Baltimore, then described his method of hystero-myomectomy with suspension of the stump in the lower angle of the wound. This method was applicable, he said, where a pedicle could be formed below the tumor. A long incision was made in the linea alba, and the tumor delivered; then, when the pedicle was brought to view, or was formed by enucleation, the rubber ligature was applied, and the masses were removed, leaving one or two inches of pedicle. The neck was divided in a wedge-shaped manner, and the cervical canal dissected out. The raw surfaces were now brought into close apposition by buried catgut sutures, and the peritoneal surfaces by interrupted silk sutures placed deeply enough to include a certain amount of muscular tissue. The ends of the latter sutures were not cut off. All sutures, both deep and superficial, should be drawn tight, and should include all visible bloodvessels. After complete union of all the parts, the rubber ligature was removed, and the edges of the wound inspected. If hæmorrhage appeared, the uterine artery of the corresponding side was ligated by passing a thread around it by a curved needle. Both uterine arteries could be ligatured, if necessary. In performing this ligation the stump was readily managed by means of the long ends of the surface sutures. The drainage-tube was placed well above the stump, and the peritoneum of the latter was united with that of the parietes, suspending the stump from the lower angle of the wound. A gauze dressing was then packed in the superficial wound and around the long silk sutures. The wound rapidly closed by granulations, the silk sutures coming away in about ten days. The advantages of this method are that hæmorrhage is at once detected, the danger of sepsis is, to a great extent, avoided, and only very moderate traction is made on the stump.

In discussion Dr. A. E. Hoadley, of Chicago, was opposed to the use of catgut, since it was not always aseptic. Dr. Martin, of Chicago, described an operation similar to Dr. Kelly's, but differing from it in the fact that the sutured stump was turned into the vagina, forceps being applied which could be immediately tightened in case of hæmorrhage. Dr. Kelly, in reply, stated that catgut was used in the deep sutures because, since suppuration takes place, stitch abscesses would be formed which might greatly prolong convalescence. The large pedicle of many cases of myoma would make the operation of turning into the vagina very difficult.

The next paper read was that of DR. J. B. DEAVER[1] upon the value of the incandescent-lamp urethroscope, in the diagnosis of chronic urethral discharges. The essayist described the mechanism of the instrument, and the appearances presented by the healthy urethral mucous membrane. The evenness with which the urethral walls contract, on withdrawing the instrument, was an important point in making an examination. Certain cases of gleet were quite independent of the existence of stricture, and their nature could be determined only by urethroscopic examination, and by no other instrument could applications for their relief be properly made. A careful classification of the pathological conditions commonly found in the urethra was given, and a number of

[1] Will appear shortly in THE MEDICAL NEWS.

cases were cited showing the signal value of this instrument in the diagnosis and treatment of obscure and obstinate cases of urethritis.

Dr. B. A. Watson, stated that the instrument was one which required so much skill in its use that there was little chance of its general adoption by the profession.

DR. ROBERT MORRIS, of New York, then read an essay upon the "Value of Peroxide of Hydrogen in Suppuration." He stated that the suppurative process was at once stopped by a thorough application of the drug, and that the parts immediately became sterile. Abscesses became aseptic cavities, and the septic walls of sinuses were sterilized by one application. While bichloride of mercury was a valuable antiseptic when suppuration was fairly established, its power was exceedingly slight compared with that of the drug under discussion. It should be followed by balsam of Peru to encourage granulation.

The final paper of the day was read by DR. EDWARD MARTIN, of Philadelphia, on "Fractures in Children." The results of a careful study of over one thousand cases were detailed, the author stating that the most frequent seats of fractures in children were the radius, humerus, clavicle, and, finally, the femur. The rarity of true epiphyseal fracture was alluded to, the injury being frequently situated near but not at the epiphyseal line. "Green-stick" fracture was also discussed, the statement being made that this was nearly always a true break of the bone fibres, and not simply a bend. The treatment of the most common fractures was considered, and the most satisfactory methods of dressing were described. The essayist was unable to find any report of fracture of the patella in children, and but three instances of fracture of the ribs.

Dr. E. M. Moore, of Rochester, stated that he believed epiphyseal fractures involving the upper extremity of the humerus were more common than was generally supposed, these cases being mistaken for sub-luxations. He described his method of diagnosing and treating the injury.

SECTION OF PRACTICE OF MEDICINE, MATERIA MEDICA, AND PHYSIOLOGY.

The proceedings were opened by a paper of DR. GEORGE FACKLER, of Cincinnati, Ohio, on "Calomel as a Diuretic." After a brief *résumé* of the literature of the subject, Dr. Fackler discussed the various views held as to the mode of action of calomel as a diuretic, and gave the history of some cases to whom it was administered. From observations on these cases he drew the following conclusions: 1. Calomel, and all other mercurial drugs, are diuretic in certain doses and under certain conditions. 2. If given in proper doses, the effect is seen in from two to ten days. 3. The action is most marked in dropsy from disease of the heart, is not apparent in that of hepatic origin, and is uncertain in pathological changes of the kidney. 4. Small doses should not be used. 5. The diuretic action is, in all probability, due to the irritating effect of the mercury on the renal epithelium.

Dr. Olrich corroborated the speaker in regard to the diuretic action of calomel. Dr. Caldwell, of Florida, said he had used bichloride of mercury with muriate of ammonium, and claimed that the combination was more certain than calomel, and less liable to salivate. Dr. de Saussure said he had used bichloride with good results, and also calomel with success, but in larger doses than Dr. Fackler. Dr. Fackler, in closing the discussion, said calomel was, on the whole, better borne by the stomach, and less liable to cause salivation than bichloride.

The discussion on the continued fevers of the South, as announced, was opened by a paper prepared by DR. W. W. JOHNSTON, of Washington, D. C., read by the Secretary. The following conclusions were arrived at: 1. Enteric fever is a rare disease in the South in a typical or intense form. 2. There is probably a change going on in the type of enteric fever—it is losing its typical character and assuming a milder form. 3. Many cases of mild continued fever, which have no well-defined or characteristic symptoms, are cases of mild enteric fever. 4. While malarial continued fevers are found in the South, many so-called cases of "adynamic malarial fever," "remittent fever," etc., are in reality cases of enteric fever. 5. There are no reasons for believing that there is such a disease as typho-malarial fever.

Dr. J. P. Wall, of Tampa, Fla., said he had come to the conclusion through clinical study and post-mortem examination, that the continued fevers in question were all cases of typhoid fever. He did not accept the germ theory of the origin of typhoid fever. Drs. T. J. Happel and J. C. Shephard, of Tennessee, spoke of the continued fevers of that State.

Dr. George Dock, of Texas, said that, while his views coincided on the whole with those of Dr. Johnston, it seemed, in the light of Kinyoun's researches, that we must accept the existence of a combined infection, resulting in the typho-malarial fever of Woodward. He thought it would be well to consider the fevers called catarrhal or inflammatory in some parts of the South, in which malaria seemed not to play a part. In his experience, such cases, on post-mortem examination, showed the lesions of enteric fever.

Dr. Sears, of Texas, said that he had had much experience with continued malarial fever, which often runs into the typhoid state. In his practice all patients who were given quinine recovered though the fever was not reduced. He gave quinine to the amount of two ounces during the course of the disease. Dr. J. H. Vaneman, of Missouri, said that all the fatal cases of unclassified fevers in his practice had been found enteric at the autopsies. He believed that two ounces of quinine were sufficient to kill.

Two papers on typhoid fever followed, one by DR. J. H. VANEMAN, of Kansas City, on "Specific Treatment of Typhoid Fever," the other by DR. HAPPEL, of Tennessee, on the question, "Has Progress been made in the Treatment of Typhoid Fever?"

Dr. H. A. HARE, of Philadelphia, read a paper on the "Treatment of Insomnia and Neuralgia by Butyl-chloral Hydrate."[1]

Dr. Crawford, of Illinois, presented a patient with obscure symptoms and asked for a diagnosis. The Chairman recommended that the secretary appoint a committee to examine the subject and report. A paper by Dr. J. P SAWYER, of Cleveland, followed on "Auto-intoxication from Nitrogenous Elements of Food when taken in Excess."

[1] To appear in THE MEDICAL NEWS.

On the recommendation of the Chairman a motion was made and carried, that a committee be appointed to investigate the fevers of the South and report next year.

Section of Obstetrics and Diseases of Women.

The session was opened by a paper of Dr. E. Van de Warker, of Syracuse, N. Y., on "Stricture of the Urethra in Women." Dr. Van de Warker criticises the statement of Dr. Fordyce Barker that the lesion rarely occurs. Dr. A. J. C. Skene differs and believes that stricture near the meatus is frequent and is due to caustic applications for other urethral troubles. Our knowledge of this lesion is slight and we know no more of stricture in the female than was understood of stricture in the male a generation ago. The sound only determines the existence and does not locate the disease accurately. Dr. Van de Warker concluded that a No. 14 or 17 sound will easily pass the female urethra, and that we do not find the small tight strictures in women that are common in men. Retention, incontinence, dysuria are more common in woman than man. Stricture near the meatus may be forcibly dilated by the operator's finger and the stricture may easily be felt and the bladder itself explored. A large stricture causing very painful urination may be cured by digital stretching when a sound will not detect it. The lumen of the female urethra is greatest half-way between the meatus and the bladder. The treatment is painful and cocaine should always be used. The author has seen but few cases of absolute retention, and prefers to call the condition "retarded flow." Another condition met with is extroversion of the lining membrane just within the meatus, which the author considers a form of annular stricture. It appears as a red mass of mucous membrane just without the meatus.

In discussing Dr. Van de Warker's paper, Dr. Currier, of New York, did not agree with the author in his opinion as to the frequency of strictures in women. He detailed cases in his own practice due to toxic causes—one of them to an over-dose of cantharides. He also thought that stricture in the male is not as common as is usually supposed.

Dr. Engelmann, of St. Louis, said that he had not observed strictures in females frequently, possibly because he has not usually searched for them. He asked if they were usually inflammatory. He himself treats strictures by electricity, using a weak sedative current and a non-metallic electrode. He thinks such a current is of more use than dilatation or cutting.

Dr. Reed, of Ohio, stated that he had but limited experience in treating stricture. He uses a self-retaining catheter kept in place during the night. He has seen in one case severe peritonitis follow dilatation.

Dr. Van de Warker, in closing said, in answer to Dr. Engelmann, that the sound assists in causing absorption of the constriction, the self-retaining catheter advocated by Dr. Reed acting in the same manner. He locates the stricture by the olive-point bougie.

A paper of Dr. A. F. Currier, of New York, upon "A New Operation for the Relief of Prolapse of the Anterior Vaginal Wall" followed, in which the author stated that the causes of the condition may be labor alone, straining at stool, or many labors coming in rapid succession. To cure the condition the vaginal wall must be shortened antero-posteriorly, as well as laterally. The old operations of Sims and Emmet were considered by the author as faulty. His own operation overcomes the defect of the others by making tension in two lines at right angles to each other, cutting out two elliptical-shaped pieces of tissue in the anterior vaginal wall, with their axes transverse. Continuous catgut sutures are used. The result is a right-angled wound. During the operation the bladder must be carefully avoided. Venous hæmorrhage is usually considerable. Iodoform-collodion may be applied, or dressings may be entirely omitted. Primary union is the rule. The author's diagrams were well executed, and clearly demonstrated the various steps in his method. Dr. Van de Warker stated that hitherto no one operation has fulfilled the condition required to effect a cure. The muscular coat atrophies and thus increases the symptoms, and diminution of the sacral curve is often an additional factor. Dr. Currier's operation is the best he has seen. Dr. T. A. Reamy does an operation very similar to Dr. Currier's, only that he removes a little more tissue. Nor does it matter if he opens the bladder, as healing is prompt.

Dr. Johnson, of Danville, Ky., did not think the trouble is in the anterior wall but that the perineum is at fault, and cure of the latter is followed by cure of the former. Dr. Hoffman, of Philadelphia, thought that while opening the bladder is not feared by Dr. Reamy, yet fistulæ may result. Why not, if such an accident happen, excise a part of the bladder? Dr. Engelmann has had an unsatisfactory experience in such troubles, but he did not think his method is at fault. The theory proposed is wrong. Both walls must be denuded and at the proper place. Dr. Kerr, of Tennessee, asked what the position of the uterus was in such cases. Dr. Currier, in closing, said that the tension in his operation is more evenly distributed than in that of Dr. Reamy. He does not claim that it is invariably successful, for any operation will sometimes fail.

Dr. E. W. Mitchell, of Cincinnati, read a report of two cases of "Hyperemesis Gravidarum," which was a clinical history. The usual treatment was adopted, and an ice-bag gave more relief than the other measures. Morphine was given in increasing doses.

A telegram was read announcing the death of Dr. W. H. Byford, of Chicago.

On motion, the Chair appointed the following committee to draft suitable resolutions: Drs. F. H. Martin, T. A. Reamy, and Meacham. Drs. Clarke, of Massachusetts and Jaggard, of Chicago, being absent, their papers upon "Placenta Prævia" were read by title only.

Dr. L. N. Dunning, of Indiana, then read a paper on "Uterus Bilocularis." In this condition the uterine sound reveals the presence of two chambers, and determines whether they are complete or not. Dr. Dunning then reported a case complicating pregnancy which he saw last year. Digital examination revealed nothing at first, but later a second placenta being delivered, the septum could be easily felt. This case, thirteen years previously, had been delivered at term, and when seen by the author was aborting. The death-rate in puerperal women with a double-chambered uterus is $26\frac{3}{16}$ per cent. In some cases when pregnancy occurs in one chamber menstruation goes on in the other.

Dr. T. B. Greenly, of Kentucky, then read a paper upon "Antisepsis in Obstetrics." The author advocates

uterine douches of carbolic acid solution with external washes of bichloride of mercury during parturition and after it, until the lochia cease. Dr. Currier discussed this paper, maintaining that asepsis was the main thing to be desired. Dr. Hoffman believes that clean obstetrics gives us the lowest mortality, and antiseptics cannot aid if the operator himself be not clean. True antisepsis is only cleanliness. Dr. G. E. Shoemaker, of Philadelphia, advocated cleanliness, and detailed the trouble of obtaining strict cleanliness without an antiseptic agent. He does not believe that it can be secured without some chemical agent.

DR. MEACHAM, of Wisconsin, read a paper upon "The Great Utility of Bleeding in Puerperal Convulsions," detailing a series of fifteen cases so treated, all recovering.

The Committee on Nominations reported the following officers for the ensuing year:

President, Dr. Charles A. Reed, of Cincinnati.

Secretary, Dr. Howard A. Kelly, of Baltimore.

These were elected.

SECTION OF OPHTHALMOLOGY.

Dr. L. Conner, of Detroit, was chosen President, and Dr. T. E. Murrell, of Little Rock, Secretary, for the coming year. DR. G. E. DE SCHWEINITZ, of Philadelphia, reported a clinical study of a series of cases exhibiting slight macular and perimacular changes. In some cases the lesion accompanied eye-strain, in others, a slight transient albuminuria. Vision remained normal throughout.

DR. MURRELL read a paper entitled "Some Observations on the Correction of Low Degrees of Astigmatism," urging the correction of the lowest degrees when they seemed to cause eye-strain.

DR. J. MORRISON RAY, of Louisville, reported a case of transplantation without a pedicle for cicatricial ectropion by Wolf's method. The flap in this case was three by one and three-quarters inches. It subsequently contracted to one-third of this size.

DR. EDWARD JACKSON, of Philadelphia, discussed "Tests of Visual Acuteness and the Standard of Normal Vision." He claimed that the present standard is too low if the test be made with a good light, and he exhibited a more accurate and satisfactory test.

DR. ROBERT TILLEY, of Chicago, reported a case of left lateral homonymous hemianopsia associated with a wound of the occipito-parietal region of the right side of the head. No other cerebral symptoms were present, and the hemianopsia was absolute. Dr. Tilley also exhibited an instrument for the measurement of the radii of curvature of lenses.

DR. C. R. HOLMES, of Cincinnati, reported a case of hæmorrhage after cataract extraction. A similar cataract had been extracted from the other eye two weeks before without accident. Dr. Holmes advocated boric acid and massage in pannus. Improvement was speedily effected when this was added to the ordinary treatment.

SECTION OF DISEASES OF CHILDREN.

Meeting called to order at 3 P. M. by Dr. I. N. Love, of St. Louis. Dr. McThom, of Cincinnati, extended an invitation from the Laryngological Section to the members of this Section, to be present on the following afternoon, and to take part in a discussion on diphtheria, which would then come up. Dr. H. A. Hare, of Philadelphia, moved that the kind invitation be accepted with thanks. (Carried.) The first paper was entitled "The Value of Sulphonal in Children's Diseases," by DR. W. C. WILE, of Danbury, Conn. The practitioner is often at his wits' end to produce rest and quiet sleep, and to control delirium in small children. Opium and bromides are often dangerous, and their use has not given satisfactory results. Sulphonal does not produce bad effects, and can be used with safety. The following case was cited:

A child, aged one and one-half years, was seen while in severe convulsions. Dr. Wile ordered six ten-grain sulphonal powders, and directed that one should be immediately given, to be followed by another in half an hour; following the second dose there was marked diminution in the severity of the attack. The father repeated the dose in one hour. At the end of three hours, as the child was still somewhat restless, another powder was given, and so on throughout the night. In the morning the father came to Dr. Wile and asked for more of the powders. Dr. Wile had not intended that the child should receive more than two or three powders, and was alarmed when he learned that all had been taken. On visiting the case he found the patient in a gentle but profound slumber, which continued for many hours. Upon waking, the patient was free from convulsions, and had no recurrence. We thus see that large doses of sulphonal can, in some instances, safely be given to children.

The next paper was upon "The Value of Atropine in Enuresis," by DR. R. B. JAMES, of New York, which was read by Dr. Cummins in the absence of the author. In 1888, a paper was published bringing to the notice of the profession the value of atropine in the nocturnal enuresis of children, and at the meeting at Newport, in 1889, Dr. W. P. Watson reported a number of cases. Many have resorted to its use, however, without the expected result. The writer has seen many cases lately, and has adopted the following line of treatment: A solution is used of which each teaspoonful represents $\frac{1}{100}$ of a grain. Of this he gives one teaspoonful at 6 P. M., and repeats at 9 P. M. This amount is to be increased until the controlling dose is found, which is usually about six or eight teaspoonfuls. None were benefited with less than two doses. This treatment must be kept up often for months, and then gradually diminished; increasing again should relapse occur. Patients often continued well for a few months after stopping treatment, but almost invariably relapsed.

The author then reported a list of fifteen cases detailing the age, sex, controlling dose, relapse, and result of treatment. In one case only did symptoms of poisoning occur, and these were not alarming. Every case but one was controlled so long as treatment was kept up. Of the fifteen cases, two mild ones were cured, two were benefited, and ten showed no improvement after the drug was stopped. Small doses did not serve to keep up the effect of the controlling dose. In conclusion the writer thinks we have a valuable remedy in atropine to control the evil until the patient outgrows the unfortunate condition. After the age of twelve years atropine seems to have no effect.

In discussion, Dr. Watson stated that last year, before this Section, he reported thirty unselected cases. Twenty-seven were cured. Two relapsed, but when put on atropine again were cured. The results were remarkable, but more remarkable still is the fact that he has not had the same success since. He confessed that he was unable to explain this. His usual method was to administer a solution containing one grain to an ounce of water, of which as many drops were given at a dose as the child numbered years. In one case the urethra was found very sensitive, and, in addition to the atropine, a No. 2 bougie was used. This was gradually increased to a No. 8 every second day, and was followed by relief; when asked whether this result was due to the atropine or to the bougie, the doctor said he thought it was due to both.

Dr. H. A. Hare said that it was not just to attribute to Dr. Watson the first use of atropine in enuresis, as Dr. Watson had not made such a sweeping claim at any time. We cannot say that atropine is the drug to be used in every case, for many instances are due to causes which cannot be controlled by the drug. Again, atropine has the effect of concentrating the urine, thereby increasing the tendency to incontinence. It would be more rational, therefore, to lessen the concentration of the urine by citrate of potassium or other alkaline diuretics and then begin the use of atropine.

Dr. D. H. Boyde, of Indiana, related his experiences with the assayed fluid extract of belladonna. It relieved almost every case, but they usually relapsed, and he was disposed to think that when relapse did not occur the patient had outgrown the habit. Dr. I. N. Love stated that he had tried the remedy and was favorably impressed by it, but recognized that it could not be used indiscriminately.

The third paper was on "Milk-sugar in Infant-feeding," by Dr. E. T. Brush. Not long ago, in using Meigs's mixture, he found that the addition of the milk-sugar caused a peculiar change in the color of the mixture. What was in the sugar he did not know, and, unfortunately, a second sample could not be procured. This led him to investigate the subject of sugar in infant feeding. It has been stated and usually believed that sugar of milk is the most harmless substance which can be introduced into the economy. The sugar of milk of commerce is eliminated by most of the excretory organs, whereas the same substance in its natural condition is not so eliminated. He believed that cane-sugar is better as an addition to infant food.

The fourth paper was on "Acute Rheumatism in Children," by Dr. F. T. Marston, of Boston. The statement that acute rheumatism in children is a rare disease is not well founded. They are subjected to much the same causes as adults, but the disease often presents a different clinical picture. The sero-fibrous structures are often the first affected, and not the joints as in adults. The sheaths of the muscles are sometimes first attacked, as in the case of a boy who had recently come under the writer's notice where the first manifestation was in the calf of each leg. In two days the disease had invaded the general system; endocarditis and pericarditis rapidly ensued and death followed.

Endo- and peri-carditis are often noticed in children before any other manifestation of rheumatism. The temperature does not often rise beyond 102° or 103°, and the fever lasts but a few days. Sweating is not marked, but heart complications occur more often in children than in adults. Pleurisy may be secondary to the pericarditis, but when it occurs alone it must be considered as a direct result of rheumatism. Peritonitis and meningitis are sometimes noticed as sequelæ, and tonsillitis follows in twenty-four per cent. of all cases.

Bronchitis, chorea, and erythema are rare. Anæmia is well marked in most cases in which the heart is involved, and in children we sometimes see the development of fibrous nodules. Regarding treatment, salicylic acid may be called the sheet-anchor, the salicylate of sodium being its most effective compound. Salicin is preferred by some, but it is often necessary to give it in larger doses than the stomach will tolerate.

It is often advisable to add an alkali during the administration of salicylates. The treatment of the various symptoms was then taken up and ably considered. The next paper—"Feeding the Young," by Dr. Phelps, of California—was read by Dr. Cutler, of Boston. This paper dealt with the common mistakes made by parents in feeding their infants. The discussion which followed bore for the most part on the importance of obtaining in some way a pure milk supply for our large cities. The question of the methods of sterilizing milk also received due attention.

Third Day—General Session.

William T. Briggs, M.D., of Nashville, was elected President for the ensuing year, Wm. B. Atkinson, M.D., Secretary, and Richard J. Dunglison, M.D., Treasurer.

Washington was chosen as the city in which the meeting of 1891 would be held.

(*By Telegraph.*)

THE MEETING OF THE ASSOCIATION OF MEDICAL EDITORS.

On Monday evening, May 19th, the meeting of the Association of Medical Editors was called to order at 9 o'clock at Nashville, Tenn.

The President, Dr. I. N. Love, of St. Louis, took the chair. After making his annual address, he appointed the following Committee on Credentials and Nominations for Membership: Dr. W. C. Wile, of Connecticut; Dr. J. D. Fulton, of Kansas; and Dr. J. V. Shoemaker, of Pennsylvania.

A paper upon the "Relations of Medical Editors to the Profession at Large," by Dr. F. L. Sim, of Memphis, was read.

An interesting paper upon the "Progress of Medical Literature" was read by Dr. T. D. Crothers, and ably discussed by Dr. N. S. Davis, of Chicago, the founder of the Association.

The Nominating Committee then reported the following officers for the ensuing year: For President, Dr. F. L. Sim; for Vice-President, Dr. Frank Woodbury; for Secretary and Treasurer, Dr. J. C. Culbertson; who were unanimously elected.

The Association then adjourned to partake of the annual banquet.

The following gentlemen were elected to membership: Drs. A. K. Hills, Ferdinand King, B. W. Palmer, G. F.

Lydston, B. Lewis, J. F. Dickman, R. Aickman, R. W. C. Hill, W. C. Shenck, J. E. Minning, J. H. Thompson, W. H. Daly, C. S. Briggs, A. S. Morrison, and H. C. Wyman.

NEWS ITEMS.

Crusade Against Quacks in Italy.—The Italian governmental department having supervision over medical matters has inaugurated vigorous measures for the prevention of irregular practice throughout the kingdom. The Minister of the Interior, as he might be called, has recently sent out instructions to all prefects calling upon them to furnish at the beginning of every month a list of all the cases in their respective districts upon whom unauthorized persons have attempted to practise.

The Yale Home Hospital.—It is proposed by Dr. Seaver, of New Haven, to erect a students' hospital at Yale College. The annual attendance of students has now increased to such proportions that there are always more or less sick ones who need better attention than it is possible for them to obtain in their own rooms. The college physician estimates that the initial running expenses can be met by a fund which will yield $700 or $800 per annum in addition to such moderate charges as can be paid by the invalid students who are brought to the hospital.

Fees of Medical Witnesses.—The fee allowed in Great Britain to medical witnesses in courts of law is one guinea for every day's attendance at trials in the Supreme and County Courts, with travelling expenses. In the lower or police magistrate courts the fee is half a guinea.

Corrigendum.

THE MODERN TREATMENT OF VESICAL CALCULUS IN MALE CHILDREN.

The paper of Dr. J. William White, which appeared in the last issue of THE MEDICAL NEWS, was incorrectly stated in a footnote to have been read before the American Surgical Association.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MAY 13 TO MAY 19, 1890.

WOOD, LEONARD, *First Lieutenant and Assistant Surgeon.*—Having completed at New York City the duties assigned to him in S. O. 29, April 30th, Division of the Pacific, will return to his station in that Division. Is granted leave of absence for one month.—Pars. 19 and 10, *S. O. 115, A. G. O.*, May 16, 1890.

By direction of the Secretary of War, LEONARD Y. LORING, *Major and Surgeon*, now on sick-leave of absence until further orders, is relieved from duty in the Department of Arizona.—Par. 14, *S. O. 115, A. G. O.*, May 16, 1890.

By direction of the Secretary of War, WILLIAM H. FORWOOD, *Major and Surgeon*, is relieved from duty at Fort Snelling, Minnesota, and will report in person on the 27th inst to the Governor of the Soldiers' Home, District of Columbia, for duty as Attending Surgeon at the Home.—Par. 11, *S. O. 113, A. G. O., Washington, D. C.*, May 14, 1890.

By direction of the Secretary of War, HENRY M. CRONKHITE, *Major and Surgeon*, is relieved from station at Little Rock Barracks, Arkansas, and assigned to duty at Fort Lewis, Colorado, at which post he is now on temporary duty.—Par. 10, *S. O. 113, A. G. O., Washington, D. C.*, May 14, 1890.

By direction of the Secretary of War, CHARLES F. MASON, *First Lieutenant and Assistant Surgeon*, now on leave of absence, will report in person to the commanding officer of Fort Logan, Colorado, for temporary duty at that station.—Par. 7, *S. O. 113, A. G. O., Washington, D. C.*, May 14, 1890.

By direction of the President, the Army Retiring Board convened at Fort Leavenworth, Kansas, by War Department Order dated May 10, 1887, published in Special Order No. 107, May 10, 887, from Headquarters of the Army, is dissolved, and War Department Order dated April 26, 1890, published in Special Order No. 99, April 28, 1890, from Headquarters of the Army, directing John de B. W. Gardiner, Captain and Assistant Surgeon, to report to the President of the Board for examination, is revoked.—Par. 10, *S. O. 111, A. G. O., Washington, D. C.*, May 12, 1890.

By direction of the Secretary of War, CHARLES B. EWING, *Captain and Assistant Surgeon*, is relieved from duty at Washington Barracks, District of Columbia, and will report in person to the commanding general Department of the Missouri, St. Louis, Missouri, as Attending Surgeon at those headquarters.—Par. 8, *S. O. 110, A. G. O., Washington, D. C.*, May 10, 1890.

By direction of the Secretary of War, leave of absence from June 1st, to include October 10, 1890, is granted ANDREW V. CHERBONNIER, *Captain and Medical Storekeeper.*—Par. 4, *S. O. 110, A. G. O., Washington, D. C.*, May 10, 1890.

By direction of the Secretary of War, leave of absence for four months, with permission to go beyond the sea, to take effect on or about June 1, 1890, is granted CHARLES C. BYRNE, *Lieutenant-Colonel and Surgeon.*—Par. 3, *S. O. 110, A. G. O., Washington, D. C.*, May 10, 1890.

By direction of the President, and in accordance with Section 1246, Revised Statutes, an Army Retiring Board is appointed to meet at the War Department in this city, at 11 o'clock A.M., on Wednesday, May 14, 1890, for the examination of such officers as may be ordered before it. Detail for the Board: ANTHONY HEGER, *Lieutenant-Colonel and Surgeon;* CHARLES R. GREENLEAF, *Major and Surgeon.*—Par. 6, *S. O. 110, A. G. O., Washington, D. C.*, May 10, 1890.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING MAY 17, 1890.

MACKIE, B. S., *Surgeon.*—Ordered to the Practice-ship "Constellation," May 15th.

LOWNDES, C. H. T., *Assistant Surgeon.*—Ordered to the Practice-ship "Constellation," May 15th.

FITZSIMONS, PAUL, *Surgeon.*—Detached from the U. S. S. "Marion," and ordered home.

MARTIN, H. M., *Surgeon.*—Granted six months' leave of absence, with permission to leave the United States.

HORWITZ, P. J., *Medical Director.*—Granted nine months' leave of absence, to leave the United States

WENTWORTH, A. R., *Passed Assistant Surgeon.*—Resignation accepted, to take effect November 14, 1890.

HERNDON, C. G., *Passed Assistant Surgeon.*—Detached from the U. S. S. "Enterprise," and wait orders.

GIHON, A. L., *Medical Director.*—Appointed Delegate to represent the Medical Department of the Navy at the International Medical College, Berlin, Germany, August 4, 1890.

KINDLEBERGER, DAVID, *Medical Director.*—Appointed Delegate to represent the Medical Department of the Navy at the International Medical College, Berlin, Germany, August 4, 1890.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FROM APRIL 21 TO MAY 10, 1890.

HUTTON, W. H. H., *Surgeon.*—Detailed as Chairman of the Board for Physical Examination of Officers of Revenue-Marine Service, April 23, 1890. Detailed as Chairman of the Board for Physical Examination of Cadets, Revenue-Marine Service, May 9, 1890.

PURVIANCE, GEORGE, *Surgeon.*—Detailed as Recorder of the Board for Physical Examination of Officers of the Revenue-Marine Service, April 23, 1890.

BROOKS, S. D., *Passed Assistant Surgeon.*—When relieved at Savannah, Ga., to proceed to Cleveland, Ohio, and assume command of the Service, May 1, 1890.

CARRINGTON, P. M., *Passed Assistant Surgeon*—As soon as physically able, to proceed to Savannah, Ga., and assume command of the Service, May 1. 1890. Leave of absence extended twenty days on account of sickness, May 3, 1890.

MAGRUDER, G. M., *Assistant Surgeon.*—Detailed as Recorder of the Board for Physical Examination of Cadets, Revenue-Marine Service, May 9, 1890.

KINYOUN, J. J., *Assistant Surgeon.*—To proceed to Wilmington, Del., on special duty, May 6, 1890.

CONDICT, A. W., *Assistant Surgeon.*—Granted leave of absence for eight days, April 12 and 22, 1890.

ANTISEPSIS IN MIDWIFERY.[1]

BY WILLIAM T. LUSK, M.D.,

PROFESSOR OF OBSTETRICS AND DISEASES OF WOMEN AND CHILDREN IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE, NEW YORK.

ON a former occasion I found from an examination of the records of the Health Department of New York City that the reported number of deaths from puerperal sepsis, between the years 1867 and 1875, in New York City, was 1947, or an annual average of 215.5. In the appended table, prepared for me from the same sources by my friend Dr. Rutson Maury, it will be seen that for the five years from 1885 to 1889, inclusive, the deaths from puerperal sepsis reported were 1105, or an annual average of 221. The population of New York in 1870 was 942,292; in 1875, 1,169,305; in 1885, 1,553,730; in 1890, 1,755,292. It will be seen, therefore, that the ratio of deaths has by no means kept pace with the increase of the city's population.

A portion of this betterment is doubtless attributable to reforms in the management of our lying-in hospitals. Whereas, formerly these institutions furnished nearly one-sixth of the fatal cases of puerperal sepsis, they now, when properly equipped and organized, afford the safest places of refuge for parturient women. There has likewise been, without doubt, an improvement in results among the well-to-do classes. Among these there is a widely diffused belief that puerperal fever is a preventable disease, and that for its occurrence the physician should be held responsible, and this leads to greater painstaking on the part of the latter, even when he is disinclined to accept the deductions from modern scientific teaching. Among the poor, in their own homes, I do not believe that the dangers of childbed have been perceptibly lessened.

How serious is the question under discussion is shown by Dr. Maury's table, where it appears that, even in the past five years, one-tenth of the deaths in women between the ages of fifteen and forty-five are due to causes connected with childbirth, and that one-twentieth of the deaths among women in the childbearing period are due to puerperal sepsis.

The following record will show how important have been the changes effected by modern methods in our lying-in institutions: In the year 1873 there were 449 births in Bellevue Hospital; there were 25 maternal deaths, 15 of which were the result of septic infection. The proportion of one death from sepsis to thirty cases of childbirth was at that time the usual one in the maternities of this country and of Europe, reported differences being rather of book-keeping than of fact. There was always, likewise, a large unreckoned contingent of patients with pelvic inflammatory troubles which ended in recovery. In 1874, between the 1st of January and the 11th of June, of 166 patients confined 31 died of puerperal fever. Similar fatal epidemics were at that time of not infrequent occurrence in the best appointed maternities.

The first attempted reform consisted in the erection of wooden pavilions on Blackwell's Island for the reception of the lying-in service. This move was the work of non-professional enthusiasts, and was the outcome of the prevailing opinion that a mysterious efficacy resided in wooden walls. The death-rate, however, speedily rose to a higher average than had previously existed at Bellevue; the wooden pavilions were abandoned, and the reign of inspiration ended.

With the transfer of the maternity to Blackwell's Island it became necessary to provide for the cases, sufficiently numerous, who seek hospital care after labor has actually begun. At first special arrangements for their reception were made with private institutions, but after a brief trial the latter refused, in justice to their other inmates, to admit such emergency cases, on the plea that it was impossible to receive them and keep their wards free from infectious diseases. Thereupon orders were issued by the commissioners that the patients should be taken on board the Blackwell's Island steamboat, there to be kept until they could be transferred by the regular trips, which took place twice daily, to the Island maternity. Of necessity, many women were confined in the steamer cabin, especially during the night. No adequate provision was made for their comfort. Protests against the inhumanity of this arrangement received no attention, until, finally, in the winter of 1877–8, a patient died of cold, and became the subject of investigation by the grand jury. As a final outcome of the agitation which followed, an engine-house belonging to the old fire department was fitted up for urgent cases, under the name of the Emergency Hospital. It contains a sitting-room, a laundry and kitchen, a room for con-

Total	88,791	22,270	185,734	2011	1105	55	1 in 44	1 in 11	1 in 80⅓	1 in 20	1 in 92⅓	1 in 168

finements, and a ward containing six beds. The visiting staff consists of Dr. Polk and myself. The attendance is derived from the interne service on the medical side of the Bellevue Hospital.

I have ventured to offer these particulars because there is no pretence that the Emergency is a model for imitation. It has no fans for ventilation; no provision for a rotation of wards. It is intended for the homeless class. It receives constantly women with high temperatures due to infection before their entrance, or who have been days in labor, or who have been subjected to unavailing attempts at artificial delivery by outside physicians. It therefore furnishes an excellent test of the value of modern antiseptic methods. During the past five years there have been 837 women confined within its precincts, and there have been 16 deaths, *i. e.*, nearly 1 to 82. A glance at the record shows that these cases are the best illustrations of the difficulties with which the institution has to contend, and of the value of the antiseptic principle.

Thus, there were 5 deaths from eclampsia. The patients were all sent to the hospital after the convulsions had gained full headway.

One was a case of placenta prævia. The labor had been lengthy and the hæmorrhages profuse before the patient was admitted.

One was a case of Cæsarean section, performed on account of the obliteration of the cervix and vagina by cancer.

A patient was sent to the Emergency in labor, with delirium tremens. She died twenty-four hours after delivery.

There were two deaths following version in neglected shoulder presentations. Both women had been in labor several days previous to admission. The children were dead, and decomposition had set in.

In two cases the women had been respectively two and one-half and four days in labor when admitted. The children were dead. There was a stinking discharge and commencing decomposition of the fœtus.

In two cases the high-forceps operation had been performed surreptitiously by unqualified persons.

In both instances the lower uterine segment was ruptured, and death speedily followed.

In a twin pregnancy, where one child was delivered by forceps and the second by version after a long labor, death occurred from septicæmia.

There remains one other case, concerning which no record has been preserved.

Thus, of the 16 deaths, 1 or possibly 2 can be construed as due to puerperal fever.

Now, the regulations by which these results have been obtained are comparatively simple. The patient, on her entrance into the hospital, receives a full bath. A rectal injection is given. The lower abdomen, the inner surfaces of the thighs, the pudenda, and the anus are scrubbed with soap and water, then washed with plain water, and finally cleansed with a 1 to 1000 solution of corrosive sublimate. The vagina is first douched with soap and water and then with a 1 to 5000 solution of corrosive sublimate. In operative cases these douches are repeated before and after the introduction of the hand or instruments. The Bellevue Hospital internes, while on duty, are not permitted to visit the dead-house or the erysipelas pavilion. They are not allowed to assist at surgical operations nor to take part in the dressing of wounds. When in attendance upon a case of labor both interne and nurse wash their hands and forearms with soap and water, with pure water, and with corrosive sublimate solution (1 : 1000). Before an internal examination is made the hands are freshly washed with the bichloride solution. Infrequent examinations are recommended. Instruments are placed in a 2 per cent. solution of carbolic acid. After they have been used they are boiled and polished for future service.

The Credé method of expelling the placenta is employed. Ergot is given to secure good uterine contractions. In all cases after labor the vagina is douched with the bichloride solution (1 : 5000). In cases of protracted labor, of high-forceps operation, of version, or of any manipulations by means of which air is admitted to the uterine cavity, the douche, after preliminary vaginal irrigation, is extended to the uterine cavity. The external parts are then dusted with iodoform, and are covered with a piece of gauze freshly wet with bichloride solution (1 : 5000). Outside is placed a pad of oakum. The dressing is changed once in six hours, at which time the genitals are scrupulously cleansed. During childbed no vaginal douches are given.

In the main the plan of treatment carried out is that introduced by Garrigues at Charity Hospital five years ago. Its success is attested not only by the absence of deaths due to septic infection, but by the morbidity in the wards. The temperatures rarely rise above 100½°, and, as a rule, do not reach 100°. But the plan of treatment presupposes intelligent instruments. For us these are supplied, on the one hand, by the training-school for nurses; on the other, by the hospital interne, who enters upon his duties thoroughly familiar with the requirements of surgical cleanliness. The occasional appearance on the scene of an individual who uses his "common sense"—*i. e.*, one who does not believe there is any harm in witnessing an autopsy, or in visiting a companion in the erysipelas ward, or in holding the pus basin in an operation for pyo-thorax—is almost certainly followed by temperature elevations, which add fresh testimony to the efficacy of a rigid observance of antiseptic regulations.

It is, however, to be acknowledged that there is by no means unanimity among authorities in relation to certain of the rules prescribed. Thus, the pad to the vulva is sneered at by many as savoring of the heresy that the air can become the source of contagion. For my own part, I believe an antiseptic dressing and pad are of immense service in hospital practice, where patients are aggregated together, as a means of preventing the decomposition of the lochia. The latter is inevitable upon the external parts when the ordinary napkin is employed. It seems to me incontrovertible that the air does thereby become contaminated, and it is doing violence to the evidence to deny the pernicious influence of a germ-laden atmosphere upon puerperal wounds. The argument that such an admission has a tendency to weaken the personal responsibility of the physician is childish. Aside from the fact that science is based upon truth, and not upon teleological considerations, the belief in a twofold origin of puerperal fever simply doubles his responsibility. To be sure, Leopold[1] found that of 427 patients in the Dresden Maternity who had not been examined or treated with corrosive sublimate previous to confinement only 7 had a rise of temperature, and this fact taken by itself would seem to indicate that direct contact alone is capable of producing infection. But these patients were confined under favorable sanitary conditions. Szabo,[2] on the contrary, during an epidemic of fever in the Pesth maternity, gave orders that no examinations should be made. Of 90 patients confined under these conditions more than one-third had febrile disturbances; and 2 of the patients, upon whom, in the one case, sutures, and in the other, serres-fines, were employed for perineal laceration, died. The researches of Ott[3] and Thomen[4] show that in healthy women the bacteria con-

[1] Leopold: Dritter Beiträg zur Verhütung der Kindbiltfiebers. Archiv f. Gynäkologie, vol. xxxv. p. 149.

[2] Szabo: Zur Frager der Selbstinfection. Ibid., vol. xxxiv. p. 153.

[3] Ott: Zur Bacteriologie der Lochien. Ibid., vol. xxxii.

[4] Thomen: Bacteriologische Untersuchungen Normaler Lochien, etc. Ibid. vol. xxxvi. p. 247.

tained in lochia are found, not in the upper portion of the vagina, but near the introitus, which would certainly indicate that they are ordinarily derived from external sources. At any rate, since the use of the pad at the Emergency Hospital it has been possible to do away with the old-time rotation of wards, and the febrile temperatures, which once were so marked a feature of the winter months, when the windows were closed, are now no longer observable.

The subject of prophylactic douches during labor has likewise been one of endless contentions. Their employment at the Emergency has not, however, been the result of theory, but has been the outcome of the condition of the patients admitted, most of them having been examined previously by not over-fastidious midwives or physicians.

The differences which divide obstetrical authorities concerning the ante-partum douche is not so much the result of conflicting experiences as of doctrinal convictions. Thus, Barnes, Ahlfeld, Kaltenbach, and others, have shown that, in spite of every pains taken to exclude contact-infection, temperature elevations will occasionally occur in childbed. These febrile disturbances they regard as the product of a *materies morbi*, existent in the genital canal prior to labor; or, to use a term which at present is not only a designation, but a war-cry, such cases are due to auto-infection. It is a matter of common agreement that in severe cases of puerperal infection the utero-vaginal canal swarms with bacterial forms, and that of these the streptococcus pyogenes is the most certain accompaniment of specific inflammatory troubles. When convalescence sets in the coccus forms correspondingly disappear from the lochial discharges. But the vagina at all times contains a varied assortment of bacterial germs. Nothing would seem simpler, therefore, than the deduction that these germs are always potential sources of evil. As a logical outcome of this doctrine its extreme supporters insist upon a complete sterilization of the vagina in every case of labor as an ordinary prophylactic precaution. Thus, Steffeck[1] advises the irrigation of the vagina during labor, at two-hour intervals, with a litre of corrosive sublimate solution. To increase its efficiency he introduces two fingers into the vagina to scrub, during the douche, first, the vaginal mucous membrane, and then the interior of the cervix. Döderlein[2] recommends that the vagina be first rubbed thoroughly with a preparation of creolin and mollin and then be irrigated for ten minutes with a creolin solution.

Fortunately, these suggestions, which would have a tendency to handicap fatally the employment of antiseptic measures in midwifery, have not been received with much favor, even by the partisans of the doctrine of auto-infection. But, on the other hand, the pathogenic character of the germs contained in the vagina has been disputed. Thus, Artemieff[1] says that "the lochia of perfectly healthy puerperal women contains no microörganisms." Bökelmann[2] maintains that a healthy, normal puerperal woman is *à priori* to be regarded as aseptic. He objects to attempted sterilization on the ground that the measures employed mechanically delay the progress of labor by the removal of the normal vaginal mucus, and at the same time render more vulnerable the tears, the excoriations, and the surfaces from which the epithelium has been detached.

Kaltenbach,[3] although a defender of auto-infection, states that in easy, rapid births the germs are carried away by blood, amniotic fluid, and the passage of the child; but in tardy labors, or in case of the premature rupture of the membranes, the entrance of germs into the uterine cavity is facilitated, and many may remain in the uterus and become a source of danger. Diseases resulting from auto-infection are lighter in character than those due to inoculation. Infection is first preceded by putrefaction. A complete destruction of germs is unnecessary; those that remain *in utero* are rendered harmless by ordinary injections. Even Winter states that in the present condition of our bacteriological investigations it is not right to carry out the attempts at complete sterilization recommended by Steffeck and Döderlein.

In private practice, under ordinary conditions, the presence in the vagina of infectious forms of bacteria is hardly conceivable, except in cases where they have been directly imported by the finger or by instruments. This statement is based both upon microscopic investigations and upon clinical experience. So far, it has not been possible, in the rare instances where beaded cocci have been found in the vaginal secretions, ante-partum, to obtain by pure cultures a product capable of giving rise to spreading inflammations; and in rural districts, even with not over-cleanly surroundings, immunity from infectious puerperal diseases is the rule. That, however, the vagina, which is not a hermetically closed tube, should, like the atmosphere, contain germs capable of producing putrefaction is hardly doubtful. Under healthy conditions the uterine cavity, on the contrary, contains no bacterial forms, and it is not invaded by them in normal parturition, a fact attributed to their feeble migratory power and to the downward current of the secretions. Condi-

tions which favor the passage of germs from the vagina into the uterus are relaxation of the uterine walls and membranes hanging from the cervix. The increased morbidity which accompanied the once popular vaginal douche in childbed was doubtless owing to the circumstance that, while of feeble disinfectant power, the injected stream furnished in many instances a direct highway to the uterine cavity. True midwifery antisepsis consists not so much in douching as in furthering physiological processes. Under normal circumstances a proper handling of the patient in the third stage of labor will effect more in the way of prophylaxis than the most effective germ-destroying agents. When, however, hands or instruments are introduced into the uterine cavity, the case is different. It would be hardihood then not to precede the operative measure by thorough vaginal disinfection.

In private practice too great pains cannot be taken with the sanitary surroundings. The sheets and the napkin or pad to the vulva should be matters of personal supervision. Slovenly laundry work is dangerous. I prefer the pad because it is destroyed after having been once in use. The employment of napkins which have been left in a pail until putrefaction is well advanced, and are then soaked and dried before the fire by the monthly nurse, is a familiar procedure, and a direct temptation of Providence.

In city homes close inquiries should be made in reference to the condition of closets and sewer connections. My attention was first drawn to the similarity of typhoid and septic fever in puerperal cases by a patient sent to the hospital in a moribund condition. Her child had been removed by a high-forceps operation, and the cervix was badly lacerated. I regarded her symptoms as typical of puerperal fever, but the post-mortem examination showed a perfectly healthy condition of the pelvic organs and the characteristic intestinal lesions of typhoid. During the past few years of low water-supply in New York I have many times been called to see patients with high fever who were undergoing the customary douchings, while in the adjoining closet the basin into which the dejecta of the patient were being thrown was washed out once or twice daily by a pitcher of water poured into the basin by hand. The dangers of defective house sanitation have been ably presented by my friend Professor Playfair, and I find it difficult to understand the attitude of those who find no harm in the condition I have described because, they say, it does not affect the drinking-water.

A physician from the country called upon me to consult me about an epidemic of puerperal fever in his practice. I asked him many questions, but received no enlightening answer as to the cause. The physician was intelligent, and had seemingly taken every needful precaution. As he was about to leave me I inquired whether there was any diphtheria in his neighborhood. He answered, he had "lots of it," and seemed surprised that I should connect the diphtheria and puerperal fever together. It seems to me a thoroughly false idea that a physician can attend erysipelas, diphtheria, and scarlet fever, and at the same time pursue his midwifery practice with impunity, provided he makes free use of corrosive sublimate and carbolic acid. Indeed, I am almost disposed to regard as a special form of blindness the prevalent faith that parturient and puerperal women can only be infected by the finger and through the vagina.

The use of the vaginal douche in childbed as a routine practice is now happily a thing of the past. Still, there is a widespread belief that intra-uterine irrigation is the true treatment for puerperal fever. But the case is not so simple. It is necessary to differentiate. We have just insisted on the fact that puerperal women are not exempt from febrile disorders other than those due to sepsis. Before the douche is used the breasts should be examined. The douche can help but little in acute and suppurative inflammations awakened by labor and in patients who have had chronic unilateral salpingitis antedating pregnancy. In cases of true puerperal infection, due to the penetrative form of micrococci and associated with spreading forms of inflammation, the use of the douche is probably idle and no more effective than washing the surface of the skin in an external erysipelatous process; and yet it is common to persist in the practice in spite of negative results.

The douche repeated at short intervals is not unattended with drawbacks. Thus, it interferes with the localizing processes by which most of the pelvic inflammations become self-limited; it helps to extend the morbid condition of the uterine cavity to the tubes, and if continued long enough paralyzes the uterine walls, so that after death the fundus is found to contain a dirty pool alive with bacteria.

The employment of the douche in fevers resulting from the absorption of toxine due to the putrefaction of clots, membranes, and bits of placenta within the uterus, on the other hand, is followed by immediate favorable results and by the prompt disappearance of danger. But it is to be remembered that this is a clumsy attempt to remedy the results of past remissness.

The indications for the douche as popularly employed are especially vague. One man is governed by the odor of the lochia, but the odor in ordinary catarrhal endometritis is offensive, and yet all such cases recover unless aggravated by the douche. Again, as Bumm has pointed out, the products of

tissue disintegration may be virulently poisonous and yet the odor may be absent. Others, again, use the douche when the temperature reaches 102°. But the temperature-guide leaves out of sight the multitude of temporary temperature elevations due to trivial local troubles, to psychical causes, and to malaria.

My own belief is that the intra-uterine douche in childbed is not indicated except when there has been slovenly help rendered by the attendant at the time of childbirth. Usually a single douche is sufficient and should always be preceded by thorough vaginal disinfection. I still prefer the bichloride solution (1 : 3000), but inject slowly and not more than a quart. Then I take great pains to secure good contractions, in order to expel all of the injected fluid. I would strongly recommend, after the douche, the introduction of the iodoform "bacillus" (two and one-half drachms of iodoform). If the fever persists it is sometimes desirable to follow the advice of Doléris, and explore the uterine cavity with the curette for retained bits of tissue. But it is time to stop treatment at this point. There is nothing more fatuous than the expectation of curing the patient by redoubling the vigor of the treatment.

THREE CASES OF TUMOR OF THE FRONTAL LOBE.[1]

By W. GILMAN THOMPSON, M.D.,
VISITING PHYSICIAN TO THE PRESBYTERIAN AND NEW YORK HOSPITALS.

All cases of brain tumor are of special interest at present, since we are to-day in a position to consider not only their nature, progress, and probable site, but even the possibility of their removal by surgical interference. The cerebral hemispheres have been mapped out in the lower animals and in man, in regard to localized function, with a degree of accuracy which, although far from absolute with many functions, is full of encouragement for further study, and which within a few years has caused a complete reconstruction of our theories of the operation of many mental processes. In our maps of the cerebral hemispheres there is still a large undetermined region, the pre-frontal, regarding the functions of which there is great obscurity. In animals irritation of the posterior part of the frontal lobe has been shown to produce movements of the muscles of the head and neck, and sometimes rotation of the eyes, but the experiments are less satisfactory here than when performed in other parts of the brain. Removal of the anterior part of the frontal lobes in dogs seems to occasion loss of memory and changes in temper, the animals become restless and irritable, or, more often, dull and sleepy, but no abnormalities of motion or sensation are produced. In man very severe injuries of the frontal lobe have been reported, with considerable destruction of tissue, sometimes without any mental, motor, or sensory symptoms whatever. The historic "crow-bar patient"[1] was such a case, where extensive lesion of the frontal lobe produced no permanent impairment of mental faculties beyond slight irritability of temper. Another case, reported by Dr. Noyes,[2] was that of a man in whose orbit the breech-pin of a gun was found imbedded, a sharp end of the metal, one and a half inches long, and half an inch broad, having penetrated the cranium and entered the right frontal lobe, where it lay for five months without producing any symptoms referable to the brain. On the other hand, congenital or acquired defects of the pre-frontal region have often been observed in connection with enfeebled intelligence or idiocy. Many of the lower races of man present a relative deficiency in the development of this region, as well as of the temporo-sphenoidal lobe. Conversely, it is customary to associate a high degree of frontal development with great intelligence. Of the three cases of new-growths isolated in the anterior and middle portions of the frontal lobe, which I now report, one was a sarcoma, secondary to a sarcoma of the neck, and the two others were gummata, but with no accompanying syphilitic symptoms or history. All three patients exhibited more or less mental disturbance, either irritability of temper or dulness, or both in alternation. The two cases of gummy tumor were singularly alike in the irritation and convulsions which were present. The other patient had no such symptoms. Periodical general headache was complained of by two of the patients, not by the third. Only the important facts in the histories and autopsies of these cases are herewith presented, irrelevant details being omitted.

The patients all entered my service at the Presbyterian Hospital during the past two years, but one of them I had treated occasionally at my office during the three previous years:

Case I.—V. B., German, male, aged forty-six years, married, cabinet-maker. The patient had led a sober and industrious life, and gave no history of syphilis or alcoholism. He had always enjoyed good general health. About six years before admission he was struck on the head by a falling timber. He was not immediately unconscious, but became delirious afterward. The site of the injury could not be definitely located. He recovered from the shock in about a week, but since that time he had had occasional epileptiform convulsions, these attacks usually following business worriment. At first they occurred about twice or three times a year. Of late they became slightly more frequent, never, however, recurring at shorter intervals than two

[1] A paper read before the New York Clinical Society, April 25, 1890.

[1] Barlow, Bigelow: American Journal of the Medical Sciences, 1850, vol. lvi. p. 13.

[2] Ibid., vol. lxxxiv. p. 45, 1882.

months. Recently the attacks have grown much more severe. At first they were general, the individual convulsions continuing a few seconds with intervals of half an hour to an hour, the whole seizure lasting eight or ten hours. They were always associated with extreme constipation and with a well-marked aura. Recently, the convulsions, which were at first general and moderate, became much more intense upon the left side, and were followed by deepening coma. I had the patient under observation for three years before his admission to the hospital, and I saw him in several of these attacks. About a year before admission he had one which was followed by complete left hemiplegia, with absence of reflexes on the affected side, and slight muscular rigidity; sensation and speech remaining normal. The hemiplegia lasted for three days, with gradual but complete recovery. Between the seizures the patient worked hard, but his family and friends complained that he was abnormally irritable, excitable, and morose. His memory was very slightly impaired. The urine was always normal. Heart and lungs normal. No evidence of atheroma, or of any disease of abdominal viscera. During the attacks the temperature sometimes rose to 100°, but never above. The patient at these periods always complained of severe general headache. Three days previous to admission to the hospital the patient was seized with convulsions more severe than usual, accompanied by cyanosis and involuntary evacuations. For twenty-four hours the seizures recurred about once an hour, and in the interims he was conscious. After this they recurred every ten or fifteen minutes, and he passed into deep coma. The left hemiplegia recurred after the first twenty-four hours of this final attack, and after twelve hours more it was followed by complete hemianæsthesia of the left side of body and face. The reflexes, particularly the plantar, were increased, especially upon the left side. There was also decided convulsive twitching of the left side of the face. Pupils normal. On admission to the hospital the temperature was 102°. The convulsions did not return. The patient regained consciousness, but did not speak. The following day the heart-action suddenly became very feeble, and in a few hours the respirations were rapid and stertorous, œdema of the lungs ensued, the temperature rose to 105°, and two days after admission the patient died.

The autopsy revealed about a dozen gummy tumors, some larger, some smaller than a pea, which occupied the anterior and central parts of the right frontal lobe. Some of the tumors were quite superficial, others were deeply seated. Immediately around these growths the convolutions were pale and necrotic, with obliterating endarteritis and degeneration of the nerve cells. Nothing else of importance was detected.

I confess that I failed to diagnose this case. The possibility of traumatic epilepsy due to the pressure of a depressed fracture received from the injury six years before, occurred to me, but it could not be located, as the convulsions were at first general and there was no external evidence of violence. As the autopsy showed, no such condition had existed. Repeated hæmorrhages or irritation from emboli, for various reasons appeared equally out of consideration. It was late in life for idiopathic epilepsy to develop. The possibility of syphilitic tumor occurred to me, but I could get no history of venereal disease. The man had long been married, had a large family of perfectly healthy children and he appeared to be in remarkably sound physical condition. He was put upon various forms of treatment during the three years in which I had charge of the case, and was more relieved by large doses of the bromides than by anything else. He was also given potassium iodide, but he felt so well in the intervals between his attacks, that it was difficult to enforce any plan of treatment, and he only reported to me when alarmed by some unusually vigorous seizure. If I had been certain of the existence of a gummy or other tumor, I should have located it much further back, in the motor area.

Case II.—C. T., negress, aged thirty years; married; housewife. The patient was well up to six years before admission. She denies alcoholic or syphilitic history, and a most careful examination fails to reveal any of the ordinary lesions or symptoms of the latter, excepting very slight enlargement of the cervical glands. Her several children died young. About six years ago the patient had for the first time an epileptiform convulsion which came suddenly, without apparent exciting cause. Similar attacks have since recurred at irregular intervals, gradually becoming more and more frequent, at first twice a week, and of late more often. The day before admission she had eight attacks. The seizures afterward recurred every fifteen or twenty minutes. At first the convulsions were general and involved all the limbs and body equally. Recently the right leg and arm have been more affected, and these have shown a certain amount of paralysis between the convulsions. Otherwise the patient's physical condition between the seizures was normal and she was going about until the time of admission, but she was rather dull and foolish mentally for a long time previously. On admission the attacks commenced on the right side of the body, and the head turned toward the right. Respiration was suspended during the seizures from spasm of the diaphragm. The convulsions, though very violent, did not last over half a minute, and there was little cyanosis. Urine and fæces were retained. The patient's mind was dull between the attacks, but she responded to questions. No headache complained of. A diagnosis of probably gummy tumor was made, and the patient was given potassium iodide 75 grains *per diem*, and all the usual remedies for the control of the convulsions were tried without effect, such as potassium bromide in 60-grain doses, chloral, amyl nitrite, etc. The urine contained a trace of albumin, but was otherwise normal. No aphasia or rigidity, and the reflexes were normal. During the seizures there was a low cry on inspiration, the facial muscles were involved, and the eyes were rolled upward and to the

right; this was soon followed by tonic spasm of the muscles of all the limbs, and then by general clonic spasm with moderate opisthotonos. Thumbs strongly inverted. Pupils equal and normal. Temperature 100¾° to 101¾°.

The woman lived for thirty-six hours after admission. During the last night of her life she had nineteen convulsions despite every effort to relieve them. It was not justifiable to disturb her much, but in an interval between the seizures it was found that the patellar and plantar reflexes were diminished upon the right side. Pulmonary œdema developed and the patient died from heart-failure without spasm of the diaphragm. The convulsions continued until a few moments before death.

Autopsy.—General nutrition good. All the organs were normal, excepting the kidneys and brain. The kidneys showed the early stages of chronic diffuse nephritis. Brain normal, excepting left frontal lobe. Over the superior and middle frontal convolutions the pia was adherent and thickened, and contained about a dozen nodular gummy tumors, varying in size from a pea to a hazelnut, and with caseous centres. The convolutions beneath were somewhat softened, and contained a few similar nodules. The dura over the same region was thickened and adherent. The optic thalami and lenticular nuclei upon both sides seemed slightly more mottled than usual. The dura and pia were also thickened and adherent at the tip of the right frontal lobe, though there were no other lesions on this side.

I was able to make the diagnosis in this case merely from its extraordinary resemblance in nearly every important detail to the preceding one, which died a few months before. But the patient was seen too late for any relief from the large doses of potassium iodide which were administered.

Distinctive features common to Cases I. and II.

1. General irradiation of irritation from a local lesion.

2. Local lesion far in front of the common motor areas.

3. Entire absence of history or definite symptoms of syphilis.

4. Complete recovery between the attacks.

Case III.—The patient, a female, aged forty-seven years, had been operated upon in the Presbyterian Hospital one year previously for sarcoma of the right side of the neck. She made a good recovery, and was well until six weeks prior to her re-admission to the hospital on August 15, 1889. During this interval of six weeks she had suffered from severe headaches (not localized), followed by periods of stupor lasting a day or two at a time, the attacks becoming constantly more frequent and more severe. No lesions were discovered in the thoracic or abdominal viscera. The patient could walk, but appeared weak and disinclined to stand. She seemed very listless and dull, and sensation in both legs was diminished and retarded. She had impaired articulation, which seemed likewise to be due to her mental dulness. At times she could think of certain words and pronounce them without difficulty; at other times she had apparently both amnesic and ataxic aphasia. She was of a race (Swedish) in which I have often noticed great apathy in any illness; she spoke English imperfectly, and therefore it was difficult to test her speech and sensation thoroughly. There were no unilateral nerve symptoms, and the pupils were normal in size and reaction. The patellar and plantar reflexes seemed equally diminished on both sides. The movements of the arms and hands were normal. No disturbance of the sphincters. The most pronounced symptom was the mental dulness. This condition lasted for sixteen days, with periods of lucidity in which the patient seemed fairly intelligent and answered questions without aphasia. The dulness then increased until complete coma resulted, with stertorous respiration, cyanosis, incontinence of urine, and total loss of sensation. A loud, harsh mitral systolic bruit developed, the pulse became rapid and feeble, the temperature rose from normal to 104°, and, on the nineteenth day after admission, she died from heart-failure. There was no emaciation, and no marked cachexia.

Autopsy.—There was nothing of importance in any of the organs excepting the brain. The calvarium was normal. Both the dura and pia were congested. There was atrophy of the convolutions over the vertex of both hemispheres. In the anterior portion of the right frontal lobe was a mass 4 by 3.5 centimetres in its diameters, black in color, and quite firm. There was an excess of fluid in the left lateral ventricle. Weight of brain, 50 ounces. Vessels at the base were normal.

Microscopical examination.—Sections of the tumor of the right hemisphere show its structure to consist mainly of a fibrous connective-tissue stroma with small and large round cells in close association with the stroma. In places there are numerous alveoli. In some of these are found the above-described cells. The growth is a fibro-sarcoma. Tissue resembling non-striated muscle is seen in some portions of the tumor. The tumor also contains much pigment and numerous bloodvessels. No giant cells are observed. There are areas of a granular appearance which stain imperfectly.

The interesting features of this case are: first, the absence of unilateral or distinctly localized symptoms, with the presence of a cerebral tumor as large as a small egg; secondly, the varying mental condition of the patient. The diagnosis of a cerebral tumor was suggested by the mental condition and the patient's history of previous operation for malignant growth. If the situation of the tumor could have been exactly determined, it might have been removed by operation, as it was near enough to the surface. The tumors in the other cases could not have been excised, for they were too numerous, and some of them were too far from the surface. All three cases are interesting in regard to the periodicity which was noticed in the appearance of the symptoms.

The cases seem to add but little to our knowledge of the functions of the frontal lobe, but they confirm previous observations in regard to alterations in temper and disposition, mental irritability associated with alternating stupor, which accompany lesions of this obscure region. The convulsions may have been due to indirect pressure upon the motor areas posterior to the tumors, which was periodically augmented, perhaps by temporary alterations in the local blood-supply, perhaps by the commencement of a new focus of growth, to which the cortical cells would later become accustomed.

49 EAST THIRTIETH STREET.

A CASE OF URÆMIA WITH CHEYNE-STOKES RESPIRATION LASTING SIX DAYS, TERMINATING IN RECOVERY.[1]

BY NORTON DOWNS, M.D.,
RESIDENT PHYSICIAN, PENNSYLVANIA HOSPITAL.

IT is through the courtesy of my chief, Dr. J. M. Da Costa, that I am able to report the following case :

M. F., an Italian laborer, aged forty years, was admitted to the medical ward of the Pennsylvania Hospital on the morning of January 22, 1890. Unfortunately, we were unable to obtain any family or personal history, as the man could not speak English. He had walked several blocks at least to reach the hospital. After being admitted he presented the following symptoms: Temperature in axilla 98°. Pulse could scarcely be felt at the wrist, and was something over 120. Respiration was typically Cheyne-Stokes in character. Face intensely cyanosed. Entirely conscious. Tongue protruded without difficulty, but slightly to the right side; it was coated and tremulous. Eyelids œdematous. Pupils slightly contracted, and reacted but feebly to light. Heart's action was regular, but feeble, and sounds could just be heard. No murmur detected. No increase in cardiac dulness. Lungs everywhere filled with coarse mucous râles; no impairment of percussion resonance. Area of splenic dulness slightly increased. Legs and thighs were œdematous. The patient was immediately catheterized, and four ounces of muddy urine obtained; it had a specific gravity of 1030; alkaline in reaction. Fully three-fourths of albumin by bulk, and a large number of epithelial, granular, and hyaline casts, with free blood, mucus, and triple phosphates.

He was given a half ounce of hot whiskey, followed ten minutes later by extract of jaborandi, 30 minims, and compound jalap powder, 30 grains. One hour later the patient was in a profuse sweat, which had the characteristic urinous odor; the bowels were also freely moved. The jaborandi and jalap in the same doses were repeated during the afternoon, and acted well on the skin and bowels. By evening the temperature had risen to 100°. The Cheyne-Stokes respiration continued. No convulsion or stupor.

January 23. Cheyne-Stokes respiration remains unchanged. The patient passed a comfortable night, sleeping most of the time, apparently without being inconvenienced by the abnormal respiration. Is entirely conscious, and takes nourishment well. Was to-day placed on infusion of digitalis, 1 drachm, and acetate of potassium, 10 grains, every second hour; and fluid extract of jaborandi, 30 minims, three times a day, the bowels to be kept open with jalap. Passed naturally six ounces of urine during the night. Has sweat profusely all day. Toward evening he was placed in hot-air bath, after which he seemed decidedly brighter.

24th. The Cheyne-Stokes respiration continues without change, during sleep as well as when awake. Passed eighteen ounces of urine in past twenty-four hours, with a specific gravity of 1024; alkaline reaction; albumin three-fourths by bulk. A large number of granular and epithelial casts found. Perspiring freely.

25th. Passed fifty ounces of urine in past twenty-four hours, with a specific gravity of 1024; still loaded with albumin and casts. Pulse is decidedly stronger than when admitted. Heart sounds are more distinct, and the râles have entirely disappeared from the lungs.

26th. The Cheyne-Stokes respiration continues. Urine in past twenty-four hours eighty-two ounces; pale straw-colored, specific gravity 1016. Albumin one-half bulk. The casts have greatly diminished in number. The patient has been sweating, and bowels have been moving freely each day, while the œdema is fast disappearing from the legs.

28th. Cheyne-Stokes respiration was absent this morning for the first time since admission. The temperature for the past four days has been decidedly subnormal, reaching 95° during the night. Cheyne-Stokes respiration was present again in the evening.

30th. Patient sitting up in bed. Respirations natural. Tongue still protrudes to the right side. Urine in past twenty-four hours, fifty-three ounces; specific gravity 1016; alkaline; albumin, one-fourth bulk; no casts found in a number of specimens examined.

February 2. Infusion of digitalis stopped. Urine, thirty-two ounces; specific gravity 1018; trace of albumin; no casts.

8th. Steadily improving. Œdema has disappeared. Appetite good. Mental condition excellent.

24th. Urine to-day, one month after admission, is entirely free from albumin and casts.

March 3. Discharged recovered.

Among the many interesting features connected with this case the one to which I wish to call attention is the Cheyne-Stokes respiration followed by recovery. It will be seen from the notes that the patient walked into the hospital with this curious phenomenon present to a marked degree. How

[1] Read before the Philadelphia County Medical Society, April 23, 1890.

long it had existed before admission is impossible to say, but it did occur for six days continuously while in the hospital, during which time the patient was entirely conscious, taking his nourishment without assistance, and seeming not in the least inconvenienced by the altered condition of the respiratory action.

This phenomenon consists of two distinct stages: one of apnœa, the other of dyspnœa. At the end of the apnœal period the respiratory action begins, at first so shallow as to be hardly recognizable, but gradually increasing in force, volume, and frequency, until the period of dyspnœa is at its height and then gradually becoming slower, more shallow, and less distinct until it entirely disappears, and the stage of apnœa is again reached, thus completing the cycle. The length of time occupied by the two stages is variable; for instance, the stage of apnœa may occupy from a few to forty seconds, the stage of dyspnœa from one-half to two minutes.

In this case during the period of apnœa, which by many counts was found to last from thirty to forty seconds, the face became intensely cyanosed, the heart's action slightly slower, the eyes becoming more prominent, but complete consciousness was preserved. When in the period following, or that of dyspnœa, the face became flushed, the heart's action slightly accelerated, while a general sense of discomfort prevailed. This stage lasted, on an average, seventy to eighty seconds. In neither stage was alteration in the state of the pupil noticed, though carefully looked for.

This form of respiration was first studied by Dr. Cheyne, of Dublin,[1] in 1818, who noticed a peculiar form of ascending and descending respiration in a fatal case of fatty degeneration of the heart. From this time there do not appear to have been any observations on the subject recorded until about 1846, when it was made prominent by Dr. Stokes,[2] also of Dublin, who recorded cases of fatty degeneration of the heart, in which this symptom occurred. Since then it has received but little attention. Among the observers who have attempted to explain it may be mentioned Traub, Filehne, Little, and Bramwell.

The phenomenon may be considered rather rare, but from the variety of diseases in which it may occur it is curious that it is not seen more frequently. From the fact that the first observations made on the subject were in connection with fatty degeneration of the heart, it was considered pathognomonic of this lesion, but it was soon noticed in other cardiac affections, and in uræmic coma, and the idea of its being pathognomonic of any disease was dispelled. There can, however, be no doubt of the fact that it is an extremely frequent symptom of the diseases in which it was first studied; for of the ninety-five cases of fatty degeneration of the heart reported to the London and Dublin pathological societies,[1] twenty-nine cases presented this phenomenon. It has also been seen in simple dilatation of the aorta, and in atheroma of the aorta and of the aortic valves. Dr. James Little[2] reports three cases in which ascending and descending respiration occurred, one being fatty degeneration of the heart, another atheroma of aorta and aortic valves, and the third atheroma of the aorta. According to Gowers,[3] it has been observed in uræmic coma and in rare cases—chiefly in children—in typhoid fever, scarlet fever, diphtheria, influenza, pneumonia, whooping-cough, and opium-poisoning. Fothergill[4] states that the most typical example he has seen was in a case of apoplexy. Dr. Andrew[5] reports a case of typhoid fever with extensive consolidation of the right lung in which this phenomenon occurred. Frantzell[6] narrates an instance where it occurred after the administration of morphine; O'Neill,[7] its occurrence after chloral, and Biot, after potassium bromide. It has also been observed in brain syphilis, brain tumor, and emphysema of the lungs; and I know of an instance where it occurred during the course of acute croupous pneumonia which was followed by recovery. Gowers[8] and Pepper[9] have observed it in tubercular meningitis. W. G. Thomson[10] states that he has seen it in insolation and metallic poisoning. Dr. James Cummings[11] has observed it in dogs after the injection of chloral. Frederick Treves[12] saw the phenomenon in a case of traumatic anæmia. It is said to be a normal condition in the hibernating hedgehog and dormouse.

The state of the pupil during the phenomenon has been closely watched by many observers, and several of them report cases where contraction and dilatation occurred synchronously with the stages of apnœa and dyspnœa; for instance, Dr. Alexander Robinson[13] reports two cases of apoplexy in which Cheyne-Stokes respiration was present, and says that, "during the period of dyspnœa the pupils became widely dilated and at the same time the extremities became rigid, while during the stage of apnœa the pupils contracted firmly and the muscular

rigidity passed away." Dr. R. Kirk[1] has also noted the rhythmical contraction and dilatation of the pupil, and quotes from Ziemssen, Bernheim, and Biot on the same observation. In Dr. Kirk's case the pupils were not influenced by light. Biot gives as an explanation of this condition of the pupil the changes which are said to occur in arterial tension during the stages of apnœa and dyspnœa, the pupil contracting as the pressure falls and dilating as it rises. That there is a change in the arterial tension has been demonstrated in several instances, but it is by no means constant, and did not occur in the above case, except in a very slight degree.

In attempting to explain the cause of Cheyne-Stokes respiration one is at once struck with the number of theories which have been advanced, only to be exploded by other observers; nor is this to be wondered at when one considers the variety of diseases in which it may occur and their entire dissimilarity. I do not intend to offer any new explanation, but simply to discuss a few of the more prominent.

When the symptom was first studied in connection with fatty degeneration of the heart and later in hypertrophy and atheroma, Dr. James Little[2] considered it to be dne to the inability of the heart to propel all the blood it received through the systemic circulation, causing thereby a damming up of the arterial blood in the lungs, which blood, being charged with oxygen, would not give the required stimulus to the peripheral filaments of the pneumogastrics when the period of apnœa occurred. During the latter stage the heart would be able to overcome the stasis by reason of its action becoming more regnlar, slower and stronger, which in turn would force the venous blood from the body, snrcharged with carbonic acid, producing the stage of dyspnœa.

This very elaborate theory would, of course, not hold after it was noticed that the phenomenon might occur in cases when the heart and aorta were entirely normal. The subject was carefully studied in Germany, which led to the advancement of a theory by Traub,[3] the substance of which was that there was a diminished excitability of the respiratory centre, requiring, therefore, more carbonic acid in the blood to excite it to action. Filehne[4] attacked this theory and stated that this alone was insufficient to produce the phenomenon, at the same time advancing the theory, that there was a greater excitability of the vaso-motor centre in these conditions than of the respiratory centre—just the reverse of normal—and from this cause there was produced an alternate arterial spasm and relaxation by the accumulation and discharge of the carbonic acid in the blood. This again has been denied by Dr. G. A. Gibson,[1] on the ground that inhalations of nitrite of amyl do not lessen the periodic pauses, as it should, were the respiratory centre the chief factor. Dr. Gibson took some very interesting tracings of the respiratory movement in this condition, from which he shows that hypodermic injections of pilocarpine decidedly lessened the stage of apnœa for a period of fifteen minutes after each injection.

Landois and Sterling[2] state that the phenomenon may occur whenever the blood itself or the normal supply of blood to the brain is altered. Gowers[3] leans decidedly to Filehne's theory when he says that "unless the simple rhythmical tendency of the depressed (respiratory) centre is adequate to produce the phenomena, they can best be explained by the assumption that the rhythmical tendency is modified by some other periodical inflnence of which vaso-motor spasm is the only one which, according to onr present knowledge, can be concerned as acting and adequate." Pepper[4] believes it is due to an impaired excitability of the respiratory centre.

Bramwell,[5] who goes into the whole subject of the Cheyne-Stokes phenomenon very thoroughly, cannot see that any of the theories yet advanced exactly accounts for the symptoms, and adds that further elucidation of the subject is necessary before a correct conclusion is attained.

In the *Lancet*, 1877, p. 245, and again on March 29, 1890, there appeared interesting editorials on the subject, in which the various theories are criticised, but in neither is any conclusion reached.

The pathological lesions found in cases where this symptom is present are naturally plentiful, but as yet none of them appear to throw any direct light upon the subject.

Gowers[6] mentions the fact that it may occur in meningitis from implication of the medulla, while in Pepper's two cases tubercular meningitis was the cause.

Tizzoni[7] saw two cases where the symptoms existed, and at the post-mortem there was found an ascending inflammatory change in the vagi in one case, while in the other the same change was found in the superior half of the medulla.

Fatty degeneration of the heart is found in a larger number of instances, while atheroma of the aorta or aortic valves, contracted granular kidneys, tumors of the brain, etc., are found in others. Edes[8] mentions the fact that he has seen four cases of

Cheyne-Stokes respiration occur in one family, viz., father, mother, and two sons, and the two cases reported by Knaggs[1] were brother and sister, which I think shows that there may be some neurotic predisposition to the phenomenon.

The length of time that the phenomenon may exist depends very much upon the disease in which it occurs. Gowers quotes a case from Murri where it extended over a period of forty days. During the continuance consciousness may or may not be preserved. Dr. Samuel West[2] saw it last over two months in a case of fatty degeneration of the heart. The phenomenon very frequently disappears during the course of a disease, to return at irregular intervals.

In many cases the patients exhibit evidences of mental suffering; in some during the stage of apnœa, but I think more frequently during the dyspnœic one, though nothing approaching this was seen in the case above recorded.

The occurrence of Cheyne-Stokes respiration during the course of a disease is sufficient to make the prognosis exceedingly grave; indeed, Dr. Stephen Mackenzie considered it of sufficient importance to ask the members of the London Clinical Society,[3] at a recent meeting, if they had ever seen a case occurring in other than injury to the head, get well? Dr. West, in reply, stated that one or two cases of recovery were on record—in one, probably false diagnosis of tubercular meningitis. Since the publication of the inquiry the *Lancet* has contained numerous communications in answer to Dr. Mackenzie's question. For instance, in the number for March 15th, Dr. O'Neill reports a case where the phenomenon occurred in a man eighty years old, probably due to cardiac disease. While G. B. Flux saw it occur during puerperal septicæmia, the patient recovering, Lawford Knaggs[4] reports a recovered case of Bright's disease in which the phenomenon existed for some time.

Dr. W. O. Stillman[5] reports seeing a case recover with this symptom present, the diagnosis being serous effusion affecting the base and anterior vertex of the brain.

Both Pepper and Gowers consider the phenomenon of fatal significance when occurring in tubercular meningitis, and the same can also be said of fatty degeneration of the heart.

Dr. William O'Neill[6] draws attention to a form of respiration closely allied to that described by Drs. Cheyne and Stokes, where there is a decided pause for a considerable length of time in the respiratory act, but not accompanied with the gradual ascent and descent. He relates a case where a woman suffering with hypertrophy and dilatation of the right side of the heart presented this symptom to a marked degree. He says that when the patient closed her eyes in sleep the respiratory act would cease, and only recommence on waking. He estimates the stage of apnœa to last from twenty to thirty seconds. The gradual ascending respiration was present, but at the height of the stage of dyspnœa they would stop abruptly. I have lately seen an example of this form of breathing in a fatal case of tubercular meningitis, where for a few hours before death the patient would suddenly cease breathing, the respiratory act beginning again with a long, full, deep respiration.

CLINICAL MEMORANDA.

MEDICAL.

A Case in which Cheyne-Stokes Breathing Persisted for Three Weeks.—J. C. L., the subject of these notes, was admitted, at the age of thirty-four years, to the Pennsylvania Hospital for the Insane, January 25, 1849, from South Carolina, of which State he was a native.

When he first came under my care in December, 1884, he was in a condition of dementia, and was subject to paroxysmal excitement, during which he became noisy and at times violent.

My notes at that time record that the heart sounds were feeble and that there appeared to be a slight blowing murmur, but owing to the patient's irritable state and a habit which he had of constant low muttering, I was not able then, or at any subsequent time, to make a satisfactory examination.

Repeated examinations of his urine gave only negative results.

In March, 1886, the notes show that he had some œdema of the feet and ankles, which was relieved by confinement in bed for a few days. The heart sounds were feeble at this time.

In January of the following year the œdema was again observed. At this time another careful examination of the urine failed to reveal any kidney lesion. This œdematous condition was noted at various periods down to the time of his last illness. It was always relieved by inducing him to remain in bed for a few days. During the last two years of his life there was observed some tendency to varicosity in the veins of his lower extremities.

On July 10, 1889, the patient appeared to be suffering from some physical discomfort, but no coherent or relevant replies could be elicited from him. He had some diarrhœa, and directions were given as to his diet, and a prescription made. On the following morning my attention was attracted to him by his look of distress. He was sitting up in the ward, breathing in a labored manner, his face cyanotic, and on examination I found his hands cold and bathed in perspiration, pulse rapid and irregular. He was immediately undressed and placed in bed.

It was at once observed on making an examination, that there were scattered over the chest and abdomen numerous petechial spots. Some of these were vesicular in character and varied from the size of a large pin-head to that of a small split pea. The majority, however, had the appearance of minute sub-dermal hæmorrhages. Further examination showed that similar spots were present on the neck and extremities; they were, however, more abundant on the trunk. The most marked peculiarity observed in the patient was the character of his respiration, which was distinctly Cheyne-Stokes The whole respiratory movement, including the period of rest, occupied seventy-five seconds—that is, the respirations occupied one minute from the commencement of faint respiration, with gradual increase and then decrease in volume, rapidity and force; and were succeeded by fifteen seconds of rest or entire cessation of respiration. The number of respirations was thirty per minute. During these periods of apnœa the pupils contracted and did not respond to light, the pulse became slower and more irregular, the face assumed a cyanotic hue, and consciousness seemed abolished. The patient's temperature was but slightly above normal. His pulse was 144, feeble and very irregular, and such was his restlessness and the irregular action of the heart that it was impossible to obtain any satisfactory information as to the heart-sounds.

Stimulants were administered and the patient placed under close observation.

No material change was noted in his condition from day to day for a few days. The pulse continued irregular, and varied from 140 to 160. The respirations continued to show the peculiar Cheyne-Stokes character. On the 18th of July the number of respirations in each period was forty-eight, occupying eighty seconds of time and followed by a period of rest of twenty seconds. During sleep the period of apnœa was observed to be more prolonged; for example, at 1 A. M., July 20th, the respirations were thirty-four in number and occupied sixty seconds, while the period of apnœa was thirty-nine seconds in duration. The pulse was slower, being but 102. At 9.30 A. M., of the same day, while awake, the respirations during several periods were forty in number, occupying seventy-five seconds, followed by a period of cessation of twenty-three seconds duration.

During the night of the 21st the respirations were much more irregular in character than at any time since the commencement of the Cheyne-Stokes phenomenon. At one time, 10 P.M., forty respirations occupied seventy-five seconds with a period of rest of twenty seconds following, and in a short time it was observed that the period of apnœa had wholly disappeared. The respirations continued their peculiar Cheyne-Stokes character, rising from faint, scarcely perceptible respiration to a period of marked dyspnœa, and then falling away to very faint movements. After a few of these periods, the interval of complete cessation again appeared. It was also noticed that during the period of most marked dyspnœa the respirations were distinctly blowing.

At 1.30 P.M., on the 23d, the patient's condition appeared markedly worse. He suffered much more from dyspnœa, and his face was more cyanosed. His extremities were cold and cyanotic. Respirations, forty in eighty seconds, followed by a period of apnœa of twenty seconds. When this observation was made the patient was lying on his right side. After turning upon his back the cyanosis completely disappeared in a few seconds, and his respirations became easier, but did not lose their peculiar character. Subsequent to this it was observed on three or four occasions that a condition of marked cyanosis would disappear when the patient turned from his side to his back. This was true of either right or left side. Occasionally, from the first, just at the close of the period of apnœa, slight convulsive movements were observed in the hands and arms.

On two or three occasions, from this date until his death, the period of apnœa was absent for intervals of from six to fifteen minutes, but the respiratory movements retained the other Cheyne-Stokes phenomena. The petechiæ in some places coalesced and had the appearance of ecchymoses of considerable area. The lungs became emphysematous and the patient showed evidences of exhaustion. Repeated urinary examinations gave only negative results. During the night of August 1st the respirations were more labored and the interval of apnœa more and more prolonged, and at 7 A.M. of the 2d of August the patient died quietly.

Autopsy, eight hours after death.

Body of a fairly nourished man. Ecchymoses and petechiæ over thorax and abdomen. Lungs emphysematous: liver, nutmeg and fatty; spleen hardened; kidneys, macroscopically, apparently in second stage of parenchymatous nephritis. Pericardium contained four ounces of fluid. Heart hypertrophied, with dilatation of left ventricle. Aortic and mitral valves admit three fingers each. Atheroma of one aortic cusp and of right coronary artery. Chronic lepto-meningitis; membranes adherent over vertex; convolutions atrophied; brain œdematous. Ecchymoses in dura to the outer part and above the lateral sinuses, and in the tentorium.

Microscopic examination not yet made.

Edward N. Brush, M.D.,
Senior Assistant-Physician to the Pennsylvania Hospital for the Insane.
Philadelphia.

SURGICAL.

Fibroid Polypi of Bladder. Tubercular Peritonitis.—The following somewhat unusual cases which occurred in my practice may be of interest:

Case I.—A woman, twenty-six years old, stout and robust. About two months ago she aborted and suffered from after-pains due to the retention of clots. When convalescent, symptoms of bladder trouble began. She complained of dragging and burning pain during micturition, which was very frequent, and often accompanied with great vesical tenesmus and slight hæmaturia.

Believing her to be suffering from cystitis, I put her on alkaline treatment, and ordered absolute rest. On the third day of this treatment the pain, tenesmus, and hæmaturia became threatening, and were followed by retention of urine, demanding frequent catheterization and the administration of anodynes, which, however, gave but little relief. The bloody urine was very fœtid and contained some pus. The bladder was washed out with warm solution of borax and carbolic acid twice daily by means of a fountain syringe—filling the bladder with the solution and drawing it off with a soft catheter, which I

found more efficient than the double-current catheter. I continued this treatment for three days, during which time the patient had but little fever, her temperature ranging from 99½° F. to 100° F.

On the sixth day I noticed a hernia or protrusion from the meatus urinarius of a mass somewhat resembling congested and inflamed mucous membrane of the bladder or urethra. This I was very careful to reduce before attempting to use the catheter. The mass obstructed the meatus and distended the urethra, causing great pain and soreness.

Palpation of the bladder, through the vagina, showed its walls to be very thick, tender, and indurated from the inflammation; it also protruded as a well-marked vaginal cystocele.

On the morning of the sixth day I found the patient suffering agonies and almost in collapse. When I examined the meatus the same mass was seen protruding and of a gangrenous appearance. I seized it and made traction upward, downward, and laterally, when it came away, followed by a gush of bloody urine, and great relief to the patient. The tumor was a fibroid polypus about three inches long and one and a half inches in diameter; the pedicle was small, and apparently had sloughed away from the bladder.

The pain this woman suffered was greater than that of labor. After she had somewhat recovered from the shock I washed out the bladder with a warm solution of common salt. After this she was comfortable and suffered but little pain other than tenderness in the urethra on introducing a silver catheter. On the following day the catheter came in contact with a foreign body which seemed to be a pendulous tumor. I regard this as a rare and interesting case, and I hope to be able to remove other existing tumors *per urethram*, by dilatation instead of suprapubic or vaginal cystotomy.

CASE II.— A negro, aged twenty-six years, had been suffering for two years from some abdominal trouble, the symptoms of which were, pain, first in the region of the stomach, then in the liver, then in the umbilical and hypogastric region; vomiting at various times, especially one hour after meals, but the vomited matter never contained blood. Defecation was painful, micturition less so; appetite poor. He was constipated and very much emaciated. There was no cough or pain in the chest. The left leg was œdematous; abdomen at times swollen, and at other times retracted, and when in the latter condition, there was dulness over most of the abdomen; no fever.

The beginning of the attack was so insidious that the patient paid but little attention to it. He died from inanition.

Post-mortem.—All the abdominal viscera were agglutinated and hardened, and everywhere on the peritoneum there were innumerable white papules or milia, which were confluent on the visceral peritoneum, but discrete on the parietal portion; there were no signs of inflammation present. No tubercular deposits were found in the lungs or pleura. The case was evidently miliary tuberculosis of the peritoneum.

The interesting features of this case are the gradual onset, long duration, and that the lungs were not attacked.

W. R. JACKSON, M.D.,
Visiting Physician to City Hospital,
Mobile, Ala.

MEDICAL PROGRESS.

Naregamia as an Expectorant.—The tincture of naregamia is obtained from the stems of the Naregamia Alata, a shrub found in Goa. In some experiments instituted by PROFESSOR DRASCHE (*Therapeutische Monatshefte*) with a tincture furnished by Parke, Davis & Co., doses of 15 to 50 minims were exhibited, the agent showing itself to be a good expectorant, especially when there was an irritative cough due to scanty secretion, or when tough sputum made expectoration difficult. In the latter cases the sputum became more abundant and fluid. Naregamia rendered particularly good service in a case of bronchial catarrh with scanty, tough sputum and occasional attacks of asthma. In four cardiac cases with catarrh of the air-passages naregamia showed good effects. The drug was especially beneficial in emphysema, though in one case it invariably gave rise to vomiting. There were two patients suffering from dyspepsia who had to give up the use of the remedy on account of vomiting. Beside these, one patient (tuberculous) complained of disagreeable sensations, pressure and even headache, which ceased after the medicine was discontinued. Finally, the pure tincture, which has a repulsive taste, provoked in one patient an intolerable irritative cough, which was avoided by prescribing it with cherry-laurel water, thus:

R.—Tincture of naregamia . . 1 drachm.
Cherry-laurel water . . 1 ounce.—M.

Ten drops every hour.—*Pittsburg Medical Review*, May, 1890.

Chloride of Zinc in the Treatment of Cervical Endometritis.—Many cases of mild uterine catarrh, either of the body of the uterus or of the cervix, have been treated by VERGELY with solutions of chloride of zinc. The treatment is commenced eight days after the termination of menstruation, and in the absence of any pain in tissues contiguous to the uterus or ovaries. The vagina and cervix uteri are first irrigated with a hot 15 per cent. solution of boric acid combined with 1 to 200 solution of sublimate. The uterine cavity is then carefully cleansed of all mucus, and a 5 per cent. solution of chloride of zinc applied over the entire surface of the mucous membrane. This operation is repeated two or three times at intervals of eight days, when a more concentrated solution of the zinc may be used. The application is rarely painful, except in cases in which there is much congestion or inflammation. In the latter case the zinc may excite bleeding, which may continue moderately for several hours. Should there be fungosities, or should the ulceration not yield promptly to the zinc treatment, one may employ a solution of chromic acid (1 to 3). The latter gives very little pain, and produces a yellow slough which falls off in about six days. It may be well to alternate the chromic acid with the zinc. Great care must be used that these solutions are applied only to the diseased tissues, and after their use the tissues should be again irrigated with the boric acid sublimate solution, this being followed by the introduction of a vaginal tampon of cotton, which should be retained twenty-four hours.—*Archives of Gynæcology*, May, 1890.

Thyroid Asthma.—DR. G. A. WRIGHT has observed five cases of what he calls "thyroid asthma," which is dys-

pnœa caused by pressure upon the trachea by an enlarged thyroid gland.

In three cases the glandular enlargement was simple hypertrophy; in one case the patient was cretinoid; in one the glandular enlargement was coincident with all the symptoms of Graves's disease. In all cases the dyspnœa was due to direct pressure upon the sides of the trachea by the enlarged lateral lobes drawn tightly together by the isthmus, and the trachea was typically "scabbard-shaped."

Four cases were young adults; the fifth was a child of two or three years of age. In two of the cases tracheotomy only was performed; in two the isthmus only was divided, and in one case the trachea was opened and the isthmus divided twenty-four hours later. Four of the patients died, one (the child) from broncho-pneumonia; one from œdema of the lungs, the obstruction being only partially relieved; two from slipping of the tracheotomy tube in consequence of the depth of the trachea from the surface. The patient who recovered was the young man in whom division of the isthmus was performed in the interval between attacks of dyspnœa. Certain points seem to be fairly well established in regard to thyroid asthma, and some of them are illustrated by these cases: 1. The onset of the symptoms is often sudden, urgent, and spasmodic. 2. The symptoms are due to direct lateral pressure upon the trachea. 3. The mechanical pressure is only remediable by mechanical means. 4. Tracheotomy is attended with considerable difficulty and there are subsequent dangers of cellulitis, of slipping of the tubes, and of lung complications. It is, moreover, not curative. 5. Division of the thyroid isthmus is a comparatively simple operation, is followed in a large proportion of cases by shrinking of the gland, at once partially relieves dyspnœa, and avoids the evils which follow complete removal of the gland. It is not usually accompanied by much hæmorrhage. 6. Division of the thyroid isthmus combined with tracheotomy has been found to give a very high rate of mortality. 7. If tracheotomy is performed a specially long tube is required.

Mr. Wright thinks that to relieve symptoms and diminish mortality the proper course is to divide the isthmus at the first sign of increasing dyspnœa, and although the onset of thyroid asthma is often sudden, there is usually time to operate before the symptoms become very urgent, if there is no delay. If the case is allowed to continue long, there may not be time for the trachea to recover its shape sufficiently to allow respiration to go on. Specially long and large tubes should be employed for these cases, the depth of the trachea from the surface allowing only a very short length of any ordinary tracheotomy tube to lie in the trachea, and as swelling takes place after the operation, this short length is still further lessened. The occurrence of fatal pressure upon the trachea in Graves's disease must be exceedingly rare, and the author has not found a reference to such a case. Anæsthesia in these cases requires much care, and though in some it may diminish spasm and lessen dyspnœa, it is more likely to complete the asphyxia during the early stages of administration.—*Journal of Laryngology and Rhinology*, May, 1890.

Chloralamid Hypodermically.—SCHMIDT employs chloralamid hypodermically, the solution used being thirteen grains of chloralamid dissolved in five drachms of distilled water. Sixteen minims of this subcutaneously is usually a sufficient dose, and acts more rapidly than larger doses given by the mouth.

Morvan's Disease.—In 1883 Morvan described an "analgesic paresis with whitlows of the upper extremities," a case of which was recently lectured upon by CHARCOT (*Le Progrès Médicale*, March 15 and 22, 1890), who pointed out the following characteristics: The disease usually begins with pain in the fingers, followed by paresis and analgesia of one hand and forearm, then of the other; and, finally, whitlows form and are followed by necrosis of the phalanges. In some cases paresis and analgesia are absent, and the only symptom is the progressive formation of whitlows, which may or may not be painful, and necrosis. Other trophic affections of the hands, such as fissures, perforating ulcers of the palm, lividity of the skin, lowered temperature of the part, and increased secretion of sweat, have been observed. The duration of the disease is very long and the prognosis grave.—*Medical Chronicle*, May, 1890.

Hæmorrhage during Pregnancy.—DR. A. E. AUST-LAWRENCE recently read a paper before the Bath and Bristol Branch of the British Medical Association in which he dealt as follows with all the causes of hæmorrhage during pregnancy (*British Medical Journal*, May 10, 1890):

1. Persistence of menstruation. This the author considers possible but exceedingly unusual, and apparently thinks that most of the cases reported are errors in diagnosis.

2. Bleeding from an eroded and granular cervix. Here a little blood is lost at irregular intervals, increasing in amount at what would be the menstrual periods; or there may be a continuous discharge of brown mucus in variable amounts.

The treatment of these cases should consist in the application of nitric acid to the erosions, or of simple astringent injections. In some instances the erosion extends into the cervical canal or uterus, and if hæmorrhage is continuous and exhausting the patient, induction of labor is the only recourse. In the latter form of hæmorrhage an examination will reveal the blood exuding from the os.

3. Hæmorrhage from malignant disease of the cervix. In this form the diagnosis is, of course, readily made by a vaginal examination.

Induction of labor will always check bleeding from this cause to a great extent. If pregnancy is permitted to continue, the hæmorrhage will increase with the growth of the uterus.

4. Hæmorrhage may also be caused by simple or malignant ulceration of the vagina, by vascular growths of the meatus, and by ruptured vaginal veins.

The diagnosis of these conditions is easy, and treatment should be conducted on general principles.

5. Hæmorrhage due to some fault of the placenta. The position of the placenta may be normal but the organ deficient in the trabecular structure which supports the bloodvessels, or the vessels may be weakened by fatty degeneration. In either of these conditions slight

causes will produce hæmorrhage. Unfortunately, the author gives no data by which this form can be distinguished from bleeding erosions high in the os.

Ergot in small doses, and opium, should be administered, but if they are ineffectual and the loss of blood is reducing the woman, no time should be lost in inducing labor and clearing out the uterus.

6. Bleeding from accidental separation of the placenta. Hæmorrhage from this cause may be either external or internal and concealed. In either case the uterus should be emptied without delay.

Placenta prævia the author merely referred to as the remaining cause of hæmorrhage during pregnancy.

Thyroid-grafting in Myxœdema.—Since the intimate connection between the destruction of the thyroid and the production of myxœdema has been generally known, there have been various suggestions made for the relief of myxœdematous patients. MR. VICTOR HORSLEY has shown that it is quite possible to graft the thyroid on the peritoneum in some animals, and has suggested that some similar operation might be attempted in man. M. Lannelongue has made an attempt to carry out this suggestion on a little girl with myxœdema, for whom nothing better could be expected than a chronic cretinoid condition (*Le Progrès Médicale*). A thyroid gland was taken from a young sheep, and two-thirds of it grafted on the child's thorax just below the right breast. The operation presented no difficulty, and on March 7th, when Lannelongue reported the case to the Société de Biologie, the graft had taken firm hold and was doing well. What may be the prognosis of such a case only time can determine. M. Chauveau thought it probable that the foreign tissue would be absorbed, but M. Dastre considered this unlikely with a blood-gland like the thyroid, although it was the common fate of other tissues.—*Practitioner*, May, 1890.

Incontinence of Urine in Children.—Dr. A. JACOBI writes as follows upon the treatment of incontinence of urine in children (*Archives of Pediatrics*, June, 1890):

Attention must be paid to the capacity of the bladder. In every case, particularly in the evening, the quantity of fluid should be restricted. The sigmoid flexure and the rectum must be empty in the night, and the patient should be encouraged to evacuate both bladder and rectum before retiring. After a few hours' sleep the children ought to be taken up and roused sufficiently for both purposes.

Muscular debility of the neck of the bladder requires general and local stimulation. Strychnine or other preparations of nux vomica prove effective, to a certain extent, by improving both the general innervation and the appetite; in desperate cases an occasional subcutaneous injection into the perineum (gr. $\frac{1}{40}$ to $\frac{1}{16}$) has rendered good service; an ointment of one part of extract of nux vomica in from ten to sixteen parts of fat, introduced into the rectum, in pieces the size of a coffee or lima bean, several times daily, will also act well and can be continued for some time. The same indication is fulfilled by ergot, the fluid or the solid extract of which may be employed internally. The interrupted electrical current is perhaps the most powerful local stimulant; one of the electrodes must be applied to the perineum, the other to the hypogastrium or the lumbar region. It is not advisable to apply one pole to the interior of the urethra or bladder, because of the danger of urethritis and cystitis.

Whenever there is oxalic acid or sugar or an excess of urates and phosphates in the urine, the source of the disturbance must be attended to. The hyperæsthesia of the bladder, complicated or not with catarrh, requires belladonna or its alkaloid. In many cases a single evening dose of extract of belladonna (gr. $\frac{1}{4}$ to $\frac{3}{4}$ to 1) or sulphate of atropine (gr. $\frac{1}{100}$ to $\frac{1}{75}$) answers well, sometimes to an unexpected degree. Bromide of potassium (grs. vj to xxv), camphor (gr. ij to v), fluid extract of hops (♏ iv to x), or the elixir humuli of the National Formulary in teaspoonful doses, given at bedtime, are also useful.

Irritability of the neck of the bladder and the prostatic part of the urethra has been treated by Henry Thompson with cauterization by means of a two per cent. solution of nitrate of silver. A solution of 1 to 1000 will be found sufficient, or a solution of tannin or alum 1 or 2 to 100. A still better plan is to introduce either an elastic catheter or a metal sound into the bladder, every few days, for two or four minutes. A few drops of a solution of cocaine instilled into the urethra a few minutes before the insertion of the instrument will in many cases render general anæsthesia superfluous.

Formulæ for Intestinal Antiseptics.—DUJARDIN-BEAUMETZ recommends salicylate of bismuth as an intestinal antiseptic, and gives it according to the following formulæ:

1. R.—Salicylate of bismuth, Magnesia, Sodium bicarbonate, of each, 2½ drachms. —M.
Divide into 30 powders.

2. R.—Salicylate of bismuth, Prepared chalk, Phosphate of lime, of each, 2½ drachms. —M.
Divide into 30 powders.

3. R.—Salicylate of bismuth, Beta-naphthol, Powdered charcoal, of each, 2½ drachms. —M.
Divide into 30 powders.

4. R.—Salicylate of bismuth, Salol, Powdered charcoal, of each, 2½ drachms. —M.
Divide into 30 parts and administer in capsules or wafers.—*Therapeutic Gazette*, May 15, 1890.

An Enormous Vesical Calculus.—BRIGADE-SURGEON BARTER, of Nagpore, reports the case of a broken-down man who applied to him for the removal of a vesical calculus (*Indian Medical Journal*, March, 1890). A full-sized lithotrite was introduced, but could not be made to grasp the stone. The lateral perineal incision was then made, but it was impossible to extract the stone through this opening, and the suprapubic operation was finally resorted to. The stone weighed nineteen ounces five drachms, and was ten inches in circumference. The patient died forty-eight hours after the operation.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author.

Address the Editor: H. A. HARE, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including Postage.

PER ANNUM, IN ADVANCE . . . . . $4.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, MAY 31, 1890.

INTESTINAL OBSTRUCTION FOLLOWING HYSTERECTOMY.

ONE of the most annoying and dangerous sequelæ of abdominal and pelvic operations is obstruction of the intestines resulting from adhesive inflammation. After laparotomy, it not infrequently happens that the patient, after recovering from the primary operation, has repeated attacks of pain, with rise of temperature and abdominal tenderness. In some cases these symptoms disappear after free catharsis and counter-irritation over the abdomen. In others, however, the affection is not so easily cured, and to relieve the patient a second operation is necessary. Thus, in a case recently observed, the removal of the tubes and ovaries was followed by apparent recovery, but some weeks after operation abdominal pain, high temperature, and tenderness rendered a second opening of the abdomen necessary. Intestinal adhesions were separated, and the abdomen was allowed to remain open sufficiently to enable the operator to inject repeatedly a weak solution of boro-glyceride into the abdominal cavity. Although the patient was extremely ill, recovery finally ensued.

In the *American Journal of Obstetrics* for May, 1890, COE, of New York, calls attention to intestinal obstruction following vaginal extirpation of the uterus. The case was the second in his experience, and the tenth which he had been able to find recorded. The extirpation was successfully accomplished without the application of ligatures, the right ovary and tube being removed, the left remaining. Iodoform gauze was used as a tampon and, to prevent prolapse of the intestine, was pushed higher up than usual. The patient did well until the evening of the second day, when the abdomen became distended, the temperature elevated, and the pulse increased in frequency. Fæcal vomiting determined the necessity for laparotomy. Two or three coils of ileum were adherent to the edges of the peritoneal wound and were easily detached. There were no indications of peritonitis, and the edges of the womb felt healthy. Death followed from shock, and the autopsy showed that the principal point of obstruction had been in the lower eighteen inches of the ileum. The small intestine was generally collapsed, the large moderately distended. There were evidences of commencing peritonitis. Septic infection could not be recognized.

In discussing the case, Dr. Coe raises the question why the secondary operation is so often fatal when laparotomy for primary obstruction is not infrequently successful. He also questions whether an improvement in the technique of extirpation might not remove this danger. It has been observed that the danger of this sequelæ is reduced to a minimum if the peritoneal cavity is closed at the time of operation. This is done by suturing the peritoneum to the edge of the vaginal wound. In many cases, however, it is impossible to do this by reason of the narrowness of the field of operation. The stumps of the broad ligaments should be brought down and attached to the edge of the vaginal wound, which will place the sloughing tissues outside the peritoneum, and there will remain no raw surface in the pelvis to which a loop of intestine might become adherent. If adherence does occur, it can be satisfactorily treated only by laparotomy. This should be done as soon as possible, and without disturbing the patient more than is necessary. These cases, however, have manifested an unusual fatality after the secondary operation, and the complication of intestinal obstruction after vaginal hysterectomy must be regarded at present as fatal, and should stimulate further study and investigation on the part of those who perform these operations. It is, of course, needless to say that septic infection is the most frequent cause of inflammation, and that the first precaution is the securing of absolute asepsis.

SOCIETY PROCEEDINGS.

THE AMERICAN MEDICAL ASSOCIATION.

Forty-first Annual Meeting, held at Nashville, Tenn., May 21, 22, and 23, 1890.

(Continued from p. 579)

Third Day—General Session.

The meeting was called to order by the President, Dr. Moore, at 10 A.M. Following this, the Rev. R. L. Cave offered prayer.

The chairman of the Nominating Committee, Dr. Eugene Grissom, submitted the following report of the names of the persons nominated by the Committee on Nominations to fill the various offices in the Association for the ensuing year:

President.—W. T. Briggs, M.D., Tennessee.

First Vice-President.—C. A. Lindley, M.D., Connecticut.

Second Vice-President.—R. C. Moore, M.D., Nebraska.

Third Vice-President.—H. C. Wyman, M.D., Michigan.

Fourth Vice-President.—L. P. Gibson, M.D., Arkansas.

Treasurer.—R. J. Dunglison, M.D., Pennsylvania.

Permanent Secretary.—W. B. Atkinson, M.D., Pennsylvania.

Librarian.—C. L. Richardson, M. D., District of Columbia.

Trustees of Journal.—J. B. Hamilton, M.D., District of Columbia; J. V. Shoemaker, M.D., Pennsylvania; D. E. Nelson, M.D., Tennessee.

Judicial Council.—X. C. Scott, M.D., Ohio; W. F. Peck, M.D., Iowa; J. A. Lane, M.D., Kansas; J. H. Murphy, M.D., Minnesota; J. J. Happel, M.D. Tennessee; D. J. Roberts, M.D., Tennessee; A. Garcelon, M.D., Maine.

San Francisco, California, was chosen by the committee as the place of next meeting. Date, first Tuesday in May, 1891.

E. L. Shurley, M.D., of Michigan, was appointed to give the Address on General Medicine.

Joseph M. Mathews, M.D., of Kentucky, Address on General Surgery.

W. L. Schenck, M.D., of Kansas, Address on State Medicine.

The Convention adopted the report of the committee, substituting, however, Washington, District of Columbia, for San Francisco, California, as the place of meeting in 1891.

Dr. W. C. Patterson, M.D., was appointed chairman, and C. H. A. Kleinschmidt, M.D., secretary of the local committee.

ADDRESS ON GENERAL SURGERY.

In the address on General Surgery by Dr. Samuel Logan, of New Orleans, a very careful synopsis of recent surgical progress was given. The author summarized the conclusions of the famous Hyderabad Chloroform Commission, and contrasted with their results the findings of Dr. H. C. Wood and Dr. H. A. Hare, both of Philadelphia, who state that though pariah dogs may perish from chloroform-poisoning by primary respiratory failure, experiments on an equal number of American dogs show that in them heart failure first appeared. The speaker stated that further investigation, and particularly large numbers of careful clinical observations, were necessary before the question could be settled. He particularly cautioned against giving chloroform vapor in concentrated form, and against continuing the administration when there is the slightest embarrassment in breathing. Gradual introduction of the vapor is the golden rule in using this agent. Allusion was made to recent deaths following the administration of chloroform, and to experimental research showing fatty degeneration of the heart in such cases. Local anæsthesia was briefly discussed, then antiseptics, particular attention being given to Lister's double cyanide gauze, introduced into this country by Professor J. William White, of Philadelphia. The dry method of wound treatment was advocated on the ground that prompt primary union followed in all suitable cases; drainage was advocated only when the surgeon could not be sure that the wound was aseptic, and where, through difficulty in producing close approximation, a cavity was left for the accumulation of fluids. In cerebral surgery the speaker was greatly influenced by von Bergmann's valuable monograph upon this subject. The skull should not be opened except where there is a positive diagnosis, and even then, in case of tumor, the outlook for the patient is gloomy. A brilliant future was predicted for spinal surgery and a tribute paid to the writings of Professor J. William White upon this subject. Abdominal surgery was dwelt upon at length. The speaker, alluding to the curative effect of abdominal section *per se*, not only in cases of tubercular peritonitis, but also where large tumors, such as uterine myomata, were present, Appendicitis and its sequelæ were considered, and an operation for relief of relapsing cases in the interval of attacks was advised only when these attacks were increasing so much in frequency and severity as to cause fear of perforation.

ADDRESS ON DIETETICS.

The address of Dr. E. A. Wood, Chairman of the Committee on Dietetics, then followed.

The speaker pointed out the evil results which follow the unguided administration of food to children. Many persons in the white race of this country are weak and poorly developed, with small bones and bad teeth. The jaws and teeth of children should receive their proper exercise, in order that they may attain their proper development and serve their proper function in the process of digestion.

Starch foods washed into the stomach without admixture with saliva are not digested. The average child fed on firm food requiring mastication will grow up with strong, square jaws, and will become a vigorous and well-developed adult. The speaker exhorted the medical profession to come to the rescue, and instruct parents how to feed their children.

The Committee on Dietetics reported through Dr. Frank Woodbury, of Philadelphia, and offered the following motion:

Resolved, That the word "Physiology" be taken away from Section I., and that a new section be formed called the "Section on Dietetics and Physiology."

The motion was carried.

A report followed from the Committee on American

Colleges, advising preliminary examinations for admission to medical schools, annual examinations, and a three years' course.

The Convention accepted the report, and passed a resolution heartily endorsing the sentiments expressed therein.

Dr. Moyer, of Chicago, offered the following:

Resolved, That at future meetings of this Association the business of the general session shall be conducted entirely from the floor of the house, and no one occupying a seat on the platform, excepting the Secretary, shall be recognized by the President; provided, however, that nothing in this resolution shall be construed so as to prevent the Chairman from inviting members to address the Association from the platform.

Dr. Davis moved to amend by adding "and the Chairman of the Committee of Arrangements" after the word Secretary. Carried.

Section of Diseases of Children.

The meeting was called to order at 2.30 P. M. by J. A. Larrabee, M.D.

A paper was read by Dr. W. L. Stowell, of New York, on "The Significance of High Temperature in Children."

The author summarized his article as follows:

The child's temperature is normally higher than that of the adult. The temperature may be very high from apparently trifling causes, usually nervous impressions or reflex disturbance. All the febrile diseases have what might be called their normal range of temperature, and it does not indicate treatment unless excessive or out of its normal course. Antipyretics are to be used with caution, lest while they lessen fever they, by weakening the heart, lessen the chance of favorable termination of the disease.

The temperature may often be lessened indirectly by heart tonics, general tonics, and food.

The tendency of nutrition in childhood is toward growth and repair, not degeneration, hence careful nursing and feeding will do more toward a favorable result than converting the child into an assaying pot for drugs.

Dr. Watson thought that we are too much inclined to treat the fever and not the cause of it. He is never alarmed at high temperature unless it becomes excessive or heart trouble is present. The high temperature sometimes produces a weak heart or some nervous manifestations. In these cases he uses small doses of antipyrine combined with digitalis. In other cases he prefers sponging the body with cold or luke-warm water. Special care should be given to diet.

The gastric juice in high temperature undergoes such changes that digestion and proper absorption of drugs cannot be expected. It is then far better to resort to sponging.

Dr. Woodbury, of Philadelphia, said that he tries to differentiate cases of fever into those where the temperature is a result of some previous excitement in which a nervous element exists, which cases he treats by quiet and cool applications; and cases due to some poison in the blood in which the primary indication is to get rid of the cause. Is the fever an effort of nature to get rid of some offending force? Fever is a form of energy, its source being food and oxygen. This energy is expended in three ways: First, it serves to keep up the temperature of the body; second, it keeps up the energy demanded to perform the involuntary actions of the body; and, thirdly, it is expended in keeping up the voluntary movements. Foods should be used which can be digested in the small intestine. The suggestion recently made in some of the foreign journals to allow patients to cool off uncovered in a cold room is not advisable in the exanthematous diseases.

Dr. Brush, of New York, stated that he does not believe the thermometer to be an instrument of such accuracy as is generally believed. He thinks there is an *expression* in temperature shown often by the manner in which the mercury rises. When it ascends rapidly, shoots up, so to speak, in children, he knows that there is not going to be much trouble with the case, but when the mercury ascends slowly but steadily, danger can be anticipated. He finds that a warm, stimulating injection in these cases often has a most beneficial result.

Dr. Larrabee stated that he does not pretend to treat, but that he *manages* fever. Severe hyperpyrexia, of course, must be controlled. His method is to wring out a sheet in hot water, and then when it is warm, to envelop the child with it and give an enema.

The Section now adjourned to meet with that on Laryngology to discuss diphtheria and croup.

Dr. Carl Seiler, of Philadelphia, in opening the discussion on the duality of croup and diphtheria said that in his belief they were certainly different diseases. In diphtheria there is always a peculiar characteristic odor about the body and a marked difference between the membrane found in the two states. Again, diphtheria comes suddenly, while croup develops slowly. The poison of diphtheria varies very much in its effects in children of the same family sick at the same time.

Dr. Porter, of St. Louis, thought duality not yet proved and recognized no such thing as membranous croup as distinct from diphtheria. He did not believe that diphtheria always came on suddenly, and had seen cases develop very slowly. There is no difference in the membranes, and difference in the color of the membrane has nothing to do with the diagnosis.

Dr. Jackson, of Syracuse, thought that diphtheria was purely a local infectious disease. He has seen many cases where the pharynx was clear and the membrane could only be found in the larynx, but primary laryngeal diphtheria often ascends to the pharynx. It may even ascend from a diphtheritic bronchitis. As to symptoms, he thought that the characteristic odor was not always present. The Germans make a pathological difference between croup and diphtheria. When the membrane lies simply upon the surface and can be easily coughed up or dislodged, and when it is incorporated with the surface upon which it lies by infiltration. If a case shows constitutional septic infection and gives rise to other cases, we must look upon it as one of diphtheria. In no disease is the temperature less of a guide as to diagnosis and prognosis than in diphtheria. In conclusion the speaker stated that he did not recognize the difference between membranous and diphtheritic croup.

Dr. E. R. Early, of Pennsylvania, then read a paper on "Croup," in which he gave the history of the disease, its clinical features and treatment. His treatment con-

sists of a primary emetic, gentle rubbing and friction of the body, large and repeated doses of quinine, and in hyperpyrexia the administration of the chlorate of potassium or sodium. He never gives calomel or any remedies which would weaken the system.

Dr. H. D. Didama, of Syracuse, thinks that there is a difference to be recognized between croup and diphtheria.

Dr. W. H. Daly, of Pennsylvania, reiterated his own plan of treatment and called upon the profession to give it a trial. He gave his method as follows: To a child three or four years of age he gives five grains of pure unmixed calomel, and repeats the dose in from one to two, or three hours, or until free catharsis follows—the stools should be of a light green pea-soup color. Then he lengthens the interval of the dose, being careful not to diminish the amount, but being careful to keep up the mild catharsis for at least one or two days. Ptyalism and depression rarely follow this treatment; the membrane exfoliates and re-forms with less and less readiness. At the same time care should be given to diet, which must be light but highly nutritious. The patient must be kept in a recumbent posture until convalescence is well established.

Dr. Shimwell, of Philadelphia, speaking of operative measures, said he had had some experience with intubation and much preferred it to the more serious operation of laryngotomy. He advised early interference.

Dr. Brush said that he had had only three successes out of thirty-three cases, but that he was still in favor of the operation. It is often most difficult to feed the child, but this can be overcome by the use of a long-tubed nursing bottle and letting the child lie flat on the bed without any pillow. It will almost invariably suck.

Dr. H. C. Scott advocated a plan of local treatment with which he has had great success. He uses a saturated solution of iodoform in ether. Applications should be made twice daily with a brush or by spray. It stops pain within five minutes and he finds the membrane does not extend but soon exfoliates. Dr. Scott has cured many cases of diphtheritic conjunctivitis by the use of this method.

Friday, May 20, 1890.—No papers were read in the Section on this day, the only business being the election of new officers. Dr. William Perry Watson, of Jersey City, was made Chairman, and Dr. H. A. Hare, of Philadelphia, Secretary.

SECTION OF PRACTICE OF MEDICINE, MATERIA MEDICA, AND PHYSIOLOGY.

J. H. MUSSER, M.D., of Philadelphia, *Chairman.*

The following papers were read by title: "Influenza," by Dr. J. B. Johnson, of Washington, D. C.; "Treatment of Bright's Disease with Chloride of Sodium," by Dr. A. Memminger, of Charleston, S. C.; "Abuses of Antipyretic Medication," by Dr. S. Solis-Cohen, of Philadelphia; "Note on a Case of Fatal Leukæmia following Prolonged Lactation," by Dr. W. W. Jaggard, of Chicago, Ill.; "Facial and Thoracic Deformities Incident to Obstruction of the Naso-pharynx," by Dr. W. E. Casselberry, of Chicago; "Antisepsis," by Dr. Hiram Corson, of Conshohocken, Pa.; "Cleanliness and Pure Air in Maternity Work," by Dr. Joseph Price, of Philadelphia; "The Ocular Complications of Malaria," by Dr. George E. de Schweinitz, of Philadelphia; "Continued Fever of Charleston, S. C., or Gastro-hepatic Fever," by Dr. Thomas Legare, of Charleston, S. C.; "Chemical and Bacteriological Examination of Water Supposed to have Caused Typhoid Fever," by Dr. Victor C. Vaughan, of Ann Arbor, Mich.; "Naphthol in Typhoid Fever," by Dr. L. Wolff, of Philadelphia.

Following these DR. J. M. FRENCH, of Cincinnati, Ohio, read a paper on "Oxygen; its True Value as a Therapeutic Agent."

DR. E. L. SHURLEY, of Detroit, then read a paper on "The Local Treatment of Phthisis Pulmonalis," in which he advocated the local use of creasote by a modification of insufflation and forced inspiration.

In discussion, Dr. W. F. Bateman, of Indiana, thought prophylaxis should be our chief study, but that when phthisis was already developed roborant treatment gave the best results.

Dr. Powell, of Tennessee, said he had used creasote in his own case, but without benefit.

Dr. McIntosh, of Georgia, thought local treatment relieved only the catarrhal symptoms.

Dr. Bailey looked on the method advocated as marking a distinct advance in therapy.

Dr. de Saussure, of Charleston, S. C., had found benefit from local treatment in phthisis, which he distinguished from tuberculosis.

Dr. Shurley, in closing, said he had purposely not considered tuberculosis, and that he always combined general with local treatment.

A paper on "Functional Albuminuria" was then read by DR. WILLIAM B. DAVIS, of Cincinnati. This was a very able and exhaustive essay, in which the subject was considered in all its aspects. In one patient seen by the author, albuminuria persisted for five years without other symptoms of disease, the albumin sometimes amounting to one-tenth the bulk of the urine on boiling. In another case, after alcoholic excess, the urine became solid on boiling.

Dr. V. C. Vaughan, of Ann Arbor, said that he had systematically examined the urine of 3000 students, and in only ten had he found albumin. He looked on three tests only as reliable—viz., heat and nitric acid, overlaying, and the ferrocyanide and acetic acid test. All the other methods gave reactions with many substances beside albumin, such as quinine and other alkaloids, etc.

He thought in all cases in which albuminuria was more than temporarily present, renal lesions followed in time.

DR. HAROLD N. MOYER, of Chicago, then read a paper entitled "Hydrophobia, a Clinical Study, with Statistics and Reports of Cases." The speaker objected to the word hydrophobia as misleading, and describing only a symptom and not peculiar to the disease under consideration. He preferred the term rabies.

The author's conclusions are, that there is a substantial identity between rabies, as seen in this country and Europe; that it is not a psychosis, and bears little or no relation to diseases of the mind.

Dr. A. Lagorio, of Chicago, then read an exhaustive account of Pasteur's investigations and methods.

Dr. Kiernan, of Chicago, said he believed that so-called hydrophobia was really lyssophobia, and he denied the existence of the former as a distinct infectious disease.

Dr. Scott, of Cleveland, Ohio, said that numerous examples of rabies could not be gainsaid, but he thought that Pasteur's statistics showed less success with rabies than with lyssophobia.

Dr. Bulkley, of New York, described the case of a child bitten in the face by a rabid dog four years ago, and treated by Pasteur, and showed the great candor and honesty of Pasteur in regard to his statistics.

Dr. Sears, of Texas, mentioned the "polecat-origin" theory of rabies, and said that he knew from experience the reality of rabies as a disease.

Dr. N. S. Davis, of Chicago, said he had treated but one case of hydrophobia, and in that it was impossible to find the external lesion. He used applications of carbolic acid and hyposulphite of sodium externally in cases of dog-bites.

Dr. Sawyer, of Cleveland, Ohio, showed a modification of the kymographion.

Dr. H. B. Baker, of Lansing, Mich., read a paper on "Malaria, and the Causation of Periodic Fevers, Showing their Dependence on Certain Meteorological Conditions."

Dr. George Dock, of Galveston, Texas, read a paper on "Researches in the Etiology of Malaria and the Microörganisms of Laveran."

A number of papers were read by title and ordered to be printed.

Section of Obstetrics and Diseases of Women.

Dr. Marie Werner, of Philadelphia, read a paper upon the "Fistulous Escape of Ligatures after Abdominal Operations" in which she advocated good drainage, and detailed the dangers following abdominal section. Dr. Werner described two cases in which the stump ligatures were thrown off by fistulous tracts on account of leaving the drain too long time in place—eight days in one case, three weeks in the other. Statistics were read to prove that nearly every operator has had just this trouble.

In discussion, Dr. Wathen, of Louisville, Ky., said that all who do abdominal work have seen such fistulæ, which are analogous to stitch-hole abscess. Such abscesses can best be obviated by using the smallest size twisted silk suture. He thought it unwise to place catgut or kangaroo tendon in the peritoneal cavity. He did not think it necessary to remove both ovaries when only one was diseased.

Dr. Reamy denied with warmth the theory that salpingitis was always due to gonorrhœa.

Dr. A. F. Currier, of New York, said that the surgeon should remove diseased parts only.

Dr. Howard Kelly, of Baltimore, has had forty pus cases. In his first operation he left the healthy appendages. In two years the remaining appendages required removal. In none of his cases, where one ovary was much diseased, did the second ever appear perfectly healthy. He advocated small silk ligatures.

Dr. Van Emen, of Kansas City, did not believe that because one ovary is diseased the other should be removed to anticipate future trouble. The speaker has never seen unilateral salpingitis.

Dr. Myers, of Fort Wayne, Ind., said that catgut ligatures are the muscular coats of the bowels and readily take up septic matter. He uses silkworm gut.

Dr. Reed, of Cincinnati, asked if Dr. Myers used silkworm gut as an intra-peritoneal ligature. To which Dr. Myers replied that he did. Dr. Reed was surprised at this, for silkworm gut is not absorbed, and is a dangerous foreign body ready to set up mischief.

Dr. Johnstone, of Danville, Kentucky, used American silk five years ago, but found that it formed abscesses. He now uses English silk and has no trouble. He has found all American silk more or less adulterated with flax and cotton.

Dr. J. Price, of Philadelphia, believed that fistulæ and discharge of ligature are due to imperfect work and not to the material used. Such accidents arise from not tying close to the uterus, and from leaving cheesy, broken-down matter behind. He was surprised that anyone should advise the use of catgut or silkworm-gut in the abdominal cavity. He always uses light, carefully prepared silk. The drainage-tube is usually not the cause of the discharge of ligatures, as the stump is some distance from the end of the tube.

Dr. Hoffman, of Philadelphia, objected to catgut ligatures. One would not leave a rubber ligature on a stump because it keeps up continuous pressure, and catgut acts in the same way. Silk is the ideal ligature. In operating, Dr. Hoffman believes that if a pus tube on one side be due to specific disease, the other tube should not be allowed to remain. He also said that Dr. Price removes both for a unilateral hydrosalpinx, for pus tubes frequently follow this disease.

Dr. Wathen said that physicians are frequently begged to save one ovary for child-bearing purposes after recovery, and that tubal trouble is seldom unilateral.

Dr. Reamy said that many patients with unilateral pyo- and hydro-salpinx bear children afterward. This ability is a test of recovery.

Dr. Price called Dr. Reamy's attention to a case said to have recovered and conceived, yet her husband had been castrated five years previously.

Dr. E. E. Montgomery, of Philadelphia, was unavoidably absent, and his paper upon "Extra-uterine Pregnancy" was read by title only.

Dr. Reed, of Ohio, spoke in favor of employing a stenographer for reporting the discussions, the cost to be borne by the Section. He moved that the amount be assessed *pro rata*. Carried.

The next paper was by Dr. Joseph Hoffman, of Philadelphia, and was entitled "A Plea for the Adoption of the Traction Forceps." He said that these forceps should not be used to lessen the physician's work, but that in certain cases they will save both mother and child from injury. Old forceps are pressure instruments, and work upon the principle of fire-tongs. When there is much maternal pressure the force is great upon the fœtal head, and here we get the factor which causes the perineum to be torn. External forces, to be efficient, must act in the direction of the pelvic axis. The Tarnier modification is the latest and best form presented in which the centre of pull approximates the centre of the fœtal head. Dr. Hoffman exhibited several forms of forceps to the Section, and said that the Tarnier modification cannot rupture the perineum, because the traction rods fall within the blades of the forceps. Rotation determines the path in which the head will go. Axis-traction forceps give us a lower mortality-rate to the mother and child than any other instrument.

Dr. Joseph Price, of Philadelphia, in discussing Dr.

Hoffman's paper, said that by using these forceps many large-headed children, which we formerly lost, could be saved. Dr. Price prefers the Hodge or Simpson blade. He agreed with Dr. Hoffman as to the use of axis-traction forceps, by the use of which fewer tears result, and fewer still-births.

Dr. Currier, of New York, said that any one understanding mechanics could see the great advantage of traction forceps, and that much was due to Dr. Hoffman for his lucid explanation of the forceps and their use.

DR. JOSEPH PRICE, of Philadelphia, read "A Retrospect of Pelvic Surgery." Time, he said, has greatly changed methods of diagnosis. The good surgeon now must know when to operate and what to operate on; in other words, in what cases operation would be of no avail to the patient. Ectopic gestation was formerly left alone. Now electricity or injections of morphine are being advocated to relieve the condition which only the knife can cure. Tubal troubles are still dubbed cellulitis by some. Electricity may alleviate the pain of these diseases, but cannot cure by removing the cause.

Are the so-called conservative surgeons safe? We do not attempt to cure abscesses or fibroid tumors outside of the pelvis by electricity. Why, then, use it for pelvic abscesses? Early operation was advised for neoplasms as well as for tubal disease. Too many surgeons fear and attempt to explain away unfortunate sequelæ by accusing instruments, tubes, etc., when the operator alone is at fault. Hernia, however, cannot always be avoided, even by the most careful. They are, therefore, excluded from the avoidable sequelæ.

The next paper was by DR. GEORGE E. SHOEMAKER, of Philadelphia, and was entitled "Drainage in Abdominal Surgery." Dr. Shoemaker said that the drainage-tube is of great advantage when hæmorrhage or active sepsis has occurred, but that the peritoneum can probably absorb all aseptic matter. Small and invisible bowel-perforations may occur and cause trouble if the tube is not used.

An objection urged against the tube is that it may aid in causing a hernia. This may be obviated by inserting sutures close to the tube; by keeping the patient in bed, and by causing her to wear a supporting band. Again, it is said that the tube permits septic material to enter the peritoneal cavity. The tube should be kept clear, and when removed replaced by a rubber drain. We should use the drainage-tube in all cases of doubt.

In the discussion of the papers of Dr. Price and Dr. Shoemaker, Dr. Bond, of St. Louis, gave his unqualified praise to both.

Dr. Hoffman said that he had put drainage to the most severe tests and agreed in every particular with Dr. Shoemaker. The speaker detailed a pus case lost, as he now believes, from not using a drainage-tube. The action of the tube depends on the fact that moisture attracts moisture and he suspected that the surgeons who condemn the tube do not understand its theory or proper care.

Dr. Myers, of Indiana, endorsed Dr. Price's paper, and strongly advocated drainage. Dr. Reed, of Ohio, also approved of drainage. In the forty cases of abdominal section in the Cincinnati Hospital since January 1st a drainage-tube was used in each. Some were removed in one or a few hours.

Dr. Hypes, of St. Louis, asked Dr. Price whether he advised early or late operation for ectopic gestation.

Dr. Price answered that the cases come into the "surgeon's hand as a rule after rupture; should they come before that he would operate at once."

Dr. Bond did not entirely agree with Dr. Price. He would operate at once only when the rupture takes place in the upper part of the tube and into the abdominal cavity, not when it ruptures into the broad ligament for then the child may live and develop. In dealing with the placenta in such cases, Mr. Tait ties the cord and abstracts blood by a hypodermic syringe; others leave the cord hanging out at the lower angle of the wound.

The Committee appointed on the previous day reported their minutes respecting the late Dr. W. H. Byford, long a member of this Section and Vice-President of the Association.

SECTION OF SURGERY.

DR. B. A. WATSON, of Jersey City, *Chairman*.

DR. J. G. CARPENTER, of Stanford, Ky., read a paper upon the necessity of early abdominal section in intestinal obstruction. The author stated that by Senn's method of gaseous insufflation obstruction could be readily and safely diagnosed. He strongly objected to the use of opium; would operate the moment obstruction was diagnosed, and would use every means to hasten operative procedures.

In discussion Dr. McComas, of Maryland, alluded to the great difficulty of diagnosis.

Dr. King, of Kansas City, Missouri, emphasized the importance of early operation in obstructive cases. He stated that the gas test will, at times, fail even in cases of wound of the intestine.

Dr. Price, of Philadelphia, attributed the delay in operation to the fact that these cases were first treated by physicians, who were slow to call in surgical assistance; he hoped the time would come when such cases would go directly to the surgeon.

Dr. Senn, of Milwaukee, advised immediate operation, not only *after* diagnosis, but as a means of diagnosis. In obstruction due to a paretic inflamed bowel he would restore the continuity of the intestinal canal by lateral apposition—since the increased vascularization of the gut walls will cause union even more rapidly than that which takes place in normal intestines. The condition of the gut is such that circular enterorrhaphy is absolutely unjustifiable.

DR. JOSEPH PRICE, of Philadelphia, then read a paper upon abdominal section and drainage for purulent peritonitis. He urged the necessity of immediate operation, stating that by other means the prognosis was hopeless. There were many recent illustrative cases of the truth of this opinion. Several cases were cited of both general and local true puerperal peritonitis, against which medical treatment had been unavailing, and all were undoubtedly saved by operation. A number of well-executed water-color paintings of specimens were shown.

Dr. Hoffman, of Philadelphia, stated that the important feature of Dr. Price's paper was the report of a series of cases which were regarded as uniformly fatal in medical practice. Treatment of large accumulations of pus by means other than operative must always be futile. The knife alone can afford relief.

Dr. Edward Martin, of Philadelphia, stated that the ground that all cases of suppurative peritonitis were fatal if not subjected to the knife was not tenable. While thoroughly convinced that where pus was found immediate evacuation was indicated, diagnosis was frequently impossible. This was generally conceded, especially by men of the widest experience. In infants there was a form of purulent peritonitis which was exceedingly prone to discharge spontaneously through the umbilicus. Again, even gunshot wounds with extravasation at times terminated in abscess and spontaneous discharge. There were two distinct forms of peritonitis, one diffuse and fulminant terminating quickly in death, the other localized and slowly extending. In the latter the pus was shut off from the general peritoneal cavity by adhesions. These formed so rapidly that even ulcerative perforation sometimes resulted in simple abscess rather than in diffuse peritonitis. For the localized peritonitis incision into each collection of pus, with free drainage, was advisable rather than formal laparotomy. The adhesions were protective and should be most carefully respected. The pus collection could be diagnosed by palpation and percussion, and successful cases were on record where four or five operations were required before all collections were evacuated. The subject of irrigation was most important. Since toxic symptoms had followed the use of 1 to 1000 bichloride solutions, and since no antiseptic could destroy the germs lodged in the infiltrated tissues, such solutions should never be used. Hot, sterile water, or still better, hot normal saline solution, would do all that could be hoped from any form of irrigation. Where toxic substances were used in solution they should be preceded by water or saline solution, since it was found that absorption from the peritoneal surfaces was exceedingly rapid for the first few minutes, and ceased when the blood was fully charged. After this, antiseptics could be used with impunity in so far as systemic results were concerned.

Dr. Carpenter, of Kentucky, said that he had seen many of Dr. Price's cases, of which those cited were typical examples.

Dr. Price stated that surgical curiosities should not be used as an argument against established surgical procedure. The matter of diagnosis was a matter of apprenticeship to this particular branch of surgery. Probably no surgeon who was in the war could reproach himself for having opened an abdomen, but how many could look back with remorse to fatal cases which might have been saved by operation!

The management of major amputations was then ably discussed by Dr. John A. Wyeth, of New York. His address opened with the statement that the prevention of hæmorrhage is of chief importance in these operations, and after this comes the preservation of as much of the limb as possible. The author's method of bloodless amputation of the hip is as follows: An Esmarch bandage is first applied, not including diseased areas for fear of driving septic matter into the circulation. Two steel mattress-needles, each three-sixteenths of an inch in diameter and a foot long, are next introduced. The point of one is introduced an inch and a half below the anterior superior spine of the ilium and slightly to the inner side of this prominence, and is made to traverse the muscles and deep fascia, passing about half-way between the great trochanter and the iliac spine, external to the neck of the femur, and through the substance of the tensor vaginæ femoris, coming out just back of the trochanter. The point of the second needle is entered an inch below the level of the crotch, internally to the saphenous opening, and passing through the adductors comes out about an inch and a half in front of the tuber ischii. The points are protected by corks, to prevent injury to the operator's hands. A piece of strong rubber tubing is now wound very tightly above the fixation needles. The Esmarch bandage is removed and a circular incision made five inches below the tourniquet. The skin and subcutaneous tissues are now dissected up to the level of the lesser trochanter, the muscles cut squarely through, and the bone sawed off. The remaining portion of the bone is now readily removed by dividing its muscular attachments. If shock is great, enucleation may be delayed for several days. In cases of osteomyelitis, after scraping the canal with Volkmann's spoon, a long drainage-tube without holes is introduced throughout the length of the diseased canal. Through this canal the cavity is kept washed out with antiseptic solutions till granulations are formed. This often obviates the necessity for amputation.

This paper was discussed by Dr. Harmer, of Wisconsin, Dr. Watson, of Jersey City, and Dr. Ransohoff, of Cincinnati. It was pointed out that the method was somewhat similar to those of Trendelenberg and Furneaux Jordan.

Dr. Harmer stated that he had seen amputation done in precisely the same manner as that suggested by Dr. Wyeth, bayonets being used in place of needles.

In closing the discussion, Dr. Wyeth stated that no claim was made for the originality of his method in its entirety. His paper contains allusions to other similar methods, but certain details in his technique were original.

The next paper was by Dr. H. O. Marcy, of Boston, upon "The Surgical Treatment of Biliary Obstruction." Several cases were carefully reported, and a *résumé* of the whole subject of the surgical management of this class of cases was given.

The author thinks that cholecystotomy should be performed in every case of wound or perforation of the gall-bladder, in empyema of the gall-bladder, in cystic dilatation, and in cases of biliary obstruction not amenable to medical treatment. Cholecystectomy is indicated only in those cases where the gall-bladder and its duct have undergone such marked pathological changes that there is no possibility of the function of this viscus being restored, yet even these cases will often be as surely and much more safely treated by suturing to the abdominal wall and subsequent drainage. When the gall-bladder is resected the entire secreting membrane of the cyst must be removed, and the edges must be brought together by a continuous sero-serous suture. When a stone is found in the common duct, it may often be dislodged by gentle pressure and subsequently removed from the gall-bladder. When this is impossible, crushing with well-padded forceps is indicated. If this procedure is contraindicated, either cessation from all further operative procedure or incision into the duct, with suture after the removal of calculi, will be indicated. In one case reported by the author the common duct was in-

cised, the edges of the wound everted, and the stone removed. The wound was then united by three rows of sutures, one for the thickened mucous membrane, one for the peritoneal edges, and, finally, sero-serous stitches were applied, folding-in the edges of the wound. The continuous kangaroo-tendon suture was used. Where the common duct is permanently occluded from inflammatory or other changes, the cystic duct remaining open and the gall-bladder being not particularly disorganized or adherent, a permanent fistulous opening into the intestine may be considered.

In performing the operation of cholecystotomy it must be borne in mind that the gall-bladder walls are very thin, hence all manipulation must be conducted gently. Under some circumstances suture of the gall-bladder to the parietal peritoneum will be advisable before opening the former. If a fistulous opening is determined upon, a soft-rubber drainage-tube should be inserted, and the wound should be dressed with absorbent material. The author used with advantage a soft-rubber double tube, inserted through a diaphragm about the size of a half dollar. If the common duct remains patulous, the fistula will close spontaneously. Aseptic animal sutures should be used, not only because they are far safer than silk, but because they possess the great advantage of causing an abundant proliferation of connective tissue along the tracks of the buried sutures.

In discussing this paper Dr. Senn, of Milwaukee, said that he had found in two cases a calculus in the common duct, surrounded by malignant disease. In one the calculus was replaced by taxis and the abdomen closed. The patient recovered but perished ultimately of malignant disease. In the other case the calculus was removed by incision, but this had no effect in restoring the continuity of the passage. An external biliary fistula was established in this case.

Dr. John B. Deaver, of Philadelphia, removed in one case fifty-two stones, leaving a fistula which subsequently closed. He assisted at two other operations where the stone was in the common duct. He preferred incision in the right linea semilunaris and also would advise dividing the operation into two portions—first simply suturing the gall-bladder to the parietal peritoneum, then opening after firm adhesions had been formed.

DR. DAVID BARROW, of Lexington, Kentucky, reported two cases of gunshot wound of the abdomen. In the first the wound was near the umbilicus. Shock was only moderate, and section was performed as soon as possible. The wound of entrance into the peritoneal cavity was found, together with six wounds of the intestines. Irrigation and drainage were employed, and though the patient was profoundly shocked, convalescence was fairly rapid.

The second case occurred in the person of a lad of thirteen years. The wound was inflicted at 4 P.M., by a 32-calibre revolver. The operation was performed four hours later, though there were no symptoms indicating serious injury. The wound of entrance was two inches to the right of and one inch below the umbilicus. A four-inch incision, including the bullet wound, was made. Five intestinal perforations were found, two of the small and three of the large intestine. These wounds were closed by the Czerny-Lembert suture, the operation lasting one-half hour. In two days vomiting set in, and the abdomen was opened and irrigated. On the third day the patient died from septic peritonitis. All the wounds were found tightly closed. A drainage-tube should, however, have been left in the abdominal opening. In all Dr. Barrow has operated on six of these cases with two recoveries. He advised against delay after gunshot wounds, since most patients perish from this cause. Thorough irrigation is essential in all these cases, the best method of securing this being that of Dr. Joseph Price, of Philadelphia, who uses a funnel and a large rubber tube through which hot water can be poured, the force and rapidity of the stream being regulated by the elevation of the funnel. In conclusion he stated his belief in the following propositions:

1. All gunshot wounds of the abdominal cavity should be treated by laparotomy, and this should be the rule, even though the viscera escape injury. Absolutely no reliance can be placed on symptoms.

2. Penetration should be determined by probing, or by enlarging the track of the bullet.

3. Since shock from anæsthesia and manipulation is marked, all operative procedures should be hurried as much as possible.

4. In extreme shock the open peritoneal method should be adopted rather than any procedure requiring more time and manipulation.

5. Since exsection has always been followed by death, anastomosis should replace this operation. By omental grafts intestinal tissue may be saved and suture lines may be strengthened.

6. In liver wounds, after stopping hæmorrhage, it is sometimes well to drain by a separate glass tube, as was done by Dr. Mordecai Price, of Philadelphia. The kidney, if wounded and bleeding, must be removed.

7. The hydrogen test should be used just before the closure of the abdominal wound, to detect any intestinal lesion which may have been overlooked.

8. Irrigation should always be employed and should be copious and thorough, since it combats shock and septic peritonitis. The drainage-tube should not be omitted.

Dr. Senn did not think that every perforative wound of the abdomen indicates laparotomy. The indication for laparotomy is hæmorrhage, as shown by the classical symptoms.

In a recent case, where exploration along the bullet track indicated perforation, the hydrogen test was applied, and proved that the intestinal canal was intact. On passing the catheter, however, the urine was found charged with blood. Conservative treatment was adopted and the patient recovered.

In another case, aged six years, a 38-calibre bullet entered the belly near the umbilicus. The track was explored, and penetration was proven. The colon and stomach were each insufflated, and found uninjured, though both of these organs were in the line of fire. The opening was then enlarged and the small intestines were examined and found intact. No drainage was employed. The child recovered, and would have recovered still more satisfactorily without meddlesome interference. In six cases of abdominal wounds which he has seen, two were not accompanied by visceral wound. From a medico-legal standpoint the question is one of

great importance. Had the first case died, the question would have been: Did the patient perish from the injury or from the surgeon's knife? In his own experience the gas test has never failed. In a patient wounded by a 22-calibre ball, one perforation was found, but in spite of constant escape of gas the other perforation could not be discovered. By inserting the pipe through the first wound, however, and insufflating, the other wound was readily found. It was not seen before, because it was directly between the mesenteric folds.

This method of gaseous insufflation requires skill and constant drilling. After three years of use its inventor felt that he was but just beginning to be familiar with its proper application; and without great experience in the use of this method no surgeon should presume to criticise it.

Dr Barrow, in conclusion, stated that there were many conditions which the hydrogen gas test failed to indicate. The immense distention induced by the gas was frequently an embarrassing feature in the case. The danger of exploration he considered infinitely less than that of undetected wound.

Dr. Marcy, of Boston, asked whether other gases might not be used, such as oxygen. He stated that he himself had employed the latter substance.

Dr. J. Lee McComas then reported the following case of gunshot wound of the brain: The patient, aged sixteen years, right-handed, was shot with a 22-calibre short ball. It passed through the frontal sinus downward and backward to the left, and the brain protruded and bled. The probe passed in three inches. The wound was disinfected and cleansed. Ergot and ammonia were given, and the patient gradually reacted and passed into a condition of cerebral irritability. As his condition improved it was found that he was completely aphasic. This seemed to be mainly motor, and gradually improved. Some two weeks after the injury it was discovered that he was suffering from agraphia. It was difficult to determine what symptoms were due to extravasation and what to the presence of the ball. Some six months after the injury the patient was found pursuing his trade of house-painting. His family stated that beyond an increased irritability of temper, they could detect no further signs of brain degeneration.

Friday morning.—The session was opened by some remarks on intubation by Dr. Bell, of Indiana. The speaker stated that the operation could be so quickly and easily performed that no gag was necessary, and that the main difficulty was that of feeding.

The treatment of flat-foot by Thomas's method was next considered by Dr. W. R. Townsend, of New York. The method consists, briefly, in so padding the sole of the shoe that a moderate varus is produced. This padding should extend from the extremity of the heel to the base of the great toe. A "building up" of one-quarter or one-half inch is usually sufficient.

Flat-foot is characterized by pain, especially on going up-stairs, by stiffness, and by deformity, accompanied by so much congestion of the soft parts that caries is frequently suspected. In mild cases, even where there is slight spasm and great pain, the treatment described is perfectly satisfactory; in severe cases accompanied by sub-luxation, marked spasm, and great tenderness, this treatment alone is of little avail. After more radical measures, however, even the most aggravated cases are benefited by continued use of the wedge-shaped sole.

Dr. John B. Deaver complimented Dr. Townsend on the excellent classification he had given in cases of flat-foot. The simplicity of the method commended it. He had at times been compelled to dissect out diseased synovial sheaths in cases of neglected valgus, and forcibly to break adhesions. As an after-treatment, he could warmly commend this padded shoe.

Dr. Edward Martin stated that for several years he had been in the habit of using this shoe, and that it was peculiarly applicable to children just beginning to walk, since in them the original deformity had often not been aggravated by the weight of the body, and consequently is in its first or second stage. He had seen many cures from this method, but in cases complicated by partial luxation he applied the shoe only after more radical methods. The apparatus described was particularly valuable from the fact that it provided a species of passive motion at each step of the patient.

Papers upon "Fractures of the Base of the Skull," by Dr. H. C. Wyman, of Detroit, and "Abscess of the Prostate Gland and its Treatment," by Dr. R. H. Harte, of Philadelphia, were then read by title.

PHILADELPHIA ACADEMY OF SURGERY.

Stated Meeting, May 5, 1890.

Thomas G. Morton, M.D., in the Chair.

Dr. O. H. Allis exhibited

AN IMPROVED ETHER CAN,

and said that he had often thought that if we could prevail on Dr. Squibb, who provides us with so much ether, to put it in different shaped cans, it would be a convenience. At the request of Dr. Allis the manufacturer had made a few specimen cans which were presented. They were flat, hardly larger than a cigar-case, and held one-quarter of a pound of ether. The maker objects to them because they cannot be washed or made so conveniently, as those of the usual shape. If the Academy considered them an improvement, Dr. Allis thought it would be well to request the manufacturer to furnish cans similar to the specimen.

Dr. Thomas G. Morton then reported a case of

PERFORATION OF THE VERMIFORM APPENDIX, PERITYPHLITIC ABSCESS, GENERAL PERITONITIS, SLOUGHING OF INTESTINE, ABDOMINAL SECTION; DEATH.

The patient, aged seven years, had always been healthy, never having been confined to bed on account of sickness. On Sunday, April 27th, he had a slight cold, for which a laxative was given; on Monday he was at play all day, and apparently quite well, but that night he was seized with intense abdominal pain, and constant vomiting. The abdomen became tympanitic and distended, the pain was general, and could not be localized; calomel, salines, and enemata produced no result.

The temperature fluctuated between 100° and 102°; during the succeeding four days there was no special change of symptoms, except progressive weakness.

On Sunday, May 4th, Dr. Morton saw the case in consultation. The symptoms were those of general perito-

nitis, pulse was 120, temperature 101⅘, abdomen greatly distended and tympanitic; no localized, but general abdominal pain; there was no tumefaction, hardness of tissues, nor swelling; rectal examination was negative. There had been no rigor or chill, and no sweat, and the only noticeable change on the abdominal surface was a distention of the superficial veins over the right iliac region.

The severe peritonitis, symptoms of bowel obstruction due probably to lymph adhesions, the intense pain, coming on suddenly and apparently without cause in a patient so youthful indicated the appendix as the source of the trouble.

Athough the patient's condition was exceedingly grave, Dr. Morton at once made a lateral abdominal section. The peritoneum was of an ashy gray color which indicated pus. On opening the abdominal cavity nearly two ounces of very fœtid pus escaped. On completing the incision, the parts were found matted together by recent lymph; a large part of the intestine was found in a gangrenous condition; the appendix was glued to adjacent structures, enormously enlarged just beyond its cæcal attachment, and evidently contained a very large foreign body; just beyond this the organ was perforated for an inch, while the distal end was nourished by the mesentery of the organ which extended its entire length. This was tied in several places, and the appendix was removed.

It was impossible to deal with the diseased bowel, so extensive were the adhesions, and so disorganized were the tissues. The abscess cavity was cleansed and a glass drain carried to the bottom of the pelvis. The wound was united as usual.

The patient sank gradually and died the following day.

The appendix was perforated and gangrenous to some extent. The foreign body proved to be a large intestinal concretion made up of many layers, and about the size of a cherry. The walls of the appendix were enormously thickened and distended, the distal extremity of the organ had been kept nourished through the mesentery.

This case is interesting from the fact that the symptoms at no time pointed to the appendix as the source of trouble; but taking into consideration the violence of the peritonitis, the intense pain, bowel obstruction, rapid march of the disease, and age of the patient, the probability was in favor of the appendix as the cause, and the diagnosis was made accordingly. The serious bowel complication indicated a probable fatal termination. It is hardly necessary to state that the earlier the diagnosis can be made in any such case the more successful will be the results of operation.

In the discussion which followed, Dr. De Forest Willard asked if there were any superficial indications pointing to inflammatory trouble? any œdema of the skin or thickening or hardening? and if the fingers could be carried into the iliac fossa?

He also asked if Dr. Morton had said that in young persons there were no other sources of peritonitis than traumatism and appendicitis, and if intussusception would not lead to peritonitis?

In reply, Dr. Morton said that there was no œdema, tumefaction, hardness, or tumor: the entire abdomen was tympanitic, percussion was clear, with no dulness anywhere; intussusception and volvulus were easily excluded from the diagnosis, so that disease of the appendix alone remained.

Dr. William Hunt said that he had understood that Dr. Morton was disposed to believe that disease of the appendix originated in the appendix and not from the foreign bodies coming from above. Why such a body should not cause the trouble he did not understand. The specimen showed an apparent nucleus. To say that this nucleus originated in the appendix seemed more improbable than that it should have passed from the alimentary canal into the opening of the appendix.

Dr. Morton stated that he had never seen anything of this kind.

Dr. Hunt said that there is in the Wood Museum a preparation, from nature, showing the presence of seeds in the appendix.

Dr. Morton said that the foreign bodies found so commonly in the appendix are fæcal in character. In some thirteen or more post-mortem examinations recently made at the Pennsylvania Hospital, in every case but one, such foreign bodies were found in the appendix. He did not know of a cherry or date stone, or any other such large substance, having been found in the appendix.

Dr. Willard said that one week ago he was called into the country, in consultation, to see a case presenting symptoms very similar to those mentioned by Dr. Morton. The patient was a man fifty years of age, who had been seized with violent pain three days before. This was attributed to drinking a glass of ice-water. All the symptoms of peritonitis, with tympanitic abdomen and vomiting of greenish matter, were present. There was considerable tenderness over the whole abdomen. The pulse was 88, and the temperature not over 100°, usually about 99°. The pain was not localized, and careful examination in the right iliac region revealed nothing. The existence of hernia at every possible site was most rigidly investigated. There had been neither chill nor sweating, and no indication of pus. The condition of the man being good, and as there had never been any fæcal vomiting, Dr. Willard felt that an operation was not justifiable on that day. The next day he was better, and the improvement continued during the week, though the eventual result cannot be stated. Here was a case presenting a series of symptoms which seemed probably due to appendix trouble, but as no positive indication of such lesion could be found, he was unable to convince himself of the justifiability of an exploratory incision, although he had made the journey prepared to operate.

CORRESPONDENCE.

NASHVILLE.

The Nashville City Hospital.

While attending the meeting of the American Medical Association, the writer was given an invitation to inspect the only hospital in Nashville, which, as it was only recently opened, he was glad to do. The building is situated upon the highest ground in East Nashville, about one-half hour's ride by electric cars from the centre of the city. It is nearly one hundred yards from the high bluff of the river bank, and standing upon the piazza one can see over the whole town of Nashville to the

east, directly up the valley of the Cumberland River for many miles to the west, Mount Olivet to the south, and to the far-away Tennessee hills to the north. The view is far-reaching in each direction, and to the east very beautiful.

The building itself is of brick with stone trimmings, is three stories in height and has about 250 feet frontage. The administrative department, in the centre, contains reception rooms for visitors and patients, an office for the superintendent and resident physicians, and the apothecary's department. The wards on both first and second floors extend north and south from this building, to which they are connected by long enclosed corridors. The capacity of the hospital is one hundred free patients, while twelve private rooms accommodate those who are able to pay. Each ward (and they are five in number) will receive twenty patients. The furnishing consists of an iron cot, an oak table and chair, and a small rug, to each occupant. At the end of each ward farthest from the executive department is a diet kitchen upon one side, and upon the other the bath-rooms, water-closets, and sinks. The plumbing is of the latest improved pattern, and all pipes and traps are exposed to view so that no leakage or dirt may escape the attendant's eye. The ceilings are high, and ventilation is both natural and forced. The hospital is finished throughout in hard wood.

The clinic-room on the second floor of the executive department is a large amphitheatre seating about three hundred students, and is well lighted from above and from the sides.

The training-school, which is as yet in its infancy, is under the charge of Miss Charlotte M. Perkins, a graduate of the Pennsylvania Hospital training school, in Philadelphia. Miss Perkins has a corps of twelve nurses under her charge, and hopes within a few months to be enabled to supply the Nashville physicians with competent, trained nurses. The government of the Hospital is in the hands of three Nashville gentlemen who compose the Board of Public Works.

The writer desires to make acknowledgment of his indebtedness for the courtesy shown him during his brief visit to the Hospital to Miss Perkins, Dr. Brower, the Superintendent, and to the resident physicians.

NEWS ITEMS.

The University of the South.—The University of the South, Seewanee, Tennessee, an institution of learning under the patronage of the Episcopal church, will establish, in October, at Chattanooga a grammar department, and also a department of medicine and of law.

The outline of the medical department indicates a medical school of the highest character, strict preliminary examinations by the college faculty being held prior to admission, and three full winter courses of lectures being necessarily attended before graduation.

The faculty, as so far announced, consists of the following gentlemen:

Dr. Key, surgery; Dr. Trippe, gynecology; Dr. Holtzclaw, anatomy; Dr. Eaton, practice of medicine; Dr. Reeves, pathology, microscopy, and clinical medicine; Dr. Wilson, therapeutics; Dr. Gahagan, physiology, and Dr. Sims, sanitary science.

Changes in the Faculty of the Medico-Chirurgical College.—Dr. J. M. Anders has been transferred from the Professorship of Children's Diseases to the Chair of Clinical Medicine. Dr. Ernest Laplace has been made Professor of Pathology and of Clinical Surgery, and Dr. Samuel Wolfe has been elected Professor of Physiology.

New Appointments.—Dr. Robert W. Taylor has been appointed to the Professorship of Venereal Diseases, formerly occupied by Dr. Fessenden N. Otis, in the College of Physicians and Surgeons of New York.

Dr. A. H. Buckmaster has been appointed Assistant Surgeon to the Woman's Hospital, of New York, to fill the vacancy caused by the resignation of Dr. Sherman Van Ness, and has removed from Brooklyn to No. 50 East Thirteenth Street, New York.

The Mary A. Dixon-Jones Case.—The recent action of the District Attorney of Brooklyn, in dismissing the second of the indictments found against Dr. Mary A. Dixon-Jones and her son more than a year ago, closes the criminal side of one of the most dastardly attempts to ruin a professional reputation ever made in this country.

It is unnecessary to enter into the details of this malicious charge, which is, unfortunately, still fresh in the minds of many. Every physician in America will most heartily congratulate Dr. Jones upon the final closure of the case.

The Census of Hallucinations.—Professor William James, of Harvard, is compiling the "Census of Hallucinations" in this country. The Census was begun several years ago by the Society for Psychical Research, but is now under the auspices of the International Congress of Experimental Psychology, which met in Paris last summer.

The object of the inquiry is twofold: first, to get a mass of facts about hallucinations which may serve as a basis for scientific study of these phenomena; and, second, to ascertain approximately the proportion of persons who have had such experiences. Until the average frequency of hallucinations in the community is known, it can never be decided whether the so-called "veridical" hallucinations (visions or other "warnings" of the death, etc., of people at a distance) which are so frequently reported, are accidental coincidences or something more.

Some 8000 or more persons in England, France, and the United States have already returned answers to the question which heads the Census sheets, and which runs as follows:

"Have you ever, when completely awake, had a vivid impression of seeing or being touched by a living being or inanimate object, or of hearing a voice; which impression, so far as you could discover, was not due to any external physical cause?"

The "Congress" hopes that at its next meeting, in England in 1892, as many as 50,000 answers will have been collected. It is obvious, that for the purely statistical inquiry, the answer "No" is as important as the answer "Yes."

Dr. James has been appointed to superintend the Census in America, and requests the coöperation of all who may be interested in the subject. Each Census

blank contains instructions to the collector and spaces for twenty-five names; and special blanks for the "Yes" cases are furnished in addition. Dr. James will supply these blanks to anyone who makes application. Requests should be directed to Professor William James, Harvard University, Cambridge, Mass.

Legacies to the Hospitals of Philadelphia.—By the generous will of the late George S. Pepper nearly every charitable institution in Philadelphia is enriched. The following are the more important legacies:

To the University of Pennsylvania, $60,000, for the endowment of a professorship, to be selected by William Pepper, M.D.

To the Hospital of the University of Pennsylvania, $50,000.

To the Presbyterian Hospital, $50,500.

To the Hospital of the Protestant Episcopal Church, $50,000.

To the Orthopædic Hospital, $25,000.

To the Pennsylvania Hospital, $50,000.

To the Hospital of the Jefferson Medical University, $50,000.

To the Charity Hospital, $25,000.

To the St. Joseph's Hospital, $25,000.

To the Children's Hospital, $25,000.

To the Wills Hospital, $10,000.

To the St. Christopher's Hospital for Children, $25,000.

To the Hospital and Dispensary of St. Clement's Church, $10,000.

To the Children's Hospital, Country Branch, $10,000.

To the Maternity Hospital, $25,000.

To the Northern Dispensary, Southern Dispensary, Philadelphia Dispensary, Howard Dispensary, each $5000.

A Sanitary Organization of Women.—The women of Brooklyn have united to form a Ladies' Health Protective Association, similar to one which has for years been so useful in New York City. The lines of its work will be in the direction of such nuisances as offensive pursuits, uncared-for tenement houses, and filthy streets. The wives of physicians form a considerable proportion of the organization.

The Electrical Execution Law.—The law in New York State substituting electricity for hanging as the means of execution, has at last been passed upon by the Court of Appeals, and considered to be constitutional, after a struggle lasting nearly a year. The court virtually declares that killing by electricity is more humane than that by hanging, and this declaration is based upon strong and repeated testimony that the application of electricity in the manner contemplated by the statute must result in instantaneous and, therefore, painless, death.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MAY 20 TO MAY 26, 1890.

HEIZMANN, CHARLES L., *Major and Surgeon.*—Is granted leave of absence for one month.—Par. 1, *S. O. 39, Department of Texas*, May 19, 1890.

By direction of the Secretary of War, a Board of Medical Officers, to consist of: ANTHONY HEGER, *Lieutenant-Colonel and Surgeon;* JOHN BROOKE, *Major and Surgeon;* and ROBERT H. WHITE, *Major and Surgeon*, will assemble at the U. S. Military Academy, West Point, New York, on June 7, 1890, to examine into the physical qualifications of the candidates for admission to the Academy, and, in connection with the Superintendent of the Academy and Commandant of Cadets, the members of the graduating class. Reports of the proceedings of the Board will be forwarded through the Superintendent of the Academy to the Adjutant-General of the Army. Special reports will be made in the cases of any graduates deemed to be physically unfit for the military service, and also in the cases of candidates who may be admitted on probation or rejected.—Par. 3, *S. O. 121, A. G. O., Washington, D. C.*, May 23, 1890.

GIRARD, J. B., *Major and Surgeon.*—Is granted leave of absence for one month, to take effect as soon after June 1st proximo as a medical officer can be sent to Fort Lowell for temporary duty.—Par. 1, *S. O. 48, Headquarters Department of Arizona*, May 17, 1890.

DEWITT, THEODORE F., *First Lieutenant and Assistant Surgeon.*—Is relieved from duty at Willet's Point, New York, and will report in person to the commanding officer Fort Ringgold, Texas, for duty at that station, relieving W. Fitzhugh Carter, Captain and Assistant Surgeon. Captain Carter, upon being thus relieved, will proceed to West Point, New York, and report in person to the Superintendent U. S. Military Academy, for duty at that station.—Par. 2, *S. O. 119, A. G. O.*, May 21, 1890.

BENHAM, ROBERT B., *Captain and Assistant Surgeon.*—Is relieved from duty at Madison Barracks, New York, and will report in person to the commanding officer Fort Wadsworth, New New York, for duty at that station, relieving Charles K. Winne, Captain and Assistant Surgeon. Captain Winne, upon being thus relieved, will proceed to Fort Snelling, Minnesota, and report in person to the commanding officer thereof, for duty at that post.—Par. 2, *S. O. 119, A. G. O.*, May 21, 1890.

By direction of the Secretary of War, the following-named officers of the Medical Department will proceed to Berlin, Germany, as Delegates to the International Medical Congress which is to meet in that city in August next: CHARLES H. ALDEN, *Lieutenant-Colonel and Surgeon*, and JOHN S. BILLINGS, *Major and Surgeon.* After the adjournment of the Congress, the officers named will return to the United States, and rejoin their proper stations.—Par. 11, *S. O. 116, Headquarters of the Army, A. G. O., Washington, D. C.*, May 17, 1890.

By direction of the Secretary of War, JOHN S. BILLINGS, *Major and Surgeon*, will, while abroad under his orders to attend the International Medical Congress at Berlin, Germany, and before returning to the United States, visit, on official business, such points in Great Britain, France, Italy, Germany, Belgium, Holland, and elsewhere, as may be deemed necessary by the Surgeon-General of the Army, and under such special instructions as he may receive from the Surgeon-General.—Par. 12, *S. O. 116, Headquarters of the Army, A. G. O., Washington, D. C.*, May 17, 1890.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING MAY 24, 1890.

CRANDELL, RAND P., *Assistant Surgeon.*—Ordered to the Naval Hospital, New York.

BERRYHILL, THOMAS A., *Passed Assistant Surgeon.*—Detached from Hospital, New York, and ordered to Hospital, Mare Island, California.

ANDERSON, FRANK, *Passed Assistant Surgeon.*—Ordered to special duty in Bureau of Medicine and Surgery.

VAN REYPEN, W. K., *Medical Inspector.*—Ordered to New York on special temporary duty.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked. Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL ARTICLES.

THE OCULAR COMPLICATIONS OF MALARIA.[1]

BY G. E. DE SCHWEINITZ, M.D.,

OPHTHALMIC SURGEON TO THE PHILADELPHIA AND CHILDREN'S HOSPITALS, OPHTHALMOLOGIST TO THE ORTHOPÆDIC HOSPITAL AND INFIRMARY FOR NERVOUS DISEASES.

FÖRSTER,[2] writing in 1877 concerning the ocular changes in malaria, says:

"If we take into consideration that protracted pernicious malaria may originate the severest disturbances in the entire organism—melanæmia, decided cerebral symptoms, probably dependent upon circulatory disturbance in the central organ of the nervous system, profuse diarrhœa and intestinal hæmorrhage, albuminuria and hæmaturia, irremediable cachexia, hæmorrhagic diathesis, fatty degeneration of the glandular organs of the abdomen, etc.,—then, in some measure, it is remarkable that little is reported concerning the disturbances of the eye, the result of malarial poisoning."

It is the object of the present paper to record the various diseases of the eyes which have been studied either as the direct result of the malarial poison, or which have appeared in association with malarial toxæmia.

Diseases of the Conjunctiva. Intermittent Ophthalmia.—W. F. Norris[3] writes:

"Intermittent ophthalmia is but rarely encountered in countries where only a mild form of intermittent fever is present; in fact, it was so rare in Scotland, that Mackenzie, in the earlier editions of his work, denied its existence, but a larger experience enabled him (in 1854) to give three cases. In 1828 and 1829 it was so infrequent in Marburg that Hueter (*Jahrbücher für Chirurgie u. Augenheilkunde*, Berlin, 1828, xii. 271–279) devoted two papers to its study—one of a case of the quotidian type, and the second, of the septan form of the ophthalmia."

Between the years 1838 and 1868 the files of the *Annales d' Oculistique* contain references to ten papers upon this subject. In 1843 J. E. F. Schaepman wrote his thesis[4] upon intermittent ophthalmia, and described three varieties: 1. Those which appear under the mask of intermittent fever; 2. Those which are only one symptom of intermittent fever; and 3. Those which result from the change in the form of an intermittent fever.

In countries where malaria is prevalent intermittent ophthalmia is common, and may appear simply as a vascular irritability of the eye, without true inflammation (phlegmasia dolens oculi or ophthalmia nervosa of the older writers); in association with ordinary trigeminal neuralgia, which—as is the case with all neuralgias—may assume a periodic type; as a congestion of the conjunctival vessels, with photophobia and lachrymation, together with malarial neuralgia—incurable until the true nature of the disorder is discovered; or, as Griesenger[1] has said, it may terminate in stationary chronic conjunctivitis, opacity of the cornea, and even atrophy of the bulb.

Wehle[2] describes among intermittent cases in Hungary a form of ophthalmia characterized by erysipelatous swelling of the lids, studding of conjunctiva with red dots, tumefaction of the ocular conjunctiva, and occasional involvement of the cornea and destruction of vision.

Eulenberg and Landois,[3] in a discussion on vasomotor neurosis, refer to intermittent ophthalmia, giving the important literature from Edmonstone's treatise in 1816 to Derby's article in 1865, as a circumscribed affection of the trigeminal filaments supplying the conjunctival vessels arising under the influence of malaria—a vasomotor infection-neurosis.

In the cases reported by Pagenstecher conjunctivitis, sometimes accompanied with paresis of accommodation, was the only symptom of malaria, and formerly was called "febris intermittens larvata."

Finally, an ophthalmia may arise to which, when it is already advanced, intermittent fever may be added. To the latter class, perhaps, should be referred those epidemics of ophthalmia between which and malaria an affinity has been traced. An example of this character is furnished by the study of the epidemic ophthalmia which pervaded South Carolina in the summer and fall of 1882, and which E. Miller ascribed to the influence[4] of malaria—a position in which he was supported by Rhett, Kollock, of Cheraw, and Munroe, of Marion; but unsupported by Howe, of Columbia; Cowles, of Johnson's, and F. L. Parker, of Charleston.

Diseases of the Cornea. Malarial Keratitis.—The cornea may be involved in a form of inflammation specially dependent upon the malarial poisoning, or

become inflamed in a subject of intermittent fever as an associated disease. Thus, long ago, Bürhrlen[1] while discussing intermittent ophthalmia pointed out that keratitis may occur in a malarial individual during the course of the disease, and should be described as "intermittens cum keratite." A vascular keratitis is recorded as an illustration. This influence of the malarial impression upon the course of a keratitis, either because the patient resides in paludal regions or himself is the subject of malaria, is a matter of common observation and stock knowledge, and to such an influence should be accredited the cases of herpes febrilis corneæ observed by Godo,[2] one-third of which he traced to malaria. Chronic interstitial keratitis, either directly malarial or occurring in malarial subjects, has been observed in a number of instances. Arlt[3] has recorded eight cases; Levrier[4] another; more recently the influence of this cachexia in the production of this type of corneal disease has been dwelt upon by Landolt, Poncet, Javal, and others, while Sedan, of Toulon,[5] among thirty-four cases found malaria in twenty-seven instances.

Keratitis the direct result of malaria, and existing in the form of a superficial lesion, has been known for a long period. Becker[6] referring to a variety of keratitis after cataract extraction, describes its appearance as identical with that of the painful keratitis following malaria, mentioned by the older writers, but not mentioned in the more modern literature. In this country we are indebted especially to Kipp, of Newark, for a masterly study of malarial keratitis. His first publication appeared in 1880,[7] and in the *Transactions* of the American Ophthalmological Society for 1889 he gives his most recent results based upon one hundred and twenty observations. In 90 per cent. of the cases the lesion consisted in a "peculiar narrow, serpiginous, superficial ulcer, with lateral offshoots," like the skeleton of veins in a lanceolate leaf, usually accompanied with photophobia and lachrymation, and sometimes ushered in with severe supraorbital neuralgia. This appearance Dr. Kipp formerly considered characteristic, but in five instances it was replaced by a large superficial abrasion of the cornea, while the peculiar appearance just described he has observed in non-malarial subjects. Cases appeared in every month of the year—69 per cent. during June, July, August, September, and October. Dr. Kipp's observations have been repeated and confirmed by Hotz,[1] H. G. Miller,[2] and Sutphen.[3] Noyes, whose cases were reported by Minor,[4] for years has been accustomed to observe a form of superficial keratitis as the result of malaria; the characteristic symptoms were exaggerated tenderness of the supraorbital nerve and anæsthesia of the cornea. Van Milligen,[5] in 1888, described a peculiar form of keratitis, resembling the keratitis dendritica mycotica of Grut, Hock,[6] and Emmert, as the result of malaria, and characterized by the appearance of a superficial erosion on the temporal border of the cornea or a fungus-like lesion in some other point; local pain, ciliary neuralgia, and anæsthesia of the cornea were associated symptoms. Keratitis bullosa, a disease in which large vesicles form, filled with clear serum and of uncertain origin, in some instances has appeared to have its source in malaria, and Tangeman, of Cincinnati, suspecting this, cured his cases by the administration of quinine.

The practical deduction from these observations evidently is the importance of remembering the possible influence of malaria in corneal inflammation, and in the absence of the characteristic clinical symptoms described by Kipp, Noyes, and Van Milligen, the need of examination of the blood for the corpuscles of Laveran. The remedies indicated in addition to local measures are quinine, arsenic, and eucalyptus.

Diseases of the Iris. *Iritis.*—The development of iritis under the influence of syphilis, rheumatism, gout, gonorrhœa, and in association with tuberculosis and diabetes, would seem to indicate malarial toxæmia as a possible and even likely cause for the same inflammation. Staub[7] described intermittent iritis, passing on in some instances to intermitting and periodic hypopyon, cured by the influence of quinine. Peunoff,[8] in an investigation of a large variety of ocular troubles the result of malaria, in rare instances found iritis. Mackenzie[9] and Quaglino[10] refer to periodic iritis; and modern writers, like Noyes, include malaria among its constitutional causes. It is to be remembered, however, as Gowers[11] has pointed out, that pyæmia closely

simulates intermittent fever, and purulent affections of the eyes (purulent iritis and choroiditis) may arise under its influence and be ascribed inaccurately to malaria.

Scleritis and episcleritis—relapsing affections—no doubt appear in malarial subjects as associated disorders. Some of the reported examples of intermittent ophthalmia appear to have been of their character.

Amblyopia and Amaurosis.—Disturbances of vision during the course of intermittent fever have been observed from the earliest days, many of the recorded cases having been reported in the pre-ophthalmoscopic period. Leber[1] divides the amauroses of malaria into two varieties: typical or intermittent, and stationary amaurosis. In temporary amaurosis the fever usually is of the tertian type, and may be associated with severe nervous symptoms—delirium, coma, aphasia—or the loss of vision begins with the chill, lasts through the fever and subsides with the sweat, as was shown years ago by Kühlbrand and Tott.[2] Thus Deval[3] mentions a case of tertian intermittent with amblyopia after disappearance of the fever which only slowly and partially subsided, and Dutzmann.[4] a young man with tertian intermittent, violent convulsions, unconsciousness and complete amblyopia without fundus lesions, who was cured with quinine. In larvate intermittents, when the fever is slight or concealed, the amaurosis, according to Himley (quoted by Leber), more usually is monolateral—a point observed by von Störck as long ago as 1759.

Stationary amaurosis from larvate intermittents is more unusual, and may be an amblyopia with exacerbations, either unilateral or bilateral in character. (Leber.) Periodical amblyopia may be associated with spasm of the retinal vessels, as in the cases recorded by Ramorius,[5] pale disks, shrunken veins and arteries, and simultaneous congestion of the face and ears.

The result of numerous observations is that amblyopia not infrequently complicates malaria and appears in the form of a transient loss of vision, or as complete blindness. Its duration varies from a few moments to several hours, days, or even months, and it disappears under antiperiodic treatment, as Teillais[6] has said, "with the same quickness with which it came without leaving a single trace of its passage at the bottom of the eye." In most of the amblyopias just referred to, the ophthalmoscopic findings were negative, or the descriptions are included in the vague terms applied to the retina or optic nerve —"congestion," "hyperæmia," "redder than normal." In the monolateral cases these terms have been at times limited to the affected side, while the other was described as "normal."

Two questions of differential diagnosis are of importance in the consideration of malarial amblyopia —amaurosis from associated kidney disease, and blindness the result of large doses of quinine; examination of the urine should exclude the one, and the peculiarities of the retinal arteries and the behavior of the color-fields the other. Adopting a classification given by Teillais[1] we may say in regard to malarial amblyopia that it is of three varieties:

1. Amblyopia without lesion due to a special action of the malarial poison on the optic nerve and the retina.

2. Amblyopia in which the lesions are not appreciable with the ordinary means of investigation.

3. Amblyopia with lesions apparent at the bottom of the eye-ground.

It is to the lesions of the latter group to which I now wish to call attention. These consist in œdema of the end of the optic nerve and optic neuritis, optic atrophy, retino-choroiditis, hæmorrhages into the retina and into the vitreous humor.

Malarial Neuritis and Neuro-retinitis.—In 1866 McNamara referred to instances of intermittent hemicrania with neuritis in connection with malaria, and several years later reported[2] a case of neuro-retinitis, the result of malarial toxæmia in a native Indian, cured by quinine. These cases he believed to be common in that region. Noël Gueneau de Mussy[3] relates a case of double optic neuritis and hæmorrhages into the retina alleviated by quinine. Galezowski[4] refers to neuritis; Poncet,[5] who observed changes in 10 per cent. of the cases of malarial cachexia in Algeria, beside hemorrhages found peri-papillary œdema and neuro-retinitis. Jacobi[6] describes œdema of the papilla in a woman of thirty-four years of age, with quotidian ague and enlarged spleen, who was cured by quinine and iron, and in Peunoff's[7] extensive list of ocular disorders attributed to malaria, several cases of neuro-retinitis are detailed. Hammond[8] saw two cases of malaria with optic neuritis and remarkable collections of stellate pigment in the retina. In a recent communication McNamara[9] reports three cases of neuritis due to malarial poisoning.

Hæmorrhages into the retina may occur with neuritis or without other changes. Numerous reports have appeared, prominent among which are those by Peunoff,[1] Fernandez (quoted by Poncet), Poncet,[2] Karpinsky,[3] whose cases happened in southern Russia, in some instances associated with marked fever; and Stephen Mackenzie,[4] who found in three examples the hæmorrhages especially along the course of the large vessels, and when they faded away shiny white spots marked their position. In our own country a number of communications upon this topic have been published. Thus Edward W. Jones,[5] of New Orleans, reports five cases of retinal hæmorrhage. In one, a man aged thirty-four, the fever was of the remittent type, and in another there was also unilateral optic neuritis. J. Dickson Bruns,[6] of New Orleans, describes two examples of hæmorrhages into the retina—the one with fever of the tertian type, and the other in which the chills occurred at first daily, and later every other day. Usually the hæmorrhages are found near the disk, along the course of the larger vessels, as in Mackenzie's cases, sometimes on the disks in the form of fine specks of blood, and occasionally in the macular region assuming unusual shapes; Bruns examined one formed like a "meat-chopper." Amenitsky[7] reports blindness attributed to embolism of the central artery of the retina in a girl of seventeen, the subject of tertiary intermittent fever; the diagnosis is open to doubt.

Optic Atrophy. — Galezowski[8] describes optic atrophy with the pernicious forms of malaria; it is rare in the intermittents of temperate climates. Instructive cases have been recorded by McNamara, and in our country by Bull.[9] (The influence of quinine was excluded.) Edward Jones[10] among twelve cases of retinal disease, the results of malaria, saw only one go on to atrophy. Even when the atrophy is advanced marked improvement under treatment (strychnine and potassium iodide) may take place, as in a remarkable case of recovery of vision after atrophy of the optic nerves consecutive to malaria, reported by Brudenell Carter.[11]

The *pathology of the retinal and optic nerve changes* in these cases is not settled. The hæmorrhages have been ascribed to pigmentary embolism, although, as Gowers points out, this may be present, according to Mackenzie, in the absence of melanæmia. Poncet[12] believes the vessels of the choroid may be the seat of emboli of leucocytes, and attributes the hæmorrhages to this condition. According to Lopez y Veitia,[1] the immediate cause of the extravasations of blood is an augmentation of the blood tension, and he believes the hæmorrhages are increased by fresh accessions of fever. H. D. Brunt[2] thinks the smaller hæmorrhages due to diapedesis, the larger ones to rupture of the finer bloodvessels of the retina. Concerning retinal hæmorrhage and its frequency Brunt[3] writes that during the years 1882–1886, 192 cases of malarial fever were treated in the wards of the Charity Hospital in New Orleans, but during the same time only six indubitable cases of malarial hæmorrhage are recorded in the books of the Eye-clinic.

Jacobi[4] believes a neuritis, not itself intermittent in character, bears no direct relation to malaria. According to him, this depends upon severe recurring hyperæmias of the opticus and retina, separated by such short intervals that the dilated bloodvessels cause œdema and incarceration of the intraocular end of the optic nerve within the scleral ring (according to von Graefe).

McNamara[5] "inclines to the idea that the inflamed state of the optic papilla is due to something of the nature of a microbe which becomes planted in the affected tissue, and growing there produces ptomaines, which in their turn cause irritation of the tissues, engorgement of the vessels, and the transudation of serum and leucocytes into the retina and optic papilla."

In some instances optic neuritis is secondary to meningitis. Galezowski ascribed the atrophy to pigmentary embolism; in the majority of cases it is consecutive to a neuritis.

It is of prime importance to exclude chronic kidney and hepatic disease before attributing these retinal and optic nerve lesions to miasmatic poison, and in the atrophies the influence of quinine must be eliminated. Bull[6] has examined 150 cases of malaria, and omitting the instances in which co-existing hepatic and renal disease existed, believes the examples of "degeneration or inflammation of the optic nerve due directly to miasmatic influence" to be infrequent, a position in which he is supported by Kipp.[7] McNamara, on the contrary, writing of England, thinks the instances more common where malaria prevails than is generally supposed. The writer has examined numerous malarial subjects in Pennsylvania and found only rarely coarse retinal changes.

Lesions in the Vitreous and Choroid.—The lesion of the vitreous which most usually has been recorded

is hæmorrhage. In one case related by von Kries[1] this occurred in a patient who suffered from ague on the first day after the paroxysm had been arrested by quinine. Levrier[2] quotes Galezowski as relating an example of periorbital neuralgia with atrophic choroiditis and flocculi in the vitreous, and Peunoff reports choroiditis and vitreous opacities. In this country hæmorrhage into the vitreous has been noted by E. W. Jones.[3] and W. W. Seely[4] records two examples of serous effusion into the vitreous due probably to malaria. In the first case the vitreous was filled with an "impenetrable mist" which gradually cleared in two months. The patient had one severe chill, and the urine was normal. In the second case there was only a gray reflex from the fundus; supra-orbital neuralgia was associated. Brunt[5] has seen one similar case. The most important communication on vitreous hæmorrhage in cases assumed to be malarial, is from the pen of C. S. Bull.[6] Seventeen cases are reported in which the hæmorrhages occurred almost always in one, though they also occurred in both eyes, but never simultaneously. All of the patients were over forty years of age, and all the subjects of pronounced malaria contracted in markedly miasmatic regions. Valvular disease of the heart, chronic renal change, rheumatism and gout were excluded. In the majority of the cases the blood was extravasated generally through the vitreous; in a few it was in the posterior part. The hæmorrhages appear to have been due to rupture of choroidal or ciliary vessels, and possibly the vessels of the sheath of the optic nerve during the congestive stage of the malarial attack. After absorption of the blood, which was slow and left behind membranous opacities, areas of atrophic choroiditis were seen in the periphery of the eye-ground.

Changes in the Field of Vision.—Malarial amblyopia is always accompanied with more or less restriction of the visual field. A central scotoma may exist, small at first, or large enough to invade the whole field and produce the blindness (Teillais), or contraction of field and amblyopia with each paroxysm. In case of atrophy there is marked contraction, color scotoma (Bull), and color blindness (Peunoff). A remarkable phenomenon is hemianopsia. Peunoff[7] describes lateral hemianopsia with the approach of fever. Reich[8] himself had right lateral hemianopsia while suffering from the fever, and I refer by permission to a case under the care of Dr. Joseph Leidy, Jr., in the wards of the Pennsylvania Hospital in which there was bi-temporal hemianopsia. The corpuscles of Laveran led to a correct diagnosis, and the condition was cured by quinine.

The Pupils and Accommodation.—In some of Pagenstecher's cases of intermittent ophthalmia, paresis of accommodation was an associated symptom, and according to Bull the intermittent forms of visual disturbance probably are due to paralysis of accommodation. Mannhardt[1] reports three examples of paralysis of accommodation in subjects of stubborn quotidian and tertian intermittent (quinine produced a cure), and Stellwag[2] on the authority of this author places malaria among the causes of this derangement of the functions of the ciliary muscle. Stilling[3] reports larvate intermittent fever under the form of supra-orbital and ciliary neuralgia which reflexly brought forth spasm of accommodation.

Various authors have described the pupils as dilated and inactive, or unaffected; the latter when there has been complete blindness, a condition which is analogous to that which is seen in uræmic amaurosis.

Finally, as a functional disturbance, night blindness has been reported by C. Zimmerman[4] and by Poncet, who says it may be associated with peripapillary œdema.

Paralysis of the external eye muscles has been recorded in a few instances, but must be a rare manifestation. It is not mentioned in Mauthner's *Diagnostik und Therapie der Augenmuskellähmungen*, Wiesbaden, 1889.

Illustrative Cases.—During the last year the writer has examined a large number of cases of acute intermittent fever and chronic malaria without discovering, except in a few instances, serious ocular changes. Practically all of these cases had contracted their intermittents in the climate around Philadelphia—in other words, in regions not noted for types of pernicious fever. In the Eye Dispensary of the University Hospital, and in the wards of the Philadelphia Hospital, a number of cases of keratitis have appeared in malarial subjects, but they did not present the characteristic lesions noted by Kipp, Noyes and Van Milligen. In short, they should be described as "intermittents with keratitis," and not as examples of true malarial keratitis. In two cases there were multiple retinal hæmorrhages, and in one superficial optic neuritis with a single hæmorrhage.

CASE I. *Retinal hæmorrhages.*—A man, aged thirty-five, a laborer, working on an embankment and subject to much night exposure, was admitted

to the hospital, and without any thorough examination classed as "general debility." An ophthalmoscopic examination revealed in each eye large oval hæmorrhages at the outer side of each disk. The spleen was enlarged. Under anti-malarial treatment the case improved, but disappeared from observation before a cure was obtained. The urine and heart were normal.[1]

This case was in all probability an example of true malarial hæmorrhage occurring in a man who had contracted his disease in a miasmatic neighborhood, and in whom the disease had become chronic with associated anæmia.

Case II. *Multiple retinal hæmorrhages, probably malarial in origin.*—This patient, a man, aged forty-eight, living in Maryland, was seen in consultation with Dr. J. Madison Taylor, in May, 1888. He had suffered from intermittent fever of the tertian type for ten years, and three times contracted remittent fever. The spleen was enlarged. Two blood-counts made in 1888, at short intervals, yielded 2,800,000 red blood-corpuscles to the cubic millimetre, and later 3,200,000, the hæmoglobin being respectively 28 per cent. and 30 per cent. Subsequent examinations showed improvement in corpuscular richness and corresponding rise in the percentage of hæmoglobin. The heart presented no organic disease; repeated examinations of the urine, the absence of any indications of chronic Bright's disease. In the right eye the cornea was conical; the disk gray, containing a sharp central cup, and on its surface a flame-shaped hemorrhage, while above and to the nasal side there were three round hæmorrhages. In the left eye the disk was also very gray, and up and out from its margin, and down and in likewise, there were two small, round hæmorrhages. The macula contained numerous fine yellowish dots, and several small dot-like hæmorrhages.

This case at first sight led to the suspicion of pernicious anæmia; the gradual improvement, however, under the influence of iron and arsenic disproved this theory, and the anæmia was attributed to the malaria. This patient died subsequently of pneumonia, although before his death there had been marked improvement in the general condition.

Case III. *Superficial optic neuritis; one small retinal hæmorrhage; probable influence of malaria.*—This case, a child, aged twelve years, was brought for constant frontal headache and some habit-chorea of the orbicularis. He lives in a malarious district on the banks of a river, and every summer for three years has had chills and fever. His last chill occurred on January 1st of this year. Since this date there have been no chills but numerous attacks of headache. Each optic disk was swollen slightly above the level of the eye-ground (+ 1.5 D.). All edges of the disks were veiled, the nasal sides hidden. The central lymph sheaths were full, white lines extending some distance along the vessels. In the right eye on the nasal side of the disk along the course of the nasal artery there was an oval, partially absorbed hæmorrhage. The urine was normal, the heart normal, the spleen slightly enlarged, the hæmoglobin 75 per cent., the blood-corpuscles 4,262,500, or, in other words, for the amount of red blood-corpuscles enumerated there was a deficiency of 10 per cent. in hæmoglobin. Repeated examinations of the blood failed to demonstrate the corpuscles of Laveran. This is probably explained by the fact that the child had always been given large doses of quinine up to the date of his first visit, January 23d.

In this case the presence of hypermetropia lent some doubt in regard to the etiology of the headache. The correction of this refraction-error did not control the headaches, which, however, disappeared under the influence of ascending doses of arsenic. The same is also true of the neuritis, which at his last visit, in the latter part of April, was well-nigh dissipated. The neuritis and hæmorrhage probably were due, in spite of the absence of the corpuscles of Laveran, to malaria. The history is perfectly clear; all organs were normal, and anti-malarial treatment effected an improvement. It is, however, equally true that hypermetropia is capable of producing superficial neuritis and congestion of the end of the optic nerve, and, furthermore, as this was corrected, it may have aided in the subsidence of the neuritis, as it also may have been the cause of its appearance.

In conclusion malaria may originate:

1. An ophthalmia of the intermittent type, which sometimes replaces the ordinary manifestations of the disease.

2. A form of keratitis, properly described as "malarial keratitis," and quite distinct from those types of corneal inflammation which are simply associated with intermittent fever.

3. Various functional ocular disturbances, amblyopia, paresis of accommodation, changes in the field of vision, even hemianopsia and night blindness.

4. Gross changes in the interior of the eye, optic neuritis, optic atrophy, retinal hæmorrhages, and hæmorrhage into the vitreous.

In the event of the appearance of any of the disorders of the fourth class it is necessary before ascribing it to malaria to eliminate rheumatism, syphilis, chronic Bright's disease, and chronic hepatitis; and, in so far as atrophies are concerned, the influence of quinine. In any doubtful case, especially in larvate forms of intermittents, and, indeed, in all cases a careful examination of the blood should be made with the hope of determining the presence or absence of the corpuscles of Laveran. It remains to be shown what relation the character and number of these bodies bear to ocular diseases attributed to malaria.

THE RECONSTRUCTION OF DEFORMED NOSES BY GRAFTING A PORTION OF THE FINGER.

BY JAMES P. PARKER, M.D.,
OF KANSAS CITY, MO.

As civilization advances the demand for an unblemished appearance increases, and the number of surgeons who advise their patients to bear the affliction of an ugly nose, deformed eyelid, ear, or lip, with becoming grace and humility grows smaller. The replacing of a lip, eyelid, or nose, or any part thereof was not attempted until after the enthusiastic Tagliacozzi reported his experiments of grafting the cock's spur into the comb and the end of the rat's tail into its back. We may say that it was after these observations of Tagliacozzi that surgeons began to restore lost parts and to relieve deformities by operation. It was not until the eighteenth century that operations for harelip and cleft palate were practised with good results. During the last decade wonderful advances and grand achievements have been recorded in this branch of surgery, but we cannot think the end has been nearly reached. Grafting for the restoration of lost tissues and relief of deformities is yet in its infancy. The only special treatise on the cosmetic surgery of the nose that has been published is the excellent little book by Dr. John B. Roberts, of Philadelphia, in which the operation I offer is not described, and I have been unable to find mention of such an operation in any work on surgery. Rhinoplastic surgery is seldom dwelt on in current medical literature. I therefore ask the attention of physicians to one of the methods to which I have resorted for the reconstruction and cure of the great deformity of the nose resulting from a destruction of the nasal bones and the bony septum by ulceration and necrosis, which causes a sinking-in of the entire upper portion of the nose.

After trying, without satisfactory results, the different operations commonly resorted to for relief of the deformity, I began to look for something better. Every surgeon who has attempted to relieve the condition has appreciated that the great difficulty is to preserve the prominence and symmetry of the nasal bridge, a thing almost impossible to do with muscular or cutaneous tissue alone. If the cartilage or nasal bones be entirely absent, they must be replaced by cartilaginous or bony tissue from the patient or from one of the lower animals, in order to preserve the prominence of the nose. It occurred to me that if I could get a ridge-pole, as it were, under the muscular and cutaneous tissue, I might succeed in holding up the bridge. The phalanges of the little finger of the patient's left hand seemed the most convenient for the purpose, less objectionable to the patient than the tissues of a lower animal, and sufficient to restore the lost or atrophied tissues. To determine the best method of making the attachment of the finger requires much care and thoughtful consideration in each case. The operator must be governed by the extent of the deformity, size and length of nose and finger, and the position in which the hand can best be confined. The following case will serve to illustrate the operation :

J. C. G., aged thirty-five years, a cattle dealer, applied to me, on December 6, 1889, to have the lachrymal ducts dilated, as he was suffering from dacryo-cystitis and, by extension of the inflammation, a severe conjunctivitis.

On examination I found that the nasal bones and the bony septum had been destroyed by ulceration and necrosis. The bridge was deeply sunken. The external tissues had atrophied, leaving a rounded elevation representing the original bony bridge, with the unchanged nasal tip thus thrown into great prominence. He stated that he contracted syphilis during his early manhood. After explaining to him the difficulty of keeping open the nasal ducts, with the nose in its sunken and deformed condition, I suggested an operation for relieving the deformity, and at the same time of preserving the patency of the tear-ducts. To this he readily consented, as his eye-trouble was very annoying.

On January 14, 1890, the patient's nasal passages were thoroughly cleansed by syringing with an alkaline solution, followed by a 1-to-1000 solution of corrosive sublimate. Ether was administered, and the posterior nares plugged. I made a linear incision commencing upon the bone at the root of the nose, in the median line, and carried it well down to the prominent tip, cutting through into the nostril, opening up and elevating the parts with the iron handle of a large scalpel. (It requires great force to elevate the dense tissues at the bridge, even after they are cut through.) I then removed the nail and matrix of the little finger of his left hand, and dissected off the integument from the end of the dorsal and palmar surfaces to the upper third of the second phalanx. Having found, by measuring the nasal wound, the exact length of the graft required, I shaped the finger to fit the wound. The epidermis was removed from that part of the finger resting upon the septum. The hæmorrhage having been controlled, the prepared finger was placed in the wound with the tip of the first phalanx resting upon the bone at the root of the nose, the outer side of the finger being placed anteriorly to give the organ as natural a contour as possible. The thumb of the same hand was placed under the chin, with the first, second, and third fingers resting on the left cheek. The finger-graft was secured in place by silver-wire sutures; the edges of the skin and integument of the nose and finger were brought together and accurately coaptated by means of silk sutures. The lower canaliculi being slit open, I passed a No. 6 Bowman's lachrymal probe into the nasal ducts, on the removal of which I inserted a silver style in each duct. By means of a catheter, I placed a rubber condom in each nostril, carrying it well back into the posterior nares. Each condom was then filled with warm water by means of a syringe, tied to retain the water, and the redundant

rubber was cut off. These dilated bags conformed to all parts of the nostril, and acted as a water-bed to support the parts and to prevent hæmorrhage. The outer wound was dressed with corrosive sublimate gauze. The cheek was padded under the fingers with absorbent wool. The hand and arm were secured in position by means of a rubber bandage, and the patient put to bed. His temperature went up to 101° on the following day, but never higher. The rubber bags were renewed daily for five days, and the nostrils washed out with a solution of boric acid in camphor water. On the fifth day the bandage, dressing, rubber bags, and sutures were removed, primary union having been obtained. The finger was amputated at the second joint, leaving enough of the integument to cover the lower end of the bone. The edges of the skin of the new nose were brought together by silk sutures and dressed with flexible collodion, which remained six days, when it was moistened with alcohol and ether and removed, and the sutures were taken out, leaving the wound united throughout by first intention. The bridge then appeared too high, but some contraction followed, which reduced it to a satisfactory size. The septum and phalanx had formed a rigid union, and the skin of the finger that was placed in the nostrils became normal mucous membrane. The patient left me on April 4th, wearing eye-glasses instead of his old spectacles. He writes me that he "would cheerfully give up two fingers rather than have the old flat nose again."

While deformities about the face may not directly impair an individual's health, the burdens inflicted by the remarks of friends and the jeers of enemies may cause mental aberration and distress. Every effort consistent with safety should be made by the surgeon to relieve such deformities. Stricture of the lachrymal duct is frequent in individuals with flat or sunken noses; therefore, those of us who practise ophthalmic surgery see more of such deformities than the general surgeon, but the supply is sufficient for all.

SOME POINTS IN THE NATURAL HISTORY OF ENTERIC OR TYPHOID FEVER.[1]

By JAMES E. REEVES, M.D.,
of Chattanooga, Tenn.

From the remotest period down to the present time medical history gives no era when the world was entirely exempt from epidemic contagious fevers. Indeed, they have been universal; sometimes prevailing in a particular neighborhood and only attacking a few individuals; at other times spreading amongst vast multitudes and cutting down with a wide swath of death and desolation all ages and ranks of the population. With whatever scope of smiting visitation, whether epidemic and ravaging a continent or confined to a city, a hamlet, or rural hut, they have never been wholly extinct; but their specific germs have lurked a fatal spark among the embers of society, ready to burst forth into a consuming blaze at every favorable breeze.

An Unstable Nomenclature.—Much of the confusion which has existed concerning the natural history of some of the more prevalent specific pyrexial disease has, no doubt, been due to an unstable, and perhaps sometimes unmeaning nomenclature. This reflection, I think, is allowable in connection with the disease under consideration, for even since the beginning of the present century at least a dozen different names have been proposed and employed by systematic authorities.

Following the example of the late Professor George B. Wood, whose memory I shall always cherish, because of his goodness to a poor young man in the backwoods of Virginia, I have chosen the name employed in the title, and in recording my observations shall exclude all unnecessary reference to both the literary history and the etiology of the disease, thus restricting the measure of my self-imposed undertaking to a sincere endeavor to present a true or natural picture of enteric or typhoid fever as I have seen and studied it by the light of nearly forty years' experience—alike in sparsely settled country districts, in village, town, and city; and when influenced neither by crowd-poison, medical treatment, nor the impress of a particular idiosyncrasy.

The name *typhoid fever* was given by Louis in ignorance of a part of the ground, for he did not know, certainly, that another fever existed which ought to be called *typhus*, and in this uncertainty he named the disease *typhoid*, so as to convey, at any rate, the idea of analogy, if not identity, with what had previously been called typhus. In a letter addressed to me, in 1859, Professor Wood said:

"Now that the fact is recognized that these—typhus and typhoid—are two wholly distinct diseases, it seems to me quite unphilosophical to give to one of them a name from its supposed resemblance to the other. We say *varioloid* very properly because the affection so called is a modification of *variola*, and depends on the same cause; but the typhoid is not a modification of typhus, and depends on a different cause. It is true that in some cases, and in certain symptoms, it is like typhus; but scarcely more than it is, in other instances, like miasmatic remittent. It is certainly, I think, not more like typhus than roseola is like *scarlatina;* and yet we do not call the former *scarlatinoid*, or the latter *roseoloid*. Besides, the word typhoid has before been applied to a state occurring in numerous febrile diseases resembling typhus; as, a typhoid state of pneumonia, dysentery, bilious fever, etc., and its application to any one disease at present may lead to confusion, as, in fact, it has often led, in the mind of the learner. The name enteric fever is unobjectionable, and will, I think, ultimately triumph, because it merely indicates that the intestinal affection is characteristic, as in the case of smallpox, which we name from the eruption."

[1] Read before the Association of American Physicians, May 13, 1890.

Not a New Disease.—Belief in the spontaneous origin of the disease has greatly retarded the discovery and general diffusion of correct knowledge on the subject; for, by parity of reasoning, such faith is without substantial support when the question is studied with the life-history of the human race. On the other hand, the doctrine of permanency of original types of contagious diseases has, probably, as remote antiquity for its origin, as stable a foundation for all future time, and as many unanswerable arguments in its support as the doctrine of the permanency of the different types of the human race—each type with its entirely different capacities, physical and mental, and known to have existed for at least five thousand years, and to have been the same at that long-ago period as at this moment; retaining its specific characteristics through every variety of circumstance, climate, and condition.

Now and then fortuitous circumstances may, indeed, have produced a hybrid; but such product could no more have given origin to a distinct and permanent species than a European can be changed into a Bushman, or naked black Hottentot savages into Bacons and Shakespeares.

And thus, no doubt, through a long line of successive ages has enteric fever descended without change of its original or essential characteristics, and will continue to afflict humanity in all situations where are congregated favorable atmospheric, terrene, civic, and domiciliary conditions for the growth and multiplication of its specific germ or contagium, so long as disease and death shall compass the earth.

Epidemic Visitation.—Epidemics do not prevail at all times; therefore, some special predisposing circumstance or influence must be present and lend its aid to produce widespread visitation. The contagion of measles, scarlet fever, diphtheria, whooping-cough, or of smallpox, like that of enteric or typhoid fever, is probably never wholly extinct in any country where these diseases have once prevailed; yet their epidemic prevalence only occurs in uncertain cycles or during particular seasons. To determine why epidemics rise and spread in some years so much more generally or widely than in others, is one of the most interesting points in medical physics; but, unfortunately, no satisfactory answer has yet been given to this question, and, while the phenomenon cannot be explained, we must be content in our ignorance to refer it to the influence of what was called by Sydenham and the older physicians, "the medical constitution of the air." Precisely the same uncertainty occurs with the crops; this year luxuriant growth and an abundant harvest; next year a general or partial failure; but the *seed*, under all modifying or controlling influences of growth and multiplication, remains the same in quality. In other words, the crop may vary as to the *quantity* or abundance of the harvest, but the specific *quality* is unchanged under all conditions.

Again, some soils are unsuited for the growth of certain grains. For example, Indian corn does not grow to perfection in Ireland, while wheat, rye, oats and barley in that country come to maturity and yield the husbandman a successful harvest. The same is true of certain localities concerning the prevalence of enteric or typhoid fever, also of diphtheria and scarlet fever, as I shall show on a subsequent page.

Definitive Elements.—Enteric or typhoid fever may be formulated thus: An acute contagious febrile affection derived from an antecedent case of the disease and depending for its communication from person to person upon the presence of a specific microörganism, which is believed to be of well-known morphological characteristics—a *bacillus*—and which can be cultivated outside of the human body. The disease prevails less frequently in tropical and sub-topical countries than in the temperate zone, is both endemic and epidemic in its visitations; attacks, preferably, young persons and those in middle life; is of long duration, but varying between ten and forty days *beyond* the *prodromic* period, which may cover from one to ten or even twelve days. There is profuse diarrhœa, or, at least, a relaxed state of the bowels, with "pea-soup," or "ochre-colored" stools; and at all stages a marked susceptibility to the action of laxative medicine; intestinal hæmorrhage in many cases, and in a few perforation of the bowels; epistaxis, either slight or profuse; tympanites, with gurgling produced by pressure over the ileo-cæcal valve; dulness of hearing, with mental hebetude, or morbid vigilance; headache, disappearing during the second week; delirium, either mild or violent, with *subsultus tendinum;* rose-colored lenticular eruption during the second week, coming out in crops and disappearing in the same order; fever-curve showing steady elevation of from one to two degrees in the evening with a fall of the same number of degrees in the morning for the first four or six days, and unlike the curve of any other acute febrile or inflammatory disorder; cough and bronchial râles; singular prostration of muscular strength; early heart-failure and a dicrotous pulse. The tongue soon becomes dry, and shows, in grave cases, a brown stripe in the middle, with *sordes* on the teeth and gums; in fatal cases, death occurs during the third or fourth week, with the constant and characteristic lesion of the small intestine involving Peyer's glands; and with enlargement of the spleen. Convalescence is tedious; true relapse is not infrequent, and the dis-

ease affords as perfect immunity from subsequent attack as does scarlet fever or smallpox.

Partial History in Virginia.—Soon after my start in medical practice in Northwest Virginia—now West Virginia—in 1850, I encountered the most virulent and widespread visitation of enteric or typhoid fever it has been my fortune to witness, and I have read nothing in medical history of its epidemic prevalence and fatality, in this country, at least, which exceeded the ravages to which I allude. In thirteen adjoining counties the disease pursued its fearful march without respect to age, sex, or domiciliary condition. In fact, there was scarcely a locality in all that elevated or mountainous country which was not visited and scourged. The towns and villages did not suffer more severely than rural districts, and so varied was the gravity—in some cases, so mild or so slow and tedious; in others, so malignant and rapidly fatal—that the disease received different names to characterize its severity and fatality. In some localities it was given the name of a well-known family that had been swept off by it; in others, in which from the beginning the cases were malignant and quickly fatal, it was called the *Black Tongue*. There was such firm and general belief in its contagious character, that sufficient nurses for the sick could not always be secured, and from this cause, in many instances, the most dire results followed.

I remember some poor families who were thus afflicted and distressed, and when death came to their households they were compelled to put away with their own hands, for want of neighborly assistance, the bodies of their dead.

In other instances, because of the frightful mortality even when the cases were under the treatment of the most experienced physicians, faith in the power of medicines to do good in the disease was lost, and thus the *vis medicatrix naturæ* was left alone to battle with the pestilence. In these examples it appeared, at first thought, that the sick did as well as those who had the diligent service of their physicians, hence the opinion prevailed in some localities that patients were better off without medicine: in plainer words, "without a doctor." Again and again had I the opportunity during that epidemic of observing the march of symptoms where nothing was done for the sick other than the administration of warm teas, plenty of cool water, and a simple diet of milk and bread. But such management was not invariably successful in conducting the patient to safe convalescence; indeed, it was really unsuccessful, but the deaths were charged to the "will of God!"

It was by such impressive lessons at the very threshold of my experience in practice that I formed my acquaintance with the disease, and became assured of the value of the great truth that "violence in therapeutics is never justifiable when moderation is adequate to the same good end." And this is the foundation on which, year after year since that time, I have laid my observations, and builded the confidence which brings me with a fresh offering on some points in the natural history of enteric or typhoid fever.

Forms of the Disease.—In my studies I have been naturally led to recognize *three forms*—the simple, or mild; the intermediate; and the malignant, including the fatal—rather than a division of stages by weeks; and I think this arrangement fully warranted by the clinical history. It may be extremely difficult, in some instances, to say just where the distinguishing or dividing line should be drawn, so very gradual is the transition from one form into the other; but in the large majority of cases there is little difficulty in recognizing it.

Incubation.—The period of incubation, or the length of time between the date of the exposure to and inception of the specific poison, and the first manifestations of the disease, is as yet unknown, because the precise date of infection can rarely be ascertained; but its duration is, probably, in most cases about two weeks. Instances, however, have been given where the disease followed immediately, or within a day or two, after exposure.

Mode of Access.—The initial symptoms or mode of access may vary considerably. In a few instances, there are no premonitions; in others the formative period may be extended from two to six, eight, ten, or even twelve days; and these differences may occur without foreshadowing the exact type of the fully developed disease.

As showing the suddenness of attack in some instances, I give the case of Mr. W., a young lawyer, who, while engaged in defending a client indicted for a felony, and when reading the climax of his argument was so completely dazed for the space of half a minute or more that he stood motionless and speechless, staring at the judge. His long pause soon attracted general attention in the court-room; but just at the moment of greatest surprise at his conduct, he came to himself, connected his speech with the word at which he had left off, and went on to its conclusion without further embarrassment either of thought or speech. When he went into the court-house that morning he was in his usual good health; when he left it that afternoon to go to his home, not far off, he felt physically unwell, and mentally oppressed with the weight of some impending dreadful calamity. Feeling confident that he was about to become dangerously sick he at once prepared his will and then went to bed. Within the first week of his illness he became delirious, and rapidly passed into the gravest form of the disease from which, six weeks later, he barely escaped with his life.

Entirely the opposite, in mode of access, to the case above given, was that of Mr. T. G., aged thirty-six years, clerk of the county court, who drooped for two weeks before finding himself unable to pursue his accustomed business, and confining himself to his house. The next three weeks he arose every morning, dressed as usual, and spent the day in reading, writing, or other light occupation to while away the weary time; resting and napping on the sofa, as his inclination prompted. At the expiration of this period I was hastily called early one morning to learn that a short time before my arrival he had been suddenly seized with severe pain in the abdomen just after rising from his bed and while dressing. His countenance was pinched, and pale as death, and he died within the next thirty hours from perforation of the bowels.

Between these wide extremes the *prodromic* period may be as varied as there are days in the limits; but, as a rule, the disease is fully developed by the fourth or fifth day from the time the first feeling of *malaise* is experienced. This declaration is based on the observation of 130 consecutive cases in which I carefully endeavored to ascertain this and other not less important points concerning the disease. Headache and backache—frequently accompanied with slight nausea—start the clinical history. The pain in the head is usually referred to the occiput, but in many cases the entire head aches; while backache extends from the root of the neck to the coccyx. There is a feeling of vertigo, and both mental and bodily languor are plainly manifested. The appetite is impaired, the tongue furred, and the mouth pasty, with offensive breath, and unnatural thirst. A shivery feeling now and then comes over the surface, alternating with flushes of heat; the pulse quickens, usually to ninety or one hundred in the minute; sleep is interrupted by an evening exacerbation of febrile excitement, and the patient awakens without feeling refreshed; the urine is somewhat scanty and high-colored and the bowels are either simply relaxed or there is free diarrhœa, in either case accompanied with a sensation of increasing fulness of the stomach.

Hour after hour, or day after day, all these ill feelings become more pronounced and distressing, when, at last, a sensation of chilliness more severe and prolonged is felt, with an aggravation of the headache and backache, and the patient now willingly goes to bed to take on and pass through one or the other of the forms of the disease classified on a preceding page.

The Mild Form.—Sixty-four of the 130 cases above referred to were of the mild form, and a majority of them terminated in convalescence between the thirteenth and eighteenth day—the range for the whole number being from nine to twenty-five days.

In this class of cases, following the exacerbation of symptoms which completes the measure of the *formative stage* and ushers in the fully developed disease, the pulse becomes more frequent, say ninety or one hundred and five in the minute; there is increased heat of skin, the temperature gradually rising from one to two degrees higher in the evening than in the morning for four or six days, at the end of which time the range is between 101° and 104° Fahr. in the evening, with a fall in the morning of from one to two degrees. With the steady rise of temperature respiration becomes more hurried, and slight cough sets in and is accompanied with quite free expectoration toward the close of the fever. The headache continues from five to ten days, and when it ceases is usually lost in the obtuseness or drowsiness which is such a common trait during the second week of the disease. There is throbbing of the temples; the face is flushed, and toward evening, when the fever is highest, purple spots appear on the cheeks—first upon one cheek and then on the other; or the nose may present the same livid color and a swollen appearance. The tongue may be coated so thinly as scarcely to be called coated, or covered with a thick white or yellowish fur, thickest at the middle and occasionally dotted with aphthous-looking specks; and it is moist when the patient is not sleeping. At its tip and edge the coating loses itself, leaving the mucous membrane clean, bright, and shining. In many cases the fur disappears in large patches, giving the appearance of loss of the mucous membrane on such places. If *malaria* complicates the case, the tongue is broad, flabby, and presents a creamy coating; otherwise it is not changed in size, does not assume the pointed shape, nor show the brown stripe along its middle, so common in the graver forms of the disease; and it does not tremble when protruded. The abdomen is tumid, tender, and gives a gurgling sound from the right iliac fossa when deep pressure is made over this region; wandering pains in the stomach and bowels may be complained of, accompanied with nausea and occasionally free vomiting. There is loss of appetite, if not entire disgust for food; thirst is excessive, the patient calling for water every few minutes; the bowels incline to looseness and sometimes there is free diarrhœa; the discharges are of the "pea-soup" variety, flocculent, and of a peculiar and very offensive odor. The urine is diminished, highly colored and turbid. Sleep is not refreshing, and the sleeping hours are disturbed by unpleasant dreams. A very common mental condition during sleep is the impression that the body is severed in pieces, and much worry is occasioned by the unsuccessful efforts to reunite the fragments; or, if not

this distress, some other imaginary accident befalls the patient, who, in his efforts to extricate himself, suddenly wakes and manifests confusion as to his identity and whereabouts.

Dulness of hearing is one of the most unvarying conditions in the disease. Epistaxis is also exceedingly common, and often is repeated several times during the first two weeks. The rose-colored lenticular eruption is usually present. Indeed, I have seldom failed to find it at some stage of the disease —generally between the seventh and fifteenth day. In my experience, it has been the rule to discover the largest patches of the eruption in cases which were least troubled with profuse diarrhœa. In other words, it has seemed to me that the cases with the least intestinal alteration are those in which the eruption is most profuse. Sometimes I have seen the patient spotted from head to foot; in other instances the eruption was principally confined to the chest, abdomen, and inner part of the thighs; or showed itself on the fingers and toes, while but few spots could be found on the trunk. Again, I have frequently seen it profuse on the back, and I am inclined to believe that it occupies this part of the surface oftener than is generally known, for the reason that it is not so conveniently sought for as when upon the abdomen, chest, and extremities. Of the vesicular eruption called *sudamina*, I have but this to say: I have seen it in very few instances, all of which were in cases of the form of the disease next to be described, and preceded by profuse perspiration. Finally, there are few cases of enteric or typhoid fever in which enlargement of the spleen may not be discovered.

Amelioration of these symptoms, shown by lower temperature, relaxed and gently perspiring skin, refreshing sleep, cleaning tongue, relish for food and diminished thirst, less frequent and more consistent stools, increased secretion of urine, soft and flattened abdomen, and by brighter countenance but with marked shrinking of the features, is the pleasing warrant of Nature's triumph, and that convalescence has been reached. Yet, such a happy termination may be suddenly thwarted by an aggravation of all the symptoms and the patient placed in greater danger than before; or he may suffer from a true relapse—the cause of which may be impossible to determine—and go over again, and through great dangers, the road he has just travelled. And thus the case may run a mild course throughout or take on at the beginning of the illness the graver symptoms I have distinguished as belonging to the intermediate form.

The Intermediate Form.—In this class there are but few symptoms to be recited that have not already been included in the description of the mild form. Thirty-two of the 130 cases presented, either at the beginning of the attack or during the second week, the exacerbation of symptoms characteristic of this form. With the same variable period of incubation and difference in mode of access, the febrile exacerbations are more prolonged and followed less frequently by moisture of the skin. The temperature rises gradually to 104½° or 105° in the evening and falls not more than a degree or two in the morning. In other words, the high temperature is more constant at all hours of the day and covers a longer period. The pulse also is much accelerated, and soon becomes dicrotous because of the weak heart; the tongue takes on a thicker and darker coating except at the tip and edge, where it is red and shining, and it presents also a dark-brown stripe down the middle. Its surface is dry and concave, the edge thin and apparently contracted, the tongue resembling somewhat in form the bowl of a tablespoon with its point bluntly rounded, and cracked. When told to show his tongue the patient is slow in comprehending the request, and the effort is a trembling one, showing blunted sensibility and grave systemic involvement. At the same time *sordes* begin to form on the teeth, gums, and lips, and the angles of the mouth are cracked and bleeding. Somnolence becomes more and more profound as the case advances toward the crisis (except in the few instances where, instead, morbid vigilance is present); the countenance is dusky, and the mind and senses greatly blunted. In many cases the dulness of hearing is so extreme that it is with difficulty that the patient can be aroused and his attention secured.

Wandering of the mind, at first noticeable only at night—especially during the second week of the fever—is now present at all times in the majority of cases. The patient sees the bedposts transformed into disagreeable personages who have taken their position at the foot of his bed to annoy and insult him by their grotesque performances; and under this provocation he starts up in anger to drive them from his presence, when the physical effort thus put forth dispels the illusion, and he falls back upon his pillow wondering how it was possible he could have been so much mistaken. Soon, however, his Quixotic sally is repeated, and in that way he goes on day after day and night after night, sleeping, dreaming, and wandering, except when his attention is rationally engaged.

In this condition, notwithstanding the continued high temperature and dry and parched tongue, the patient does not ask for cooling drinks; in fact, he has now become to a great degree insensible to his natural wants, for when his bowels are moved the disposition to empty them is not felt until just before the discharge takes place, and in the hurry to get him on the bed-pan, the sheets and other bedclothing are frequently soiled. The same obtuseness

sometimes permits the bladder to become greatly distended before the desire arouses the patient to the necessity of emptying it. Diarrhœa, either mild or profuse, is always present—I mean liquid stools—and the frequency of the discharges from the bowels governs, usually, the extent of meteorism. In other words, if diarrhœa is profuse, there will be in the same proportion extensive tympany and abdominal tenderness. In many cases the diarrhœa does not exceed more than two or three stools in the course of twenty-four hours; but it is more common for the number to reach a half-dozen in that time. As a rule, the stools are darker and far more offensive than in the mild form of the disease, and they are often attended with sharp pain about the umbilicus. Now and then they are bloody; but the intestinal hæmorrhage is not so extensive as in cases of the malignant form.

The urine, passed in smaller quantities, is deeply colored, and often voided with much difficulty. Epistaxis may be so frequent and profuse as to put the patient in great jeopardy. The smaller number of rose-colored spots in this form of the disease has already been stated; and it is also unnecessary to repeat what I have said concerning the presence of sudamina. Great prostration of muscular strength is an invariable condition, and in a vast majority of cases, *subsultus tendinum* is present. It is in this form that we find, very often, troublesome cough and sputa streaked with blood.

And thus the intermediate form may go on undetermined for a few days or for many days, flattering the physician at one time with the approach of convalescence, at another time exciting his deepest anxiety. At the close of the second week, or about the beginning of the third week, it is not at all uncommon to find that a great improvement in the symptoms has taken place quite suddenly; so much so that the attending physician may find that since his visit the day before the tongue has become moist and has cleaned a little, the countenance brighter, and in every other particular a correspondingly happy change, when, as suddenly, and without apparent cause, the patient becomes worse than at any previous time. This unfavorable turn of the symptoms may continue but a few days before convalescence is reached, or it may send the patient into the gravest form of the disease, now to be described.

The Malignant Form, including the Fatal.—Enteric or typhoid fever may assume the malignant form in the beginning of the attack; but this is not generally the clinical history, for in the majority of cases it is preceded for a longer or shorter period by one or the other of the milder forms. For example, of the 130 cases to which I have before referred, and which in part furnish the basis for my positive opinions on this and other equally important points, 25 cases passed through the milder gradations, with variable duration, before reaching this form. So, in order to present a continuous and faithful description of the disease from the moment of development to its termination, it is necessary to go back to the point at which I completed the description of the *intermediate form*, and then to proceed with the graver assemblage of symptoms to the end.

After the exacerbation of symptoms which marks this form of the disease, the progress is usually rapid to the final termination. Prostration of strength is an ever-present condition. The patient is now rarely found on his side, for he has not sufficient strength to maintain that position and must lie on his back, with a disposition to slip down in the bed. The pulse is frequent and feeble; there is constant twitching of the tendons of the wrists, and sometimes the whole body is in constant tremor from muscular twitching, to such a degree in some cases that even the bed-clothing is in constant wave-like movement, or if one sit on the bed-rail a trembling sensation is distinctly perceived. The voice becomes changed; so feeble in some cases that it can scarcely be raised above a whisper; in others the articulation is so imperfect that all attempts at conversation amount to little more than a trembling jargon. The tongue takes on a thicker and black coating, and all efforts to protrude it are slow, trembling, and uncertain; and when protruded, if the patient is not otherwise directed he will probably leave it exposed. With this state of the tongue and with the general insensibility, deglutition is often interfered with and food and drinks are taken with much difficulty.

The temperature of the surface may be uniform or unequal; the head and trunk hot and dry while the extremities are cool, or the face and hands sweat freely while other parts of the body are dry. In every case with this grave condition more or less cough is present, accompanied at one time with free expectoration, at another nothing but frothy, sticky mucus is expelled; loud râles are heard, breathing becomes hurried and occasionally irregular or jerking. The temperature line shows little variation between the extremes of evening rise and morning fall; is fitful and undulatory at all times. The condition of the abdomen and state of the bowels are also fair measures of the seriousness of the case; the tympany makes a convex surface from the ensiform cartilage to the pubes, and when pressure is made the abdominal wall seems thin, hard, and resisting "as though made of pasteboard," and scattered here and there over its surface are a few *rose-colored* spots.

The stools are very offensive, of a dark color, and so sticky that the bed-pan or chamber-pot is emptied

and cleansed with difficulty. In color and consistence the discharges resemble dark-brown paint; but when slight hæmorrhage takes place and the blood is retained for a few hours, the discharges are black and tarry and exhale a most sickening odor. It is always in this form of the disease that the most frequent and profuse hæmorrhages take place. In many cases the blood discharged from the bowels is red and but little changed; in others it is dark and disintegrated. Several times I have seen the usual sized chamber-pot half filled at a sitting, and in one case the patient fainted and fell from his chair to the floor, and was put back in bed almost lifeless. In this case hæmorrhage succeeded hæmorrhage until the eighth day from the first bloody discharge, when he died. Eighteen of the 34 cases, before referred to, suffered hæmorrhage from the bowels, and of these 8 were fatal. In this form of the disease, I have seen the patient bleed from the nose, from the gums, from the bowels, from the bladder, and from the petechiæ.

The urinary secretion shows much alteration of character. It is scanty and dark as lye, and when there is hæmorrhage from the bladder small particles of coagulated blood are deposited on the bottom of the vessel. The urine may be retained, either with or without admixture of blood, requiring repeated use of the catheter. Delirium, so common in this form of the disease, may be either mild, violent, or low and muttering; the patient picks at the bed-clothing, or reaches out his hand to catch some imaginary object. In a few instances I have seen the delirium strictly monomaniacal. Involuntary discharges both of urine and fæces frequently take place and then there arises from the patient's body a most nauseating odor. In addition to the above described conditions, the skin may break on parts most exposed to pressure, as the sacrum, hips, and shoulders, which is followed by sloughing. All these show vitiated constitutional powers.

Finally, when the case is to end in recovery there is improvement of all the symptoms, and the patient passes, sometimes quickly and at other times slowly, through convalescence to health. But if death is to be the end, it may come in different ways, according to the lead of symptoms. If by coma—the most frequent mode of death in enteric or typhoid fever—the low muttering delirium from which the patient could at first be aroused, gradually becomes more and more profound until complete insensibility is reached; the jaw falls by its own weight and the mouth is open, the lips tremble, the muscles of the face twitch, the eyelids are half closed, the balls upturned and roll from canthus to canthus; petechiæ and vibices make their appearance on various parts of the surface; the parotids swell and may suppurate; the pulse beats so rapidly that it can scarcely be counted; the breathing is rapid, and automatic efforts are made to expel the secretions which choke the lungs and rattle in the throat, a cold, clammy sweat breaks out, the extremities become cold, there is a final struggle, and Death has won the mortal victory! In fewer instances the fatal result is reached by almost imperceptible degrees; from first to last the mind remains unclouded, and the patient passes away without a struggle.

Thus I have completed the description of a case either *mild* throughout, or having been mild for a longer or shorter time, passing into the *intermediate* form, then either convalescing or passing into the *malignant* form.

Of the 34 cases of this form, 9 assumed this character at the beginning of the fully developed disease, 6 of whom complained of feeling out of health for three days previous to taking to their beds: the remaining three retired as usual and in good health to awaken next morning with headache, sick stomach and vomiting, a chill, and then fever. In all of these cases the mind and senses were quickly involved, as shown by aversion to light and sound, morbid vigilance, confusion of ideas, followed as early as the second or third day by active delirium, which continued until lost in *coma*. After such beginning, a case proceeds as above described to its final termination.

Supplemental and Emphasis.—In presenting the foregoing description of the symptomatology, sufficient emphasis of certain conditions seemed impossible without interrupting and confusing the connected clinical history of each phase of the disease; hence, I shall now endeavor to cover the deficiencies to which I refer.

Headache is so constant in its presence during the first week of the disease that it was found in 127 of 128 patients who were of sufficient age to express suffering. Sometimes it is exceedingly severe, assuming a neuralgic character, and it may continue through the whole course of the disease.

The state of the mind and senses varies with the different forms of the disease, from listlessness of manner and simple wandering of mind with a blank, dejected expression of countenance, to the wildest delirium. A very common impression with the patient is that he is away from home and exposed to personal injury; thus influenced, he jumps out of bed if not restrained, and makes for the door. Delirium is equally common in children, but of milder form than in adults. Of 23 cases of the malignant form of the disease terminating in recovery it was present in 21; and of 11 fatal cases it was distinctly marked in 10, the exceptional case passing down to death without a cloud to obscure its approach. Some-

times it is of long duration, continuing for three weeks, and it may present any grade or character. In other cases there may be a sudden outbreak of mental disturbance during the period of convalescence. In one such case after the patient had proceeded so far on the road to health as to be able to go out of doors for several days, he was suddenly overcome with illusions which continued for a few days and then as suddenly disappeared, leaving no impress or mark behind.

Dulness of hearing is so complete in some cases that in order to arouse the patient he must be spoken to at the highest pitch of the voice. In a few instances the reverse of dulness exists, and the sense may be so acute that the slightest noise attracts attention, even the light step of the nurse across the floor, and unless there is perfect stillness in the room the patient is painfully discomforted.

Prostration of muscular strength is such a constant condition from the beginning to the close of the disease—such a fair measure in forming the prognosis—that its importance cannot be too strongly emphasized. Even during the formative stage, and before the patient takes to his bed, his gait is tottering, and if he attempt any manual labor he is soon fatigued. In the *mild* form when he is placed in a chair in order that his bed may be made up and aired, he soon tires and is impatient to lie down. In the *intermediate* form he must have assistance to hold up his head for a drink of water. In the *malignant* form there is utter prostration. An increase of the strength is the sure harbinger of convalescence. In the so-called "walking cases," loss of muscular strength is the most that is complained of.

Accidents and Sequelæ.—The most fearful of the accidental inflammations is peritonitis, the result of perforation of the bowels, the symptoms peculiar to which are so well known that it is unnecessary here to say more than that the accident occurs, usually, in the third or fourth week—in rare instances during convalescence—and is announced, in the majority of cases, by the sudden supervention of acute pain in the abdomen, accompanied with either a pronounced and severe chill or prolonged feeling of chilliness, with cool, clammy skin; acid eructations and vomiting; exquisite tenderness of the abdomen on pressure: great prostration of muscular strength; rapid, feeble pulse: and, after recovery from shock, abrupt rise in temperature.

I have seen in five instances all the symptoms which announce and follow perforation of the bowels, yet the patients recovered; so that I am led to believe the accident is not necessarily fatal. Four of the five cases to which I refer occurred in males, all, save one, over thirty years of age.

The safety of pregnancy seems to be but little influenced or endangered by the disease, for in all my experience I have not met with a half dozen abortions or miscarriages which could be charged to its presence. And there is good ground, I think, for belief that the pregnant state affords some immunity from the disease.

Among the sequelæ, I have seen frequent examples of swelled leg and thigh, like that which occurs in parturient women. This has been first noticed during convalescence. In one such case the swelling came on before the patient was able to quit his bed for the whole day: and in another case, at the opposite extreme, it was not noticed until during the third week after recovery from the fever. In some cases of this complication, especially those which have developed early in convalescence, the swelling is accompanied with pain and tenderness; but ordinarily with the accident there is no complaint other than of a feeling of stiffness and slight lameness. I have never seen a leg thus affected go back to its normal size and proportions.

Special Memoranda.—Season. The autumnal and winter months, according to my observations, give the largest number of cases.

Age. A large majority of cases occur between the ages of fifteen and thirty years; yet I have seen the disease in an infant of eighteen months—the mother sick at the time with the same disease—and, at the other extreme, repeatedly in subjects over sixty years of age.

Sex. The disease more frequently attacks males than females.

Race. The disease is probably less frequently met with in the negro than in the white race.

Immunity in Certain Localities.—In an early part of this paper, when referring to the wide diffusion of the disease, I mentioned the fact that in certain places it had rarely been met with, and never witnessed in endemic or epidemic form. Chattanooga is one of these remarkably favored places where enteric or typhoid fevor does not prevail, notwithstanding the city has a population of 60,000, and is embarrassed by very serious sanitary defects such as are common to all new and rapidly growing cities, namely, insufficient sewerage, many miles of unpaved streets and alleys, and thousands of open cesspools in the form of the old-fashioned privy vault.

Dr. P. D. Sims, a member of the State Board of Health, who has been in active general practice for more than thirty years in that city, and is a most competent observer, says that in all of his experience in Chattanooga he has seen but three or four cases of typhoid fever. Like testimony is furnished by Dr. J. H. Van Deman, who, until the last three or four years, had been engaged in general practice since 1865, or from the close of the war, when he left the army. The observations of Drs. Sims and Van Deman have been confirmed by a score or more of later witnesses who from time to time came to the city.

Chattanooga is situated in the great Moccasin Bend of the Tennessee River, at the foot of Lookout Mountain, with an altitude of 650 feet above sea-level, and surrounded by high hills and mountain ranges that rise above the city from 600 to 1650 feet. The prevailing winds from March until December are either from the southwest—sweeping the top of Lookout Mountain, whose base is but three miles distant from the centre of the city—or from due west, when they come laden with freshness and health from the Raccoon Range, but four miles away, which is 1400 feet above the level of the city. In winter the prevailing currents come from Walden's Ridge, six miles to the north, which walls the valley on that side. In the undulating cove in which Chattanooga stands, with her "seven hills," like the Eternal City, she is sheltered on all sides; possessing a stable, genial climate, blessed with good general health at all seasons, and adding every year thousands to her thriving, busy population.

The United States Signal Service report from Chattanooga Station for ten successive years shows the temperature to be as follows:

Mean Temperature.

For the Year.	For Winter. Dec., Jan., Feb.	For Summer. June, July, Aug.
1879. 60.7°	44.5°	76.4°
1880. 60.3°	45.7°	76.2°
1881. 60.8°	42.6°	79.0°
1882. 60.3°	44.7°	74.9°
1883. 60.8°	45.7°	76.9°
1884. 59.6°	42.0°	74.2°
1885. 57.7°	39.2°	76.4°
1886. 57.3°	36.6°	73.9°
1887. 60.1°	43.6°	76.2°
1888. 59 1°	43.2°	76.2°
1889. 60.4°	47.2°	75.1°

The total rainfall for the same period was as follows:

Total Rainfall.

For the Year.	For Winter.	For Summer
1879. 4.34 inches.	7.60 inches.	8.88 inches.
1880. 5.65 "	4.23 "	3.61 "
1881. 5.8 "	6.57 "	3.43 "
1882. 5.16 "	8.20 "	4.71 "
1883. 4.16 "	5.49 "	3.21 "
1884. 5.15 "	7.16 "	5 51 "
1885. 4.72 "	5.13 "	5.00 "
1886. 4 88 "	4.38 "	4.88 "
1887. 4.26 "	6.07 "	3.54 "
1888. 4.57 "	4.57 "	3.57 "
1889. 4.11 "	3.62 "	3.75 "

During the last three winters, or since my residence in Chattanooga, I have not seen snow on the ground.

The Annual Death-rate.—In ordinary years the death-rate does not exceed twelve per thousand per annum, including both races; and if the entire population were white, it would not, probably, exceed ten per thousand.

Conclusion.—Diphtheria is also an unknown disease in Chattanooga, and the same is nearly true of scarlet fever. No doubt that now and then examples of all three of these diseases have been met, brought in the persons and baggage of visitors; but the seed, when imported, uniformly failed to multiply.

The miasmatic remittent fever met with in Chattanooga sometimes assumes grave character, and then often presents the so-called "typhoid state;" but its clinical history in every essential particular is wholly unlike enteric or typhoid fever. Since taking up my residence in the city, I have had good opportunity to observe the changes in the blood in malarial cases, and am entirely convinced of the value of Laveran's researches in deciding the difference between malaria and enteric or typhoid fever. And here I desire to acknowledge my indebtedness to our own countrymen, Councilman and Osler, for their distinguished labors in the same field. Again and again have I been able, easily and quickly, to clear up the diagnosis by a microscopical examination of the blood in cases of doubt; for, in the language of Dr. Osler, "the characteristic changes in malaria are as distinctly determined in the blood as are those of tuberculosis of the lungs in the sputa."

CATALPA SPECIOSA (*WARDER*).[1]

By J. SCHNECK, M.D.,
of Mt. Carmel, Ill.

The genus Catalpa is represented in North America by two beautiful trees: first, *Catalpa speciosa*, Warder, which grows in low, rich bottom lands along the rivers of Southern Indiana, Southern Illinois, Tennessee, Missouri, and Arkansas: second, *Catalpa bignonioides*, Walter, which is more southern in its habitat, and is found in Georgia, Alabama, and the Carolinas. This is a smaller and more spreading tree than the former. Until the year 1853 botanists regarded them as of the same species. It is important to bear this fact in mind, as authors who write of the tree as seen in the Eastern and Southern States refer to C. bignonioides, while those whose observations are made in the Middle or Central States refer to C. speciosa. The latter is the species considered in this paper.

They are generally regarded as the same species by the laity, and are known as the catalfa, catalpa, Indian bean, catawba, and cigar tree.

The genus belongs to the *bignoniocece*, which is a large order of, chiefly tropical, American plants. They are especially noteworthy for the beauty of the flowers of many of the species. The wood, bark, and leaves of C. speciosa emit a fœtid odor when handled or burnt; this unpleasant odor is not shared by the flowers, which are pleasantly fragrant.

[1] Read before the Illinois State Medical Society, May, 1890.

From earliest childhood I had been taught that the tree was poisonous; and this view is shared by the people generally in the vicinity where it grows. On consulting early botanical literature I find this belief has existed from our first acquaintance with the tree. F. A. I. Waugenheim, a German forester, who served in the British army during the Revolutionary war, published, in 1787. *Notes on American Forest Trees.* Of *catalpa* he says:

"The white inhabitants in America affirm that the negroes in the Southern States are in possession of a secret method by which they can prepare, from the roots of this tree, a slow, but always most serious, poison. The inhabitants of Carolina, Virginia, and Maryland are so assured of it that the catalpa trees are extirpated in the vicinity of all the habitations and plantations; and that a law passes sentence of death upon the negro who secretly plants or cultivates the tree."

Ludgi Castiglioni, who travelled in this country from 1785 to 1787, published an account of his journey, in which he refers to the same prejudice. He says:

"The catalpa trees were banished from the lawns and gardens in Pennsylvania when the rumor was abroad that the negro slaves made use of them to poison their comrades."

He then discredits its poisonous properties, but says: "A decoction of the wood provokes vomiting, but it produces no other bad effects on the system."

Kämpfer and Thunberg state that, in Japan, the pods of a closely allied species are used to relieve persons suffering from asthma and bronchitis, and that a poultice made of the leaves is valuable in relieving the severe pains of neuralgia. In his inaugural thesis to the University of Pennsylvania, 1803, Dr. Robert Holmes refers to a popular belief in its prophylactic properties in warding off malarial and contagious diseases.

In the following experiments and applications I have used a tincture, prepared by myself, from the inner or live bark of the root and body of the tree. It was made by the old, or maceration, method, using an ounce of the fresh bark to make an ounce of the tincture. The experiments were made upon my friend Mr. G. B. Davidson, a man of excellent mental attainments, and myself. We were both then nearly thirty years old, and in excellent health.

RECORD OF EXPERIMENTS ON DAVIDSON.

Date.	Temp	Pulse. Sitting	Pulse. Standing.	Remarks.
1876				
Mar. 14				
3 P. M.	.....	70	...	Took one ounce of the tincture.
4 "	.....	70	...	Could feel no effects of the drug; took one ounce of tincture.
Mar. 22				
12 M.	.....	76	...	Ate a hearty meal.
1¼ P. M.	101½	76	...	Took one ounce of the tincture.
2½ "	100	72	...	No effect from the drug; took one ounce of the tincture.
3½ "	98½	72	...	" " " " " "
5½ "	99	78	...	" " " " " "
6½ "	98	72	...	No effect from the drug; ate a hearty supper.
8 "	99½	78	...	Took two ounces of the tincture.
9 "	98½	69	...	No effect from the drug; took two ounces of the tincture.
11 "	99	66	...	Nausea, and the pulse weak; nausea during remainder of the night, and the following morning two large semi-solid stools.
Mar. 25				
8½ A. M.	98¾	72	...	Took two ounces of the tincture.
9 "	98	72	...	No effect from drug; took two ounces of tincture.
9½ "	98¾	68	78	" " " " " "
10 "	98¼	66	72	Pulse irregular; slight nausea.
10½ "	98¾	66	78	Pulse irregular; took two ounces of the tincture.
11 "	98	68	78	" " " " " "
11½ "	98½	68	76	Pulse irregular and weak.
12 M.	98¼	66	80	Pulse irregular; had several copious stools during next twelve hours, semi-solid and dark color.
Mar. 27				
1 P. M.	98¾	94	103	Ate a full meal at twelve o'clock, then walked nearly a mile.
2 "	98¾	87	94	Read almost constantly between the time of making the notes.
3 "	99	87	92	These observations are made as a
4 "	98½	84	90	comparison with the foregoing.

RECORD OF EXPERIMENTS ON SCHNECK.

Date.	Temp.	Pulse. Sitting	Pulse. Standing.	Remarks.
Mar. 22				
12 M.	.....	...	...	Ate an ordinary meal.
1¼ P. M.	101¼	78	...	Took one ounce of the catalpa tincture.
2½ "	98¾	66	...	Slight burning sensation in the stomach; took one ounce of tincture.
3½ "	98¼	60	...	" " " " " "
5½ "	99¼	66	...	Burning sensation in the stomach less; have taken severe exercise since last dose; took one ounce of tincture.
6½ "	98½	72	...	Burning sensation in stomach almost stopped; ate hearty supper.
8 "	99	72	...	Felt no effect of the drug; took two ounces of tincture.
9 "	98¾	72	...	" " " " " "
10 "	98¾	72	...	" " " " " "
Mar. 25				
7 A. M	.....	...	...	Had a copious semi-solid bilious stool.
8½ "	98½	75	...	Took two ounces of tincture.
9 "	98½	76	...	Felt no effects; took two ounces of the tincture.
9½ "	98¾	66	84	" " " " " "
10 "	99	68	72	Decided nausea; pulse weak.
10½ "	97	66	78	Nausea less; pulse weak, dropping two or three beats per minute; took two ounces of the tincture.
11 "	96¾	62	73	Nausea slight; took two ounces of the tincture.
11½ "	96½	63	78	" " " " " "
12 M.	97½	63	78	Decided nausea; no desire for food.

To compare with the above, I made the following observations:

Mar. 27				
1 P. M.	98	74	81	Had taken a regular meal at 12 M
2 "	99	78	84	
3 "	99	70	72	
4 "	98½	70	72	

From the above experiments we may deduce the following:

1. That with drachm doses of the tincture unless continued for a considerable time the system is but slightly affected.

2. That if taken in large enough doses it will slow the heart-beats, weaken its action, and finally produce an intermittent pulse.

3. That it acts on the alimentary secretions, producing a mild cholagogue, cathartic effect.

4. That in sufficiently large doses it produces nausea, and probably, in still larger doses, vomiting. It is probable that in this way it acts beneficially in asthma and bronchitis.

5. That by its sedative action on the heart it acts as an antipyretic.

In its clinical application I have found it most beneficial in those cases of pneumonia where the secretions of the alimentary canal were inactive and in which there was also a rapid and full pulse. It reduces the pulse-rate and tension, and increases the biliary secretion. Two drachms of the tincture should be given every one to three hours.

During the past winter I have used it often in cases of epidemic influenza with high fever, and especially where the inflammation extended into the frontal sinuses. In all of these acute cases I have never ventured to continue the remedy after the first two or three days, and have given it for this period only in sthenic cases. I have thought it best to feel my way carefully in using a new remedy whose principal action is on an organ so vitally important as the heart.

Mr. E. O. Rau has made an imperfect chemical analysis of the seeds; he obtained from them tannin and a bitter crystalline principle.[1] Mr. F. K. Brown, by a more thorough analysis of the seed, found a resin, tannin, sugar, a fixed oil, and two undetermined crystalline bodies.[2] It is reasonable to suspect that the medicinal qualities reside in the crystalline principles mentioned in the above analyses. It remains for chemists to tell us in which part of the plant they are most abundant, and, if possible, to isolate them, so that they may be used for further and more definite experiments. I present these notes and conclusions as the results of careful observations, and hope the medical profession will give the drug a thorough trial.

CLINICAL MEMORANDA.

PÆDIATRIC.

A Case of Imperforate Anus in which the Fæces were Passed through the Penis, and later through the Umbilicus Autopsy.—This rather remarkable case occurred in the practice of Dr. C. A. Munn, of Kingston, N. Y. I first saw it when the child was three weeks old.

Dr. Munn was called on the evening of February 23d to attend Mrs. S., aged twenty-four years, a primipara, who was in labor at term. The woman was delivered in a few hours of a male child weighing about six pounds. Upon examination the infant was found to be well formed with the following exceptions: It had an imperforate anus, or, more correctly, there was complete absence of an anus or anything resembling one. The skin was perfectly smooth from the end of the coccyx to the scrotum, and there was no raphé. On examination with the finger the parts felt firm and solid, and it was impossible to push the end of the finger even a short distance into the lower end of the bowel. There was never any bulging present, as is the case when the rectum becomes distended with fæces. The child urinated naturally, and also passed its fæces through the penis.

This continued for about three weeks when the nurse stated that it passed its urine and fæces from the umbilicus. It lived to the age of five weeks, and during the last two weeks of life passed the greater part of both urine and fæces from the umbilicus, although at times urine would pass through the urethra. The discharge from the umbilicus was not constant, but took place at regular intervals.

In addition to this malformation the child presented other deformities. The bones of the right forearm were rudimentary, being only about one and one-half inches in length, and very small. The right hand was not deformed, though strongly flexed. The bones of the right leg presented a similar peculiarity; they were about the same length, and the foot was attached in much the same manner as the hand described above. The foot also turned inward, and, in truth, would be termed club-foot if the bones of the leg had been of the usual length.

The mother of this child was a quick-tempered hysterical woman, and during pregnancy had had several hysterical attacks, one of which I witnessed. Her husband was somewhat dissipated, and whenever he was under the influence of liquor she would become excited, throw herself on the floor, tear her hair, and cry until she was exhausted. Whether this had anything to do with the deformity of the child it is, of course, impossible to say.

Autopsy, twelve hours after death, by Drs. C. A. Munn and J. Chambers, assisted by the writer. Rigor mortis absent. Great emaciation. Livid discoloration of abdomen, which was intensely swollen. Intestines distended with gas. Lungs, liver, and spleen not examined. Left kidney much smaller than right, both markedly nodular. The cavity of the pelvis was greatly contracted, the tuberosities of the ischia approaching each other very closely. The anal aperture was wholly wanting. There was entire absence of a sphincter. The genital organs were normal, the penis being somewhat diminutive. The rectum terminated in a *cul-de-sac*, and at its lower extremity a fistulous communication with the bladder was found; a probe passing readily from the one to the other. The bladder was imperfectly developed and retained the characteristics of early fœtal life. It consisted practically of a tubular sac, which was continuous with the urachus. The latter was still pervious, and thus allowed the urine and fæces to escape at the umbilicus.

[1] American Journal of Pharmacy, vol. xiii. p. 204.
[2] Ibid., 1887, p. 230.

The late Professor S. D. Gross[1] writes of this condition as follows: "The rectum, instead of terminating at the anus, occasionally opens by a narrow canal into the *urinary* passages, generally at the posterior part of the urethra, or at the *bas-fond* of the bladder a short distance below the insertion of the ureter; the former mode of communication being the more frequent. The malformation is almost peculiar to males, and generally proves fatal within a few days after birth, on account of the small size of the recto-vesical outlet not allowing of a sufficiently free discharge of fæcal matter. To this rule, however, occasionally an exception occurs. Thus in a case which I attended with Dr. Kempf, and in which I made a very deep incision without reaching the bowel, the child survived six weeks, passing daily a little fæcal matter by the urethra."

In his description of the development of the urinary bladder, etc., Dalton[2] says: "This obliteration of the cavity of the allantois commences at its external portion and gradually extends inward toward the point of its emergence from the abdomen. The hollow tube, or duct, which connects the cavity of the allantois with the posterior part of the intestine, is accordingly converted, as the process of obliteration proceeds, into a solid rounded cord. This cord is termed the *urachus*. After the walls of the abdomen have come in contact, and united with each other at the umbilicus, that portion of the above duct, which is left outside the abdominal cavity, forms a part of the umbilical cord, and remains connected with the umbilical arteries and vein. That portion, on the contrary, which is included in the abdomen, *does not close completely*, but remains as a pointed fusiform sac, terminating near the umbilicus in the solid cord of the urachus, and still communicating at its base with the lower extremity of the intestinal canal. This fusiform sac becomes the *urinary bladder;* and in the fœtus at term the bladder is still conical in form, its pointed extremity being attached, by means of the urachus, to the internal surface of the abdominal walls at the situation of the umbilicus. Afterward, the bladder loses this conical form, and its fundus in the adult becomes rounded and bulging. The urinary bladder, as it appears from the above description, at first communicates freely with the intestinal cavity. The intestine, in fact, terminates, at this time, in a wide passage or *cloaca*, at its lower extremity, which serves as a common outlet for the urinary and intestinal passages. Subsequently, however, a horizontal partition makes its appearance just above the point of junction between the bladder and rectum, and grows downward and forward in such a manner as to divide the above-mentioned cloaca into two parallel and unequal passages. The anterior or smaller of these passages becomes the urethra, the posterior or larger becomes the rectum; and the lower edge of the septum between them becomes finally united with the skin, forming, at its most superficial part, a tolerably wide band of integument, the *perineum*, which intervenes between the anus and the external portion of the urethra."

This case seems to possess some peculiar features. Imperforate anus with a fistulous opening into the bladder is described in all the standard works on surgery. Stercoraceous and urinary fistulæ at the umbilicus are also alluded to, although they are extremely rare. But in this case both conditions were present. Furthermore, in fæcal fistula at the navel the anatomical arrangement is different. It is generally found to be dependent upon persistence of Meckel's diverticulum,[1] whereby the fæces pass directly from the small intestine to the opening at the navel; but in this case, as the autopsy showed, the fæces passed from the rectum through a fistulous opening into the bladder, and from thence, for the first three weeks, passed out through the penis. Afterward both urine and fæces, following the path of least resistance, made their exit through the pervious urachus at the umbilicus.

MEDICAL PROGRESS.

Strophanthine.—DR. ROTHZIEGEL communicates some important observations on strophanthine (*Internationale klinische Rundschau*, May 19, 1890) of which the following is a summary:

1. The effect of strophanthine on the circulatory system is marked, the pulse becoming much stronger and more regular. The effect on the force of the pulse is noticeable in from five to ten minutes after the ingestion of a single dose. The influence on the rhythm is not apparent until the drug has been administered for several successive days.

2. The effects on the symptoms of valvular lesions are particularly well marked, both dyspnœa and palpitation being diminished, the former usually several days before the latter.

3. In cases of renal insufficiency due to cardiac weakness, strophanthine, after it has been given for some days, increases the secretion of urine; but as a rule the increase is not so great as after the administration of digitalis or tincture of strophanthus. This effect is apparently wholly due to increased blood-pressure and not to any direct effect upon the kidneys.

4. Gastric disturbances even after prolonged use of solutions of strophanthine are very exceptional, and they can be avoided by administering the drug in capsules. On the other hand, it often causes an increase in the appetite. Strophanthine has no effect on the functions of the intestines, nor on the sweat-glands.

5. The drug has no direct influence upon the nervous system.

6. There is no danger of cumulative effects, and it can be given for long periods without fear.

7. In heart-failure the subcutaneous injection of $\frac{1}{300}$ grain of strophanthine in solution is immediately followed by increase in cardiac power, and no local irritation follows the injection if done with antiseptic precautions.

8. As a rule the tincture of strophanthus is preferable to strophanthine; but there are cases in which neither the tincture of strophanthus nor of digitalis is well borne, and in such strophanthine is a valuable substitute.

9. The indication for the employment of strophanthine is cardiac weakness, whether due to valvular insuffi-

ciency with or without disease of the myocardium, or to organic disease of the heart-muscle alone.

Rothziegel gives from $\frac{1}{24}$ to $\frac{1}{16}$ grain daily, in divided doses.

The Treatment of Endometritis by Curetting.—At a recent meeting of the Surgical Society of Paris, M. BOUILLY read a paper upon the treatment of endometritis by curetting (*Therapeutic Gazette*, May 15, 1890). He has performed the operation in 81 cases of endometritis, in 69 of which the results were carefully noted. The majority of the cases were uncomplicated, though in a few there was slight inflammation of the adnexa. He does not consider the operation advisable in cases complicated with laceration of the cervix, with ectropion, or with uterine fibromata. In most of his cases the operation was not performed until other therapeutic measures had failed. The symptoms in his cases were hæmorrhage during or between the menstrual periods, more or less abundant mucous or muco-purulent discharge, and irregular pains.

All the operations were performed during chloroform anæsthesia. The cervix was previously dilated with laminaria tents made aseptic with iodoform. The tents were inserted on two successive days; on the third the os was sufficiently dilated for the easy performance of the operation. Antiseptic precautions were rigidly enforced, and sufficient force to remove the entire uterine mucous membrane was used; the *débris* being removed with a swab. At the termination of the operation glycerin and creasote (2 : 1) was injected into the uterine cavity in cases of mucous endometritis; zinc chloride solution (1 : 10) if the disease was hæmorrhagic.

In the author's experience the operation has never been followed by complications, and in only four instances there was slight tenderness on each side of the uterus for a few days.

Of the 69 cases, 39 were cured; of the 30 cases remaining, 15 were improved and 15 were uninfluenced.

Pylorectomy.—SIR WILLIAM STOKES reports a case of pylorectomy for obstruction from pyloric cancer (*British Medical Journal*, May 3, 1890), and concludes his paper with the following propositions:

1. The recognition of the disease should, if possible, be made before any marked emaciation and weakness supervene.

2. In all doubtful cases exploratory measures should be adopted with the view of (*a*) forming a just estimate of the nature of the disease, (*b*) of determining the existence or non-existence of adhesions, or (*c*) the presence or absence of much glandular infiltration.

3. Washing out or irrigation of the stomach previously is a desirable antiseptic precaution, and can be easily carried out without exhausting the patient.

4. The protracted nature of the operation, as usually performed, unquestionably tends to promote shock and ultimate collapse.

5. With the view of shortening the operation it is desirable to determine what is an effectual and, at the same time, speedy method of inserting sutures.

Upon the last two propositions the case reported by TUHOLSKE, in THE MEDICAL NEWS of May 10th, has an important bearing.

Gurjun Oil as an Expectorant.—DR. WILLIAM MURRELL for a time used copaiba as an expectorant in chronic bronchitis, but though it was efficient, the frequency with which an eruption was produced led him to seek a substitute. He has finally adopted gurjun oil, which was at one time used to adulterate copaiba. Gurjun balsam, or "wood oil," is a balsamic exudation obtained by incision and the application of heat, from the trunk of an East Indian tree. It is a transparent liquid of the consistence of olive oil, of an opaque, dingy, greenish-gray color as seen by reflected light, and having an aromatic odor and taste not unlike that of copaiba, but without its acridity. He gave it first in doses of a drachm, and then of two drachms, three times a day, in the form of a mixture with liquor potassæ, spirit of nitrous ether, mucilage of acacia, and cinnamon water. After a time he gave it mixed with extract of malt—two drachms of the balsam to one ounce of the extract—three times a day, and this was taken without difficulty. The chronic bronchitics—many of whom had previously taken copaiba—reported that it acted admirably as an expectorant, "clearing the chest" and easing the cough. In several cases he gave in addition tincture of jaborandi or nitrate of pilocarpine at bedtime, so as to produce profuse sweating, but no eruption resulted. It seems to him that gurjun oil has all the advantages of copaiba as an expectorant, without the grave disadvantage of exciting an eruption. It has been recommended as a remedy for gonorrhœa and gleet, but he has had no experience with its use in this direction.—*Lancet*, May 3, 1890.

The Extirpation of Mammary Carcinoma.—DR. LEWIS S. PILCHER (*Brooklyn Medical Journal*, April, 1890), in discussing operations for the removal of mammary cancer, says that the researches of Heidenhain into the causes of local relapse of cancer after amputation of the breast seem to be of the greatest importance, and particularly his demonstration that in two-thirds of all cases of mammary cancer numerous cancerous deposits are to be found in the lymphatics which pass through the layers of retro-mammary adipose tissue to the pectoral fascia beneath, so that though the visible tumor may be freely movable over this fascia, nevertheless cancerous elements may be already present in the lymphatics of the fascia. These lymphatics accompany the bloodvessels which penetrate the muscle and thus become the channels of infection. Security from recurrence cannot, therefore, be obtained even in those cases in which the mammary growth is still apparently limited to the gland, except by taking away with it both the underlying pectoral fascia and a thick layer of the muscular substance itself. The practical lesson, corroborated by all the experience of the past in the almost certain recurrence after extirpation, is that no operation for the removal of cancer of the breast can be considered radical and trustworthy which does not combine free ablation of the breast and its overlying integument, with entire cleaning out of the glands and connective tissue of the axilla, and removal of the pectoral fascia and superficial layer of the portion of the pectoral muscle lying underneath the gland. Dr. Pilcher is ready to accept also, as a working hypothesis for the present, the suggestion as to the complete extirpation of the whole pectoral muscle when any part of it has become involved.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author.

Address the Editor: H. A. HARE, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including Postage.

PER ANNUM, IN ADVANCE . . . . . $4.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JUNE 7, 1890.

INTESTINAL ANTISEPSIS.

THE subject of intestinal antisepsis is not new to the readers of this journal, nor, we trust, to the profession in general. Its importance, however, is certainly not fully appreciated, if one may judge from the absence of all reference to it in recent discussions on the disease—typhoid fever—in which it is most surely indicated. This would be pardonable if intestinal antisepsis, instead of being at the command of every practitioner, were an ideal to be attained by the therapeutics of the future.

The literature on this important subject is mostly of foreign birth or extraction, and the leaders of medical thought in this country, with few exceptions, seem indisposed to admit what is in Europe generally regarded as an accomplished fact.

No one can deny that the intestine is a species of laboratory in which are manufactured poisons of the most virulent nature, and that the chief barrier against their fatal invasion of the general circulation is the liver. This barrier may, however, be forced, and this happens when the liver is overcome by an excess of leucomaines, or, on account of functional disorder—*hepatic inadequacy*, so to speak—is unable to dispose of a normal invoice of these products.

These facts are no sooner stated than acknowledged; indeed they are property common to the layman and the physician. The association between such signs of systemic poisoning as ill-humor, hypochondria, and constipation, is proverbial, and no one has been more keenly appreciative of the fact than Voltaire, who terminates an admirable description of the good nature and benevolence of those whose bowels are regular with the statement that a refusal from the mouth of such a person is more gracious than an assent from one who is constipated.

In a recent article on the treatment of diarrhœa and constipation by Dujardin-Beaumetz (*Bulletin Générale de Thérapeutique*, April 15, 1890), the importance of intestinal antisepsis in both these conditions is insisted upon. The fact is not generally appreciated that purgation and antisepsis are, to some extent, interchangeable terms, and that the relief which follows the employment of a cathartic is not so much due to the mechanical effect of "unloading the bowels" as to the expulsion of substances which are slowly poisoning the system. These substances not only act in the manner just indicated, but through their irritating effect on the intestine they tend to keep up a diarrhœa which, in its onset, may have been highly conservative. From these facts may be explained the curative effect of a purge in the early stages of some forms of diarrhœa. When, however, a catarrhal condition is fairly established and occupies a considerable portion of the intestinal tract, the indications are not fully met by cathartics. Under such circumstances admirable results are often obtained by drugs whose favorable action can only be explained by intestinal antisepsis. Among such are thymol, naphthol and salicylate of bismuth. There is none better than the first mentioned, which is perfectly innocuous in large doses and possesses an antiseptic power four times greater than that of carbolic acid. Its value as an antiseptic seems to have been more fully recognized in Italy than elsewhere, and has been endorsed by Martini, Bufalini, Testi and others. In our opinion it is, when properly administered and in suitable doses, *facile princeps* among intestinal antiseptics. Salicylate of bismuth is also an admirable remedy of this sort, and is the one most approved by Dujardin-Beaumetz in the article mentioned. He usually administers it in capsules in combination with magnesia, sodium bicarbonate, prepared chalk, phosphate of lime, beta-naphthol, or charcoal.

It is not for want of suitable drugs that intestinal

antisepsis is not more systematically carried out. The difficulty is that the indications for their employment are not generally recognized. Systematic therapeutics of any description is the outcome of systematic diagnosis, and the latter, so far as gastro-intestinal affections are concerned, is of very recent date.

There are, as Dujardin-Beaumetz points out, at least three distinct varieties of auto-intoxication proceeding from the gastro-intestinal tract. First, there are the various symptoms, too numerous to be here detailed, dependent upon habitual constipation. Secondly, a more acute condition, of which the chief symptoms are a coated tongue, loss of appetite, and sometimes fever. This is the *embarras gastrique* of the French and is caused by the ingestion of improper food, or of "*toxines*" contained in the atmosphere. The latter statement is based on the fact that the symptoms referred to often arise after a prolonged stay in a poorly ventilated and overcrowded apartment, or in a dissecting-room. The third variety is accompanied with vomiting, and is generally known in this country as acute indigestion. It is significant of more acute poisoning or of a more susceptible organism, and consequently is more frequently observed in children.

The treatment of these different forms of poisoning, whether it be exclusively dietetic or partly medicinal, is fundamentally antiseptic, and the general recognition of this fact will alone serve to bring into general use a line of treatment which is now habitually followed by a minority.

REVIEWS.

THE PULSE. By W. H. BROADBENT, M.D. Illustrated with fifty-nine sphygmographic tracings. 12mo., pp. 312. Philadelphia: Lea Brothers & Co.

THE most striking features of this compact little book, which embodies, with additions, the Croonian Lectures for 1887, are the thoroughly practical manner in which the author treats his subject and the unusual ability he has shown in making every page interesting.

Opening with a brief historical sketch, chapters follow upon the mechanism of the pulse, the proper mode of feeling the pulse, heart-sounds in relation to the pulse, abnormalities, and the pulse in various conditions of disease.

Though the book is profusely illustrated with pulse-tracings, Dr. Broadbent writes that in much of the recent teaching on the pulse and circulation, "the constant reference to the sphygmograph has been an obstacle to the application of the newly obtained knowledge to clinical work, and especially to everyday practice," and, therefore, the variations in the character of the pulse as felt by the finger receive here the first consideration. It must not be imagined from this that he underrates the value of the sphygmograph, for elsewhere he states that it has been of immense service to him.

The chapter on the pulse in fevers is particularly instructive, and should be carefully studied by those practitioners, of which there are not a few, who are guided in their prognosis and treatment chiefly by the temperature. Indeed, the whole volume is worthy of being most carefully read from beginning to end, for it is a masterly study of an important and too much neglected subject.

HOW TO EXAMINE FOR LIFE INSURANCE. By JOHN M. KEATING, M.D., President of the Association of Life Insurance Directors, etc. 8vo., pp. 211. Philadelphia: 1890.

THIS is by far the most useful book which has yet appeared on insurance examination, a subject of growing interest and importance.

Examining a candidate for insurance might, at first thought, seem to differ only slightly from much of a practitioner's routine work, but, under ordinary circumstances, when a man consults a physician he has no desire to conceal facts, while an applicant for insurance may have symptoms and weak points in his family and personal history, from which he endeavors by many means to draw the physician's attention. It is just this that makes tact and penetration on the part of the examiner of great importance. Dr. Keating in this manual offers many valuable suggestions which will be of assistance in getting at facts and "drawing out" the applicant.

Methods of physical diagnosis are also well described and illustrated by plates of the regional anatomy of the thorax.

Excellent directions for urine testing are given; heat and nitric acid being considered the most satisfactory for albumin, and fresh, carefully prepared Fehling's solution the most generally useful for sugar. With reference to transient albuminuria, Dr. Keating believes that the presence of albumin, even when not associated with other signs of disease, "renders the applicant, for the time being, uninsurable."

Not the least valuable portion of the volume is Part II., which consists of instructions issued to their examining physicians by twenty-four representative companies of this country. As the proofs of these instructions were corrected by the directors of the companies, they form the latest instructions obtainable. If for these alone, the book should be at the right hand of every physician interested in this special branch of medical science.

SOCIETY PROCEEDINGS.

FIRST ANNUAL MEETING OF THE FRENCH SOCIETY OF DERMATOLOGY AND SYPHILOGRAPHY.

Held at Paris, April 10, 1890.

PROFESSOR HARDY, of the Paris Faculty of Medicine, was elected President, after which the first paper was read by DR. HALLOPEAU, on

AN INFANTILE BULLOUS DERMATOSIS WITH INDELIBLE CICATRICES, EPIDERMIC CYSTS, AND BUCCAL MANIFESTATIONS.

This form of dermatosis, according to the author, differs in its clinical manifestations, especially in the cicatrices, from other forms. It is sometimes generalized, as was proven by cicatrices over the entire body in one case, in which it is still in active process in the mouth and on the extremities. Bullæ are observed, with citron-colored contents, which sometimes become purulent or hæmorrhagic. These bullæ begin without the slightest pain, pruritus, or febrile manifestation. The old cicatrices are confluent on the trunk, forehead, and sometimes on the extremities. The cause of this eruption is probably due to ptomaines, which are eliminated by the cutaneous glands, as the bullæ are found in situations where toxic eruptions are usually manifested. This bullous dermatosis is not confounded with the one described by Duhring and Blocq. It differs by the absence of painful sensation or pruritus. The influence of external violence in the causation of the disease, the cicatrices and the epidermic cysts, all point to a new disease.

DR. MAURIAC then read a paper on

LINGUAL HEMIATROPHY OF SYPHILITIC ORIGIN.

This he observed in a man, forty years of age, who contracted syphilis at the age of twenty-eight, and then had lesions of the pharynx and tongue, which were thought to be an ordinary syphilitic angina.

Fourteen years later the patient complained of sudden inability to pronounce certain words; next came trembling of the right hand and paralysis of that side.

When first seen by Dr. Mauriac the tongue was already asymmetrical and atrophied on the right side, with marked disturbance in the sensation. Under treatment the patient greatly improved, but the tongue remained atrophied. Soon after this the right third cranial nerve became paralyzed.

The cause of these symptoms is probably a syphiloma at the base of the brain, involving the origin of the hypoglossal and oculo-motor nerves.

DR. MOREL-LAVALLÉE presented a case which excited a discussion, on

THE DIFFICULTIES IN THE DIAGNOSIS OF TRUE CHANCRE.

In certain rare cases the syphilitic chancre has been known not to produce any glandular involvement at all, and this is especially observed in cases of gangrenous or phagedenic chancre; moreover, induration of the primary sore may be absent, especially in women, but very rarely are both of these capital symptoms absent.

This Dr. Morel-Lavalleé has observed in a man forty years of age. In this case the chancre developed in two periods, the induration developing under the cicatrix. The secondary symptoms appeared at the usual time, but, without any discoverable glandular enlargement in any region of the body.

Professor Fournier has also observed a few of these exceptional cases, amongst them a patient who presented a superficial erosion, with a very slight induration, but no glandular enlargement; cicatrization took place rapidly. A few days later the cicatrix opened again; marked induration developed, and then the secondary symptoms occurred.

Dr. Mauriac has also seen cases in which the early glandular enlargement could not be found, but later, when the induration manifested itself, glandular enlargement was present.

PROFESSOR FOURNIER then reported

A CASE OF SYPHILIDE OF THE LIP SIMULATING ERYTHEMATOUS LUPUS.

Three years ago he saw on a young woman a papulo-erythematous lesion, occupying three-fourths of the lower lip. This red plaque, somewhat elevated, with well-defined contours in front, much less so behind, was smooth and absolutely painless. This was present for eight or nine months without symptoms of syphilis. The diagnosis of erythematous lupus was made, but later an ophthalmia occurred, which Dr. Abadie recognized as parenchymatous keratitis, complicated by iritis, and which he declared to be of syphilitic origin. She was immediately placed upon energetic anti-syphilitic treatment and five weeks later was cured of both her ophthalmia and her so-called lupus.

Professor Fournier concludes: 1st. That there is a rare form of tertiary tubercular syphilide, analogous to Cazenove's erythematous lupus. 2d. That the appearance of such a syphilide is possible twenty-five years after a chancre and without previous manifestation.

DR. BURLUREAUX read a communication on the

REACTION OF SALIVA ON CALOMEL AS A MEANS OF DIAGNOSIS IN IODOFORM POISONING.

A soldier, twenty-two years of age, was admitted to the military hospital, for a generalized scarlatiniform eruption which had started on the left arm, three days after the application of an iodoform dressing. The temperature did not rise above 100½° F. Three days later desquamation occurred on the arm and other regions of the body. Dr. Burlureaux first suspected scarlet fever, although no angina or albuminuria was present. The diagnosis was modified, however, after testing as follows for iodoform, as recommended by Poncet, of Lyons:

1st. The patient complaining of an iodoform taste, a piece of silver money was placed in his mouth and he immediately noticed a taste of garlic.

2d. A small amount of calomel mixed with the saliva, gave a characteristic canary yellow color, due to the formation of a mercurous iodide.

This reaction is a very delicate one, a drop of a solution of potassium iodide (1 : 4000) is sufficient, if placed on calomel, to bring out the yellow color. The patient presented these signs as long as the eruption persisted, and they disappeared progressively during the stage of desquamation.

DR. BALZER read a paper on a

CASE OF VACCINIA COMPLICATED BY GANGRENE DURING THE EARLY STAGE OF SYPHILIS.

It was observed in a woman, twenty-three years of age, who came to the hospital suffering from secondary syphilis and gonorrhœa. She was placed under energetic treatment, during which she was vaccinated. Only one inoculation "took," which, however, soon became black and extended until it involved an area the size of a silver

dollar, limited by an inflammatory induration. Notwithstanding antiseptic local treatment with iodoform, salol, etc., it was only when large doses of potassium iodide (ninety grains in the twenty-four hours) were given that the eschar separated.

A paper on

ERUPTIONS DUE TO URIC ACID INTOXICATION,

was then read by DR. QUINQUAUD, who found that when uric acid is introduced into rabbits or guinea-pigs, no eruption is produced. If, however, the same is done with dogs, eruptions of vesicles, papules, or pustules occur, and are disseminated here and there on the skin with no regularity.

He has given from four to eight grains of uric acid in the twenty-four hours to men, and observed that the most common lesion was a furuncle; small papules becoming crater-like after removal of the crust, were also observed, and more rarely erythematous spots, but never the cardinal symptoms of eczema or of any other known dermatosis.

PROFESSOR FOURNIER then read a paper entitled

INFANTILE ECTHYMA SIMULATING A SYPHILITIC CHANCRE.

This disease was seen in the gluteal region of a child, who had several other sores of an ecthymatous character, and resembling syphilitic chancres, but in the groin only very small ganglia could be found. On the inferior extremities were a few small discrete folliculites, some of which became exactly like the pseudo-chancres.

DR. DU CASTEL followed with a paper on

ATYPICAL SYPHILITIC CHANCRES,

in which he said, chancres which do not correspond to the classical type are by no means rare. M. Vidal demonstrated, in 1872, that syphilitic chancres could present themselves in the form of a soft chancre, and other varieties have been described. The variety to which Dr. Du Castle wished to call attention, might be called "multiple syphilitic chancres." The following are the chief characteristics: Multiplicity of sores; successive development taking place on different days, and in a methodical order; severe pain; small size of the lesions, which are about one-third of an inch in diameter; tendency to become deeper than ordinary chancres and to develop an indurated ring; slight sub-chancrous induration, and but little induration of the neighboring glands.

M. Mauriac said that he also had observed multiple syphilitic chancres. He has seen a patient with a chancre on the chin, another on the lip, and seven or eight on the genital organs; they did not appear simultaneously, but within a space of time varying from ten to fifteen days.

DR. DE BEURMANN then presented three wet-nurses suffering from

MAMMARY CHANCRES,

acquired from foundlings.

Professor Fournier said, that under no pretext should unknown children be given to a wet-nurse; they should be artificially fed. He gave the following example of contagion which occurred in the practice of Dr. Jacquet: A child of a few months was suffering from infantile diarrhœa; no specific manifestation could be found, and the child was confided to a wet-nurse. A few days later the child died in consequence of the diarrhœa, and on post-mortem examination, gummata of the liver were discovered. A careful examination of the buccal cavity showed that nothing but a very light fissure of the inferior lip existed. Two gray slightly squamous spots were found near the right knee.

DR. QUINQUAUD followed with a paper on the

TREATMENT OF SYPHILIS BY CALOMEL PLASTER,

a method which this author uses to avoid the inconveniences of the other preparations of mercury. The formula recommended is:

Diachylon plaster	300 parts.
Vaporized calomel	100 "
Castor oil	30 "

made into a plaster.

The manner of using it is as follows: First thoroughly wash the surface of the skin with soap and water, then place a three-inch square of the plaster on the chosen spot. The plaster is kept in position for a week, then left off for a week, and then again put on for a week, and so on. This author has found that mercury is present in the urine during this treatment. In using a plaster not larger than that above-mentioned, there is no danger of salivation.

DR. ROLLET then read a paper entitled

THE PROBABLE NON-SPECIFIC CHARACTER OF THE GONOCOCCUS,

in which he said that studies had been made by M. Eraud, of Lyon, who arrives at the following conclusions: There exists in the normal urethral canal of man a microbe, the staphylococcus urethralis, which is capable of producing urethritis. This microbe has the same morphological characters in the newborn child and adult, and presents the same character as the microbe found in orchitis, blennorrhagia, and prostatitis; hence, we can arrive at the probable conclusion that these microbes are one and the same.

DR. ARNOZAN read a communication on the

TREATMENT OF EPITHELIOMATA ARISING IN THE SEBACEOUS GLANDS BY APPLICATIONS OF ACETIC ACID.

He has used acetic acid pure, and also diluted one-half or two-thirds, in superficial epitheliomata with great success. He has so far treated eight cases, all with satisfactory results, obtaining soft and very small cicatrices.

CORRESPONDENCE.

VIENNA.

The Treatment of Tubercular Abscesses. The German Congress for Internal Medicine.

To the Editor of THE MEDICAL NEWS,

SIR: The Easter vacation interferes with medical work in Vienna very much—the professors and assistants take vacations and the American student is puzzled to put in his time advantageously. Now, however, work has again begun.

There have been two sad accidents. One of Professor Albert's operating assistants, a young surgeon of con-

siderable talent, had examined a case of smallpox that appeared in the dispensary. A few days afterward he was taken ill with hæmorrhagic variola, and, although he had been vaccinated and all known remedies were used, he fell a victim to the disease. Within a week of this death, Docent Paltauf, assistant to the professor of medical jurisprudence, cut his hand while making a post-mortem, and in consequence had a severe attack of septicæmia. His place was filled temporarily by Dr. Handlirsch, and before Paltauf recovered this substitute had received a post-mortem wound, from which he died three days later. At least a dozen autopsies are made every morning in the general hospital, yet these are the only cases of blood-poisoning that have occurred for years.

Billroth has again made a great impression on the surgical world by an article published a few days ago. Tuberculous abscesses have long been studied and treated unsuccessfully. For the past four years Billroth has been steadily experimenting with different means of treatment till now he has reached a conclusion, which, as it is based on his enormous clinical experience, cannot fail to excite great interest. Contrary to the usual method, he cuts down upon the abscess and lays it widely open; draws off the pus and cleans out the remotest corners; follows up any fistula to its point of origin, and scrapes the lining surface of the abscess until all the so-called membrane is removed. Sometimes it is necessary to open a thigh from the popliteal space to the tuberosity, but thoroughness in regard to the fistulæ is absolutely necessary. He then waits until the bleeding has ceased, of course removing the Esmarch, if one has been used, and when the wound is glazed by the serum he fills the abscess cavity with an emulsion of 10 parts of iodoform in 100 parts of glycerin. The edges of the wound are then brought together and stitched very carefully so as to close the cavity perfectly and *without* an opening for drainage. Thoroughly antiseptic dressings are applied and left on for several days. In most cases he gets primary union and the abscess heals, the iodoform emulsion being slowly absorbed as granulation goes on. Sometimes when antisepsis has been imperfect sloughing results, but even then the abscess generally heals from the bottom without recurrence. In a few cases the results were not good, but in these the operation was not sufficiently thorough, as some of the recesses were left untouched. Strange as it may seem, iodoform poisoning has been noticed in only a few cases, and in a very slight degree.

Billroth has used the same method in tuberculous caries with equally good results, and now asks the profession to try the method. How does the iodoform act? It is known that iodoform is not a perfect antiseptic, but a most powerful stimulant of granulation. To use Billroth's words, "Iodoform exerts a great formative influence on the smaller vessels, and these soon begin to grow out and multiply in an extraordinary manner by constant production of offshoots and capillary loops. This energetic growth of the living tissue seems to rob the microbes of their nourishment; in the struggle for existence they succumb to the growing cells of the vessel walls." As granulations secrete pus only when diseased, drainage is unnecessary. When the method is used in caries the action is the same, the osteophytes in this case being stimulated.

The German physicians who devote themselves to internal medicine only, as contradistinguished from specialism, have organized a congress to which the best men in Germany, Austria, and Switzerland come annually, and also many from Italy, Russia and France. They meet every second year in Wiesbaden and the alternate years in Berlin, Leipsic, Munich, and Vienna, in rotation. This year Vienna was the place, and among the several hundred present were Leyden, Senator, Gerhardt, of Berlin, Ziemssen, His, Ziegler, Adamkiewicz, Erb, Romberg, Immerman, and many more of Europe's greatest medical authorities. There is probably no other society that has so many distinguished men among its members as this one, for membership is restricted, it seems, to the famous. Hence, of course, we looked to them with great interest. They met with Nothnagel as president, and Leyden and Curschman as vice-presidents. Every year two subjects of the greatest general interest are selected as topics for discussion at the next annual meeting, two members being appointed to open the discussion. This year the treatment of empyema and of chronic nephritis had been chosen. Immerman, of Basel, and Schede, of Hamburg, opened the discussion and were followed by Eberth, Leyden, Ziemssen, Billroth, Fürbringer, and Nothnagel. The general opinion of the society may be summed up as follows: In every case of fluid in the pleural cavity, if it becomes chronic, exploratory puncture is absolutely necessary. As soon as bacteriological examination shows the presence of pus-forming agents or pus, the fluid must be removed at once by operation. In early cases simple puncture and a drainage-tube may suffice, but resection of ribs is indicated when there is much atelectasis, in order that the size of the pleural cavity may be diminished and filled up by granulation. Billroth believes that after granulations form between the costal and pulmonary pleura their contraction may increase the capacity of the atelectatic lung. When resection is performed the ribs must be removed without opening the pleural cavity—this is easy if the bone be loosened from its periosteum. Then puncture is made and the fluid drained away under antiseptic precautions, so that microbes are excluded from the cavity. The results of resection seem to be a little better than those from simple drainage—in children the results are remarkably good from both methods. Even in cases of phthisis, operation has been followed by excellent results. After resection, massage and gymnastics are often of great advantage; approximate symmetry can be obtained even when three inches of rib have been removed, as shown by four cases.

Unna read a good paper on the physiology of the skin. The results of his experiments seem to show that covering the skin has considerable effect on temperature. A varnish of gelatin increases the transudation of fluids and has a marked effect in reducing fever, and Unna advises a trial of this in high temperature, as well as in nephritis, where we desire an excessive action of the skin. It sounds paradoxical to apply glue to the entire body for a cooling effect, but he claims that the gelatin absorbs so much water from the cutis that the function of the skin is not diminished, but rather is increased. Senator tried a similar method some years ago, but the results were not especially brilliant.

Mosler read a paper on pemphigus which was received with interest, and elicited replies from Kaposi, Neuman, and Schwimmer. Mosler has examined the fluid of the pemphigus vesicles and in every case where the proper precautions were used to get the pure fluid, no bacteria could be found. Inoculations and cultures with the fluid are also impossible. He, therefore, concludes, and Kaposi and Neuman agree with him, that pemphigus is not caused by microörganisms, but is rather a neurosis or an angio-neurosis. The clinical history lends additional evidence to this theory, and the etiology is so peculiar that no other explanation suffices. Pemphigus is not very rare in Vienna—of the 50,000 cases of skin diseases Kaposi has seen in twenty-three years, there were 210 cases of pemphigus, with a mortality of about 90 per cent. Kaposi and Neuman have had no definite success in treatment; Weber, of Halle, reports a cure from baths of permanganate of potassium, and arsenic internally.

One of the best papers read was that by Professor Adamkiewicz, of Krakow. From a number of cases in which he made thorough microscopic examination, he has established the truth of Leyden's theory that myelitis is not a result of compression of the cord—in fact, in his cases, where the pressure was greatest, there was no myelitis, the process being most intense at those places where there was no compression. He stated, further, that the nutrition of the cord is carried on by two sets of vessels, one of which entering at the anterior fissure supplies the centre of the cord, while the other entering the cord at many points on the circumference supplies the peripheral portion. In cases of anterior poliomyelitis he has found thickening of the vessels which supply the anterior horns and also infarctions in the end capillaries. In lateral sclerosis he has also found infarctions in the crossed pyramidal tracts, and on these discoveries he bases a theory of systemic origin of diseases of the cord. He thinks the degeneration of the nerve-fibres and the sclerosis are due to the microscopic infarctions which disturb the nutrition, these infarctions being caused by disturbances in the blood, probably from microörganisms and the accompanying changes in the vessel-walls. He claims to have seen the infarctions, and also in every case the concomitant changes in the endothelium of the affected vessels. Thus he builds up an ingenious theory for something hitherto unexplained.

Ziemssen, of Munich, showed two good specimens of "bullet thrombi" in the right ventricle. These thrombi are not connected with the heart-wall or valves, but lie perfectly loose in the cavity, which they nearly fill, yet they interfere but slightly with the cardiac function. They were each an inch in diameter, perfectly round and smooth. There are but six cases on record, and diagnosis *intra vitam* is not possible. Ziemssen is a medium-sized man, rather slim, nearly bald, and what hair he has is snow-white. He has a small white moustache, waxed and twisted at the ends in military style. His eyes are small but bright and piercing, and the expression of his face is highly intellectual, yet full of kindness and even mirth. Leyden is of Herculean frame, has a very closely trimmed gray beard, heavy features, somewhat unsymmetrical, for the left side of his face seems a little contracted. When thinking there is nothing exceptional in his appearance, but when speaking or interested his features seem aglow with the mighty intellect that moves them. A few weeks ago he celebrated the twenty-fifth anniversary of his first lecture as clinical teacher, and all his former assistants assembled to do him honor. Among them were five professors and more than twenty clinical teachers.

But to return to my subject: the most important feature of the Congress was the discussion on the treatment of chronic nephritis. Senator and Ziemssen opened the discussion, which represented the latest ideas of the highest German authorities on the subject. They divided chronic nephritis into two classes, parenchymatous and interstitial. In the former the Malpighian bodies are chiefly the seat of disease, and the trouble comes from an insufficient excretion of water and a waste of albumin, causing dropsy and weakness; while uræmic symptoms develop much later. The interstitial form affects the urea-secreting portion of the kidney—there is hypertrophy of the connective tissue, and consequently a contraction of the vessels. The blood is not perfectly purified, and so there are disturbances in the general capillary circulation which results in cardiac hypertrophy, while the loss of albumin is slight, and dropsy is not a marked feature. Of course, in both forms we have cardiac hypertrophy from the same cause, but it is more marked in the interstitial form.

If in the treatment we could stimulate the Malpighian bodies to a more active secretion of fluids, and at the same time prevent the loss of albumin, we would have an ideal method. A mild diuretic and food containing a minimum of albumin should be given. Milk contains considerable water and hence is a mild diuretic, and experiments have proven that of all foods which keep the body in good repair milk contains the least albumin; hence in this disease it is the nearest to a perfect diet and medicine combined. On these principles the exclusive milk diet is the best treatment. Empiricism has also proven the value of a milk diet. In interstitial nephritis, of course, there is much similarity to the parenchymatous form as regards pathology, and in this the milk diet is also of the greatest value. There is an additional element, however, in the more marked retention of urea and cardiac hypertrophy, in the slighter albuminuria, and in the absence of dropsy. The greater work thrown on the heart makes a cardiac stimulant necessary here and digitalis is our most powerful help, though strophanthus is also useful.

Ziemssen warned against much medication, although the temptations are very great. He considered the main lines of therapy to be rest and proper diet, and every case of chronic nephritis should be kept as nearly at absolute rest as possible. The diet should be, as far as possible, milk alone; but it must be varied so that the patient will not become disgusted with the treatment and give up the only reliable method we have. Besides the dietetic and rest treatment, diuretics, and diaphoretics may assist, but only the second is of special value. The hot-air bath is the best method of producing diaphoresis, next to it the steam bath and hot-water bath, and when complications contraindicate these, pilocarpine is of considerable utility. When the œdema is excessive, Ziemssen punctures the swollen limbs; making four punctures every day, one in each leg and one in

each thigh. Small canulas, like those of a hypodermic syringe but perforated at the sides, are placed deep in the tissues, and retained by dressings so arranged that the fluid can escape. The tubes are left *in situ* for twelve hours. He has drawn off as much as twenty-four pints of fluid in two days, and that without any untoward symptoms. Of diuretics the potassium salts are the best, though calomel given in small doses is also good. He disapproves of drastics. In interstitial nephritis at the first indication of cardiac weakness digitalis should be given, and ice-bags to the cardiac region are sometimes of great help. When uræmia comes on the battle is generally lost, so we must prevent it by the prophylactic treatment.

It seemed to be the impression that the mortality of chronic nephritis has been diminished, and a number of permanent cures were reported, and the universal consent to the methods indicated was remarkaable. The congress has now adjourned. There were Americans, Japanese, Chinese, Persians, Greeks, Turks, Russians, and French present, besides the German-speaking contingent, and a glance over the list of those attending will prove the international character of the attendance at Vienna's famous University.

NEW ORLEANS.

To the Editor of THE MEDICAL NEWS,

SIR: The medical profession here has been much interested in the investigation that has been going on at the United States Marine Hospital of New Orleans. It seems that two months ago Passed Assistant Surgeon S. T. Armstrong, who has charge of the hospital, told Passed Assistant Surgeon R. P. M. Ames, who is his assistant, to administer chloroform to a patient. Dr. Ames, who is an advocate of ether, refused to give chloroform, but said that he would give ether. Dr. Armstrong said that, as the head of the institution, he had the right to give what orders he wished, and suspended Dr. Ames, as the latter persisted in his refusal. Dr. Armstrong then wrote to Surgeon-General Hamilton and stated the particulars of the case, and his action was endorsed. Dr. Ames then filed the charges which appear below, and Surgeon-General Hamilton came to this city to investigate them. In opening the inquiry, the Surgeon-General had the charges read by the stenographer. Dr. Ames charged:

"1. That on February 26, 1890, in the operating-room, Dr. Armstrong's manner and language to me (Ames) was unbecoming an officer, a physician, and a gentleman, and this, too, in the presence of an attendant and patient.

"2. That he, unjustly and without cause, charged me on the records of the station with being guilty of gross insubordination and conduct prejudicial to good discipline.

"3 (*a*). That his endorsement on my letter of February 27th, reporting the death of a seaman in the custom-house office, in which chloroform had been given, is mendacious in so far as it refers to the facts contained in the letter.

"3 (*b*). That the statements in his letter of the 10th ultimo, charging me with being malicious and guilty of expressing unfounded libels, is equally false in every particular.

"4. That he has violated the following paragraphs of the *Revised Regulations* of 1889: (*a*) He has hospital attendants performing work in his own quarters. (*b*) He has oppressed and maltreated persons under his command, and abused patients under his care. His conduct in this particular has been brutal and inhuman, and in consequence many patients have deserted the hospital—jumping the wall to seek relief elsewhere. This condition of affairs has brought the management of the hospital into disrepute; patients object to being sent there, and the admissions, as the result of such a reputation, have greatly fallen off. (*c*) He is guilty of cursing and using abusive language to attendants and patients. (*d*) Paragraphs 276 and 282. He ordered the prescription and diet book removed on February 22d without any authority, and it has not been officially restored, notwithstanding the expression in bureau letter of March 3d in relation thereto.

"5. That his statements in his letters to the bureau of March 4th and 20th are false, in so far as he states that there is only one bedroom-set in his quarters (there are two), and that there was nothing in the hospital that could be used for aspirating purposes. There are two aspirators, and in good order. They were then in good working order, and are now.

"6. That he has violated the contract of William J. Walsh for care of horse and ambulance after the receipt of bureau letters."

The seventh section states that Surgeon Armstrong falsely certified to certain bills, etc.

Dr. Armstrong pleaded not guilty to all of the charges, and Surgeon-General Hamilton called on Dr. Ames for witnesses. The investigation, which was a public one, lasted two days, and many witnesses were examined. Surgeon-General Hamilton stated, before leaving for Washington, that no decision would be made before his return to the North.

Dr. Charles Chassaignac has been elected to the presidency of the Orleans Parish Medical Society, to succeed the late Dr. John P. Davidson.

The charitable institutions here have been so much abused by those who are able to pay a physician, that a conference is to be held by the representatives of the various institutions to take measures to remedy the evil.

Owing to the floods, there will be no meeting of the Louisiana State Medical Society this year. Their Committee on State Medicine will shortly present a petition to regulate the practice of medicine in this State, and it is hoped that a State Board of Examiners will be appointed and other measures adopted which will improve the profession.

Dr. Walter Bailey, Sr., a prominent homœopathic physician here, was run over and seriously injured on May 30th.

Dr. T. G. Richardson has gone to Washington. He resigned the position of Professor of Surgery at the Tulane University, on account of ill health, greatly to the regret of his many friends.

THE OLDEST LIVING GRADUATE OF THE UNIVERSITY OF PENNSYLVANIA.

To the Editor of THE MEDICAL NEWS,

SIR: So much has been said in the various journals about the oldest graduate of the Medical Department of

the University of Pennsylvania, that I thought it would be interesting to collect the names of several of the oldest living graduates, as far as known to me, and send them to you. They are as follows:

Enoch Fithian, Greenwich, N. J., Class of 1816.
James Kitchen, Philadelphia, Pa., Class of 1822.
E. W. Mobberly, Virginia, Class of 1824.
John Sappington, Shire's Landing, Md., Class of 1825.
William Wetherill, Lambertville, N. J., Class of 1825.
G. R. B. Horner, U. S. A., Warrenton, Va., Class of 1826.
Walter Somerville, Mitchell's Station, Va., Class of 1826.
Lewis Rodman, Philadelphia, Pa., Class of 1827.
J. Z. Coffman, Phœnixville, Pa., Class of 1827.
Fred. Fickhardt, Bethlehem, Pa., Class of 1827.
J. H. Hicks, Faison's, N. C., Class of 1827.
Hiram Corson, Conshohocken, Pa., Class of 1828.
J. H. Blackwell, Florence, S. C., Class of 1829.

Yours, truly,

JAMES TYSON, M.D.

NEWS ITEMS.

The Volkmann Monument.—It is proposed by the colleagues and friends of the late Professor Richard von Volkmann to erect a monument to his memory in Halle, the place of his long and successful labors. Dr. John S. Billings, of Washington, D.C., is prepared to receive contributions from Americans.

The William F. Jenks Memorial Prize.—The second triennial prize of four hundred and fifty dollars, under the deed of trust of Mrs. William F. Jenks, will be awarded to the author of the best essay on "The Symptomatology and Treatment of the Nervous Disorders Following the Acute Infectious Diseases of Infancy and Childhood."

The conditions annexed by the founder of this prize are, that the "prize or award must always be for some subject connected with obstetrics, or the diseases of women, or the diseases of children;" and that "the Trustees under this deed for the time being, can, in their discretion, publish the successful essay, or any paper written upon any subject for which they may offer a reward, provided the income in their hands may, in their judgment, be sufficient for that purpose, and the essay or paper be considered by them worthy of publication. If published, the distribution of said essay shall be entirely under the control of said trustees. In case they do not publish the said essay or paper it shall be the property of the College of Physicians of Philadelphia."

The prize is open for competition to the whole world, but the essay must be the production of a single person.

The essay, which must be written in the English language, or, if in a foreign language, accompanied by an English translation, should be sent to the College of Physicians of Philadelphia, Pennsylvania, U. S. A., before January 1, 1892, addressed to Louis Starr, M.D., Chairman of the William F. Jenks Prize Committee.

Each essay must be distinguished by a motto, and accompanied by a sealed envelope bearing the same motto and containing the name and address of the writer. No envelope will be opened except that which accompanies the successful essay.

The Committee will return the unsuccessful essays if reclaimed by their respective writers, or their agents, within one year.

The Committee reserves the right not to make an award if no essay submitted is considered worthy of the prize.

Resignation.—Dr. John Aulde has resigned his position as Demonstrator of Physical Diagnosis and Clinical Medicine in the Medico-Chirurgical College of Philadelphia.

A Summer Biological School.—A laboratory for biological study will be opened at Cold Spring Harbor, Long Island, during the coming summer. The station will be the one used in the winter season by the State Fishery Commission, and is the largest of the kind in the country. It is supplied with all the appliances suited to the study of aquatic life, both in fresh and salt water. Much attention will be devoted to the food-fishes and to the forms of vegetation upon which they subsist. The number of students during this, the first, year will be limited to twenty-five. A corps of lecturers under Professor Bashford, Dean of the College of the City of New York, has been secured from among volunteers from Harvard, Johns Hopkins, and other institutions and laboratories. The section on Natural History of the Brooklyn Institute will have the school in charge.

Dr. Brehmer's Successor.—Dr. Felix Wolff, of Hamburg, has been appointed successor to the celebrated late Dr. Brehmer in the management of the Sanitarium for Consumptives at Görbersdorf, Silesia. Dr. Wolff was for a long time chief assistant to Professor Curschmann, of Leipsic, and is eminently fitted for the post he is to fill.

Obituary.—Dr. J. B. P. Jaemary, one of the oldest practising physicians in Texas, died in Victoria on April 11th. He was born in Maysville, Kentucky, in 1811, and had practised medicine in Texas for fifty-four years. At the time of his death he was the President of the Victoria Medical Society.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MAY 27 TO JUNE 2, 1890.

By direction of the Secretary of War, so much of Par. 2, S. O. 119, A. G. O., May 21, 1890, from this office, as relates to Robert B. Benham, Captain and Assistant Surgeon, is amended to read as follows: ROBERT B. BENHAM, *Captain and Assistant Surgeon*, will proceed from Madison Barracks, New York, to Fort Wadsworth, New York, and report in person to the commanding officer of that post for temporary duty.

LAUDERDALE, JOHN V., *Major and Surgeon* (Fort Ontario, New York).—Is hereby granted leave of absence for one month, to commence on or about June 1, 1890.—Par. 4, *S. O. 123, Headquarters Division of the Atlantic, New York City*, May 27, 1890.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LVI. SATURDAY, JUNE 14, 1890. NO. 24.

ORIGINAL ARTICLES.

A METHOD OF APPLYING ANTISEPSIS IN THE TREATMENT OF RECENT ANTERIOR URETHRITIS.[1]

BY J. WILLIAM WHITE, M.D.,

PROFESSOR OF CLINICAL SURGERY IN THE UNIVERSITY OF PENNSYLVANIA; SURGEON TO THE UNIVERSITY AND GERMAN HOSPITALS.

THE application of the principle of antisepsis to the treatment of urethritis may be made for one of two reasons, and in one of two ways. The drugs employed may be given on account of their supposed action upon either the microbes of suppuration, or upon the alleged specific microbe of gonorrhœa—the gonococcus of Neisser.

They may be used locally, or may be administered by the mouth, although, even when given in that way, their action is largely a local one.

As to the *reason* for their employment, in the light of modern pathology it is not necessary to believe in an invariable and essential relation between the gonococcus and gonorrhœa to see a clear indication for the use of germicidal agents. The successful treatment of suppuration anywhere demands the employment of some such agent, though it must be admitted that when the pus is furnished by a mucous surface the difficulties of treatment—*i. e.*, of successful antisepsis—are greater than under most other circumstances; and it must likewise be admitted that those difficulties are much increased when the suppurative process is established in a canal like the male urethra, the anatomical peculiarities of which favor so markedly microbic growth or multiplication.

Its length and narrowness; the approximation of its walls during the intervals of urination; the delicate and actively absorbent mucous membrane which lines it; the passage through it at short intervals of an animal fluid of more or less irritant properties, and prone to decomposition; the opportunities offered by the various follicles and lacunæ, and by the curves and dilatations of the normal canal for the retention of any foreign matter, all render the problem of antisepsis a complicated and a difficult one.

While, as I have said, the employment of antiseptics in urethritis, or a belief in their efficacy does not necessitate a corresponding belief in the gonococcus as the sole cause of gonorrhœa, yet a consideration of the rationale of such treatment undoubtedly involves an inquiry into the natural history of that microbe, which is certainly present, whether as cause or effect, in the large majority of cases of acute gonorrhœa. Unfortunately, the results of culture experiments and of the influence of parasiticides upon gonococci external to the body do not afford satisfactory evidence as to the effect of the same agents when applied to the same germs embedded in the depths of an inflamed urethral mucous membrane. Bumm's investigations appear to show that, at first, they multiply by preference in the papillary layer, and find their way to the surface only during the latter part of the purulent, and during the subsiding (or muco-purulent) stage, and Finger uses this as a theoretical argument against the early administration of either astringents or antiseptics. Enough is known, however, to enable us to state with certainty that the agents which are effectual against the microbes of suppuration are not equally destructive of the gonococci, several competent observers having noted the fact that antiseptic solutions, when applied to gonorrhœal secretions outside of the body, have seemed to exert but little effect upon the gonococcus even when strong enough to destroy pus-cells almost immediately. The study of the question, as a problem in bacteriology, is not, however, the object of this paper.

The definite etiological relation between the gonococcus and gonorrhœa, although asserted by a large and an increasing number of respectable authorities, cannot yet be considered as absolutely demonstrated. The statement that the disease has been produced by inoculation of pure cultures of the gonococcus (the only scientific and demonstrative proof of such relation) rests, so far as I know, upon experiments which are numerically insufficient to entitle it to an unhesitating acceptance, though I am willing to admit that, after having always taught and contended for the non-specificity of gonorrhœa, I feel the weight of evidence to be gradually accumulating upon the other side of the question.

Clinically, however, we may now assume that, in the majority of cases of acute urethritis, gonococci, the microbes of suppuration, and other bacteria will be found intermingled, and that successful treatment by germicidal agents will involve the destruction of all the different varieties present. Dismissing, therefore, any further theoretical considerations, we may inquire what drugs, if any, belonging to the class of antiseptics have a curative effect upon the

[1] Read before the American Association of Andrology and Syphilology, at Altoona, June 4, 1890.

essential symptom of urethritis—the blennorrhœa; restricting our inquiry to those cases in which the disease is comparatively acute, and in which it is limited to the pendulous urethra; in other words, to the ordinary cases of uncomplicated gonorrhœa which present themselves in one's office for treatment during the first few days after its appearance. The symptoms, pathology, complications, and treatment of the so-called "posterior" urethritis are entirely different, and need not be discussed in this relation. Considering topical remedies first, and excluding a large number which have little or no claim to occupy time or attention, we may divide the remainder into three classes:

1. Those which when strong enough to exert a sufficient germicidal action, are locally so irritating as to be harmful or unbearable. This class includes nitrate of silver, carbolic acid, chloride of zinc, iodine, chloral, potassium permanganate, salicylic acid, and creasote, all of which have been faithfully tried in many cases and by competent surgeons, the concurrent testimony being, that when used in sufficient strength to sterilize the discharges they produce an amount of local irritation and swelling, ardor urinæ, chordee, and even exceptionally urethral ulceration, that far outweighs any advantage to be derived from their antiseptic properties.

2. Those which are such feeble antiseptic agents that they cannot be depended upon to destroy all the bacteria found in urethral discharges. Among these may be mentioned resorcin, thallin, quinine, the sulphate and acetate of zinc, lanolin, sulphur waters, tannin, alum, hydronaphthol, and cadmium sulphate. The clinical and the experimental evidence coincide as to most of these drugs. Each has had its more or less enthusiastic advocates, but when given a wider trial has been found disappointing, while bacteriologists have shown that the germicidal action was either limited to a very few varieties of bacteria, or was slow and uncertain.

3. The third class includes a number of agents which, while open to the same objection of too feeble or too limited antiseptic action, have the additional drawback of insolubility in ordinary media and of occasionally becoming mechanically irritating from the formation of concretions. Among these are iodoform, calomel, bismuth subnitrate, oxide of zinc, and other insoluble powders.

It must not be supposed that this list is intended to be even approximately complete. It might be increased literally a hundredfold, and nothing could better demonstrate the blind absurdity of empirical methods than the dozens of ridiculous formulæ and the hundreds of useless drugs which have from time to time been recommended for use in the various forms of urethritis.

So far, however, as they are antiseptics they would be found in one or the other of the above classes.

There are certain agents which I have purposely omitted from this classification, but which, as ordinarily employed, might have been included with considerable propriety. These are corrosive sublimate, the sulpho-carbolate of zinc, boric acid, peroxide of hydrogen, and the salicylate of bismuth—the five drugs which in various combinations are, in my opinion, of the most practical value in attempting by topical treatment to secure asepsis in an inflamed urethra. Corrosive sublimate was used in the last century and in the early part of this century by Musitanus, Malow, Gardave, Benjamin Bell, John Hunter, Gutauer, and Swediaur. It then fell into disuse but was revived again in 1846 by Mueller von Berneck and employed spasmodically and unsystematically by a few surgeons until Neisser's discovery of the gonococcus gave the drug an extraordinary vogue. The records of its effects in different hands have thus far been most contradictory. While on the one side we have Leistikow, Lewin, Eichsbaum, Grandin, Chameron, Paul, Louissot, Keyser, and Macrae advocating its employment, on the other we have Diday, Wyeth, Dujardin-Beaumetz, Lewis, Finger, Auspitz, Bardezzi, Du Castel, Dreyfous, and Fournier who either recognize no advantage from its use or who record positive unfavorable experiences. Its use by the method of irrigation in solutions varying in strength from 1 in 60,000 to 1 in 10,000 has been popularized by the excellent work of Curtis, Halstead, Vanderpoel and Brewer, and their published results seem to warrant its further trial, especially in hospital and dispensary practice.

The method of deep irrigation or retrojection involving the use of a catheter has always been unsatisfactory in my hands in private practice. It involves too much expenditure of time on the part of both patient and surgeon, and in a genuine acute inflammatory urethritis is certainly objectionable on account of the irritation produced by even the softest instrument. Keyes and others have met with cases of cystitis, prostatic abscess, epididymitis and other complications which seemed to have been produced by this treatment used early in attacks of urethritis. Palmer has called attention to its inapplicability to private practice, and I can add my testimony to theirs, though I am aware that in forty-six cases treated by retrojection Dr. Brewer claims to have met with no such difficulty.

I found it much more satisfactory to order frequent injections from a large syringe with moderate force, using the strongest solutions that could be given without causing pain and preventing the fluid from passing too deeply by instructing the patient to sit upon a folded towel during injection so as to

occlude the membranous urethra. My results were, however, disappointing so long as I used this drug alone. In a certain proportion of cases, by no means a small one, any solution, however weak, seemed to irritate, giving rise not so much to pain at the time of injection as to subsequent increased ardor urinæ. In others it was well borne but had no influence upon the discharge; in others it aggravated it and those in which it caused very decided improvement were in the small minority. Rigid dietetic and hygienic directions were always given at the same time and were, as a rule, fairly well followed, as most of the patients were of good social position.

Boric acid recommended long ago by Hyndman, of Cincinnati, tried by Chameron, Du Castel and others with unfavorable results, was used by me in a considerable number of cases six or eight years ago and dropped on account of general negative results. It has been shown to have little effect on the gonococcus but it is quite unirritating and can be used in sufficiently strong solution to destroy many of the weaker forms of vegetable life. Its germicidal action is slow but continuous. I shall allude in a moment to its internal employment. I certainly improved my results when I added it to the bichloride injection in the proportion of fifteen to thirty grains to the ounce. I felt, however, the additional need of an astringent, and for a long time employed the sulphate of zinc, for which I have recently substituted the sulpho-carbolate (two to ten grains to the ounce of the mixture). By using a ten to fifteen per cent. solution of peroxide of hydrogen as a menstruum, I then found that I had a formula which, both clinically and experimentally, showed excellent antiseptic qualities. In exceptional cases of profuse catarrhal secretion the addition of bismuth salicylate was also of advantage.

The rigid application of the antiseptic principle by means of these drugs used in this way undoubtedly brought about a distinct gain in my results; complications were fewer and the time required for cure was shorter than when I was content with employing sedatives and astringents and endeavoring to meet symptomatic indications, but there was still much to be desired.

In quite a large proportion of cases it was not possible to use this injection, or any modification of it, for some days after the disease had reached its height. I was in the habit, under these circumstances of giving boric acid internally to sterilize the urine, combining with it potassium bromide and belladonna in a solution of potassium citrate.[1] This mixture never had any very marked effect upon the amount of discharge though it constantly moderated the ardor urinæ, chordee, and vesical tenesmus of the inflammatory stage. I was also in the habit, after those symptoms began to subside, of employing one or both of the two chief "anti-blennorrhagics," cubebs and copaiba, usually in a capsule in combination with tar and pepsin. There can be little doubt that the beneficial action of these drugs as well as that of their congeners, gurjun, sandalwood, kava kava, eucalyptus, and the various terebinthinates, is chiefly due to their antiseptic powers, which not only deprive the altered and partially sterilized urine containing them of many of its harmful properties, but cause it to exert a positively curative effect upon the suppurating mucous membrane.

This statement is borne out by a number of microscopic observations upon specimens of urine before and after the administration of these drugs and by culture and inoculation experiments which will form the subject of a later publication.

This represented my routine treatment for cases of recent urethritis up to the middle of last January. My average results were certainly better than they had ever been before I made antisepsis the guiding principle of treatment, though not equal to some of those said to have been obtained by the method of irrigation, which, as I have said, I have found impracticable in private practice. My attention was then attracted by an article in the *Gazette Hebdomadaire de Médecine et de Chirurgie* (January 4 and 11, 1890), by M. Ferdinand Dreyfous, on "Antisepsis of the Urinary Organs by the Internal Administration of Remedies."

His paper contained the results of his observations in seven cases of gonorrhœa in which salol had been administered in full doses both with and without admixture with cubebs and copaiba.

Sahli (*La Semaine Médicale*, April 7, 1886) had shown that the resultants of the intestinal decomposition of salol are salicylin and carbolic acid, which are eliminated by the kidneys. He had exposed to the air for some weeks the urine of a patient under the influence of salol without the least decomposition occurring. Neneki had made the same observations. Bouchard (*Thérapeutique des Maladies Infectieuses; Antisepsie*, 1889, p. 247) had called attention to the value of the simultaneous employment of several antiseptics in internal administration. M. Dreyfous on these grounds gave salol a trial, and arrived at conclusions which were rather sweeping, considering the very limited experience on which they were

[1] Palmer has shown (American Medical Practitioner, August, 1887) the value of boric acid in sterilizing the urine, having had but one case of urethral fever in forty urethrotomies, and that occurring in a patient in whom by accident the boric acid had not been administered. The well-known effect of quinine in preventing urethral fever is probably due largely to its antiseptic action and to its elimination through the urinary apparatus. (Reginald Harrison, Letsomian Lectures, 1888.)

based, but which, taken in conjunction with the clinical histories of his patients, made so much impression upon me that I determined to investigate the subject. I accordingly asked Mr. Llewellyn, a prominent druggist, to prepare for me and keep on hand gelatin capsules, each containing

Salol	3½ grains.
Oleoresin of cubebs . .	5 "
Para balsam of copaiba .	10 "
Pepsin	1 grain.

I began at once to prescribe them in all forms and at all stages of urethral discharge, and, after a little time, in all cases in which much urethral or vesical instrumentation was required, giving from 6 to 8 daily. I have now used, as I learn from Mr. Llewellyn, nearly 10,000 capsules, and my case-books show that these have been prescribed in 97 cases. Throwing out of the latter the cases of urethrotomy, operations for vesical calculus, dilatation of strictures, etc. (in all of which I have come to regard it as of much value), there are left 72 cases in which the predominant symptom was urethral discharge. Of these, 19 were chronic and the results need not now be detailed, though I may say, *en passant*, that even among them in almost no instance did I fail to observe some benefit.

There remain 53 cases of recent urethritis, confined to the anterior urethra, but of all grades of severity. Of these, a distinct and unmistakable effect upon the discharge was produced in every instance but two, in which a violent indigestion prevented a thorough trial of the capsules. In 35, or about two-thirds of the whole number, the discharge almost or entirely disappeared during the first week after this treatment was begun. I have usually found, however, that it would return if treatment were withdrawn or even if the dose were greatly diminished; and although in 7 cases I depended from first to last upon the capsules and succeeded in effecting a cure in about seventeen days, in the majority of cases it was necessary to use the injection also. Since writing these notes I have seen an article by Mr. Ernest Lane (*The London Lancet*, March 22, 1890) giving his results in 50 cases of gonorrhœa, in which he used salol in doses varying from 5 to 30 grains, three times daily. An analysis of the 50 cases shows that 6 were cured, 25 showed considerable improvement, 15 were unaffected by the treatment, and in 4 the symptoms were aggravated. When he gave 20 grains three times daily and relied upon its internal administration without the assistance of injections he noticed an improvement in 20 out of 40 cases within a week, and 6 were cured completely in that time.

If I had seen Mr. Lane's paper earlier I would certainly have used larger doses of salol, and I have now ordered capsules to be made containing five and ten grains each. I am still of the opinion that the combination with cubebs and copaiba is of advantage, though I have tried salol alone in but a very few cases. I find it difficult to estimate with any accuracy or precision the lessening of the time required for a cure which has followed the systematic introduction into my practice of these antiseptic methods. I have already described the successive changes which I made in the topical remedy—the injection—each of which was an improvement, but I certainly noticed a much more marked and unmistakable advantage as a result of the employment of the capsules. In general terms I should say that these changes in my plan of treatment of acute urethritis have diminished the average duration of such cases by from one-third to one-half, and have even more decidedly reduced the discomfort and suffering, and lessened the frequency of complications.

In not one case in the whole number did gonorrhœal rheumatism (urethral synovitis) develop, and in three cases it was especially noteworthy that although they had never before been free from joint trouble during an attack of gonorrhœa, they had absolutely no threatening of it under this plan of treatment.

I have not attempted to give the average time of treatment in days for the reason that such statistics are worse than useless, they are misleading, unless they are based upon very large numbers of observations. A few days' difference in the time of beginning treatment, giving more or less opportunity for bacterial growth and for penetration into the deeper mucous layers, will necessarily make a still greater difference in the effectiveness of treatment and the rapidity of cure. So, too, cases of the kind upon which this paper is based, persons of fairly good position and intelligence, should not be classed with the ordinary applicant for dispensary or hospital treatment. I have, therefore, confined myself to this somewhat sketchy statement of my experience, which is, as yet, not large enough to warrant more definite assertions. It, however, taken with the general testimony upon the subject, justifies, in my opinion, the following conclusions, some of which are closely parallel with those M. Dreyfous had reached after even less extended observation:

1. The microscopical and experimental evidence in favor of the bacterial origin of gonorrhœa is confirmed by clinical and therapeutical experience.

2. The results of antiseptic treatment have not been so uniformly successful as would be expected, on account of—*a*, the anatomical and physiological peculiarities of the male urethra; *b*, the difficulty of applying sufficiently energetic local antisepsis; *c*,

the necessarily intermittent character of such applications, and *d*, the failure to combine with the topical treatment appropriate internal medication.

3. No one antiseptic agent can be depended upon, in the strength at which it can be borne by the inflamed urethral mucous membrane, completely to sterilize the discharges and the suppurating surfaces. A judicious combination of several antiseptics, if not essential to success, is at least of considerable value.

4. The internal administration of salol in conjunction with copaiba and cubebs renders the urine aseptic and probably antiseptic, so that it acts as an exceptionally thorough and efficient antiseptic injection, shortening the duration of the disease and diminishing the frequency and severity of the complications.

5. The production of urinary asepsis by internal medication is of considerable value not only in the inflammatory affections of the genito-urinary tract, but in the preparation of the patient for operation upon those organs and in the after-treatment.

THE EXAMINATION OF DRINKING-WATER WITH SPECIAL REFERENCE TO ITS RELATION TO TYPHOID FEVER.

BY VICTOR C. VAUGHAN, M.D.,
PROFESSOR OF HYGIENE AND PHYSIOLOGICAL CHEMISTRY IN THE UNIVERSITY OF MICHIGAN.

Introduction.—When the Michigan State Board of Health asked the Regents of the University of Michigan to build and equip a laboratory of hygiene, the objects of the laboratory were stated to be as follows:

1st. Original investigation into the causation of disease.

2d. The examination of samples of food and drink, at a nominal cost, on the request of local health officers; and,

3d. The instruction of students in hygienic investigations.

In accordance with the several objects, as stated above, health officers have frequently called upon the Director of the Laboratory to decide as to the potability of samples of drinking-water. Some analyses have been made for those residing in other States.

Method of Examination.—Naturally I have been anxious to make the reports on these waters as thorough as possible. I regard the following conditions as essential to a satisfactory examination of drinking-water:

1. The report must be returned to the health officer within a week, at most, after the water has been received. Typhoid fever appears in a village and a certain water supply is suspected. The health officer sends a sample of the water, and he will hardly be satisfied if he has to wait a month or longer for the report. At first I isolated the germs by means of plate cultures and inoculated animals with pure cultures of each germ. This method was pursued with the first thirty-eight samples given in the table. But the time required was too long, and the following procedure has been adopted: In all cases where the samples are collected by the laboratory assistants, a sterilized flask closed with cotton is used. In other instances, when I am informed by a health officer that he desires the analysis of a water, I send him a sterilized bottle, or instruct him how to sterilize a bottle. In other cases, the water comes usually in a new bottle or jug, which has been well rinsed with the same water. As soon as the water is received, plate cultures are made and a test-tube of beef-tea is inoculated with one drop of the water. This tube is placed in an incubator and kept at 37° C. for twenty-four hours. Then twenty drops of the beef-tea culture are injected with a sterilized syringe into the abdominal cavity of a white rat or guinea-pig. In some instances rabbits have been used, and with these the amount injected has varied from twenty to sixty drops, according to the size of the animal. If the water contains a pathogenic[1] germ the animal dies, usually within twelve hours. A post-mortem is made, the gross appearances noted and plates are prepared from the spleen, liver, kidney, and sometimes from the blood. After twenty-four hours longer these plates have generally developed (in some instances a longer time is required), and they are compared with the plates made directly from the water. On the plates made directly from the water the germs are counted and their general appearance noted after twenty-four, forty-eight, and seventy-two hours. In the meantime the chemical analysis is completed, and under favorable circumstances the report can be made three days after the water has been received. A week furnishes all the time required in any case. The germs taken from the plates can then be studied at leisure.

2. The second condition, which I regard as essential, is that the report, especially when the water is condemned, should be of such a nature that it will convince the average mind. No method of chemical analysis, with which I am acquainted, will do this. The ordinary bacteriological examination is no better. If the analyst reports a thousand germs in a drop of water, and stops at this, he will find that his report is not satisfactory. Immediately he will be asked if these germs are capable of doing any harm. It is true that the fact that a germ kills a rat does not furnish positive proof that it will cause

[1] The word *pathogenic* is used in the sense of *capable of producing death*, and it does not mean the production of any specific disease.

disease in man, but it is the most convincing proof that I know of that the water is not safe to drink. The search for certain pathogenic germs has not been attended with great success. The detection of Eberth's germ, by those who believe in its existence in all drinking-waters which cause typhoid fever, is admitted to be very difficult. I have only to refer to the recent work of Tiemann and Gärtner on the examination of drinking-water in proof of this assertion.

SAMPLES OF DRINKING WATER EXAMINED IN THE HYGIENIC LABORATARY OF MICHIGAN UNIVERSITY, FROM OCTOBER 1, 1888, TO MAY 1, 1890.

No.	Water sent from	Kind.	Class.	Free ammonia.	Albuminoid ammonia.	Chlorine.	No. of germs.	Kind of germs.	Remarks.
1	Omaha, Nebraska	Well	Second	0.168	0.118	129 0	50	No. 10 was found in all the Omaha samples; No. 8 in sample No. 4; No. 25 in Nos. 1, 3, and 4; Nos. 9 and 30 in samples 5, 7, 8, 9, and 10; undescribed germs were found in samples 2 and 4.	Pure cultures of each of these germs in beef-tea, twenty-four hours old, were injected into the abdominal cavity of rabbits and rats; all were without effect.

There is no need of my going into detail concerning the method of chemical analysis. I have nothing new to offer in that line, and have practically followed the methods of Wanklyn. The chemical analysis is much more extensive than is shown in the table. I have given only the results of the estimation of free and albuminoid ammonia and chlorine, because much importance has generally been attached to these by chemists. In addition to the figures given in the table, a record is made of the physical properties, including hardness, the amount of residue inorganic and organic, the amount of oxygen consumed in the permanganate process, of sulphates, earthy bases, nitrates and nitrites.

Explanation of the Table.—The waters are divided into three classes. The first class contains those which are supposed to be causing typhoid fever at the time the water is sent, or only a few days before the water is sent. In other words, the water has been sent on account of the present existence of typhoid fever among those using it. In the second class I have placed those waters which are not supposed to be causing typhoid fever at the time, but which are suspicious on account of unsanitary surroundings, or on account of former sickness among those using it. In the third class are given those waters which have not been suspected of causing disease, and the sanitary surroundings of which are not said to be especially bad. Several of this class have been sent for analysis, in view of their possible selection for the future water-supply of cities and villages. The figures given in the chemical part of the table represent parts per million, the chlorine being calculated as sodium chloride. The number of germs in one drop of the water is shown. In the column "kind of germ," the figures refer to the corresponding ones given in the tables of Eisenberg (*Bakteriologische Diagnostik*, Zweite Auflage), and the letters refer to germs which have proved fatal to the animals inoculated. In all cases, even in those in which the germ was recognized as one well known to be common in water, animals were inoculated. I am well aware of the fact that *old* cultures of some of the ordinary water germs may, when used in large amount, kill animals, and this has been avoided by using cultures only twenty-four hours old. Moreover, a number of the ordinary germs of water will, in quantities of from ten to twenty drops of cultures only twenty-four hours old, kill mice, therefore this animal has not been used. The rat seems especially suitable for this work, on account of its resistance to the ordinary water-germs. I think that this animal is more suitable than the rabbit or guinea-pig.

Other waters have been partially examined, some chemically only, and others bacteriologically only, but I have given only those which we have examined both chemically and bacteriologically, and only those the germs of which have been tested by inoculations.

Remarks on the Table.—It will be seen that the waters are distributed in classes as follows: In the first, 16; in the second, 29; in the third, 32. In 15 out of the 16 typhoid waters, germs pathogenic to the lower animals were found. The exception was water No. 61, from Sherwood, Mich. The number of germs in this water, as is seen, was large. The germs were all of one kind, No. 34 of Eisenberg, the white non-liquefying bacillus of water. Beumer and Peiper have shown that cultures of this germ kill mice, but that the effect is due to the poisonous chemical products of the germ in the cultures, and not due to the growth and reproduction of the organisms within the animal. Rats were repeatedly inoculated with twenty-four hours' cultures, and notwithstanding the fact that the amount employed was doubled, no effect was produced. Dr. Nelthorpe, who sent the sample of water, wrote as follows:

"The well is 40 feet deep, and distant 40 feet from a privy, and 28 feet from a hog-yard. The well was an old open one, but a gas pipe was put down 10 feet below the bottom of the well, the open part not being filled. The whole family of six children, and father and mother, have been attacked. So far, only one death has occurred."

All the circumstances being taken into consideration, the water was condemned. It will be observed that chemically it was very bad.

Out of the 29 samples of the second class, only one, No. 65, from Soudan, Minn., contained a pathogenic germ. C. T. Waters, who sent the sample, wrote:

"The well is 80 feet deep. It is situated on a considerable knoll, with still higher ground on one side, on which is a privy vault about 200 feet distant. Slightly lower than the surface of the well on the other side, at a distance of about 40 yards, is another privy."

The number of germs deserves attention. Chemically, the water was among the best. Its use was not advised, notwithstanding the chemical showing and the small number of germs. The microörganism will be described later. If I was right in condemning this water, the inadequacy of a chemical analysis and the ordinary bacteriological examination is here well demonstrated.

Of the 32 samples of the third class, two contained germs pathogenic to the lower animals, and these may be worthy of comment. No. 39 was from Grand River, and no one acquainted with the course of that river will claim that the sanitary surroundings are free from suspicion, a number of small cities discharging sewerage into it. I have hesitated about the class in which this water should be placed, and finally I classified it as I have, simply because the water was not sent to me on account of the unsani-

tary surroundings, but for the purpose of comparing it with No. 40, and in this comparison lies an interesting fact. No. 40 is said to be obtained from springs, but, as I understand it, the so-called springs are only wells sunk near the bank of the river, and into which the river-water filters. The two waters differ only in degree. They contain the same germ, which probably does not kill by growth in the body of the animal, but by the formation of poisonous chemical substances. In No. 39 the number of germs was 36,000, in No. 40 only 120. It is probable that even within twenty-four hours the larger number of germs produced enough of these poisons to kill the animal.

The next member of this class which contains a pathogenic germ is No. 62. This water was from Lake Vermilion, Minn., and this sample was taken from near the shore—water No. 63 comes from the middle of the same lake. It will be seen that in their chemical composition and number of germs. these samples differ but little.

Each of the waters of the first class deserves brief description. The first of these is No. 41. Of the cases of typhoid fever supposed to be due to this water I had personal knowledge. First, a girl of sixteen years was attacked, and I was called in attendance. I inquired concerning the drinking-water, and was told that the hydrant water *only* was used. I could not believe that this water was the cause of the fever, but ordered that all water used in house should be boiled. I was asked if the disease was contagious, and replied in the negative, but having in consideration the comfort of my patient, advised that two young brothers and a girl visiting at the house should be kept away from the sick-room. Within eight or ten days one of the brothers came down with the fever, and we learned that the visitor, who had gone to Cincinnati, was suffering from the same disease. Of course, the mother now claimed that the disease was contagious. Believing that there must be some local cause, I examined the house throughout, but without satisfaction. A little later, a young man rooming in the house was attacked. By this time the first patient who had been continuously delirious for three weeks, had become rational. When asked about having used any other than the hydrant water, she stated that she always used the cistern water to clean her teeth, and had also used it in a nasal douche, and in spraying her throat. The brother and the student also remembered that they had occasionally drank the cistern water.

The examination of the water was immediately undertaken, and, as is seen from the table, it was found to be exceedingly bad chemically, and in number and kind of germs. The stools of two of the patients were then examined and the same germ found so abundantly in the water was recognized in the stools. Of course, I cannot say that this germ was the cause of the disease. Fortunately, all of these cases finally recovered and there was no opportunity to examine their spleens. I cannot refrain from mentioning a few facts concerning the symptoms. Delirium was a marked and persistent feature; it was not the low muttering delirium, but wild, causing the patients to attempt to get out of bed. The fever ran forty-two days. There was no eruption over the abdomen. The patients who drank of the waters, Nos. 57 and 58, were also under my care, and, in general, the symptoms were similar to those given, but not so grave.

In regard to the outbreak of typhoid fever at Negaunee (waters 42 to 45), Dr. Lombard has furnished me with the following statements: The first case appeared in July, 1889, and the last in January, 1890. The total number of cases reported was 358, of which 32 proved fatal.

Negaunee takes its water-supply from Teal Lake, which covers about 600 acres of land and is supposed to be fed by underground springs. In 1886, Dr. Lombard asked the State Board of Health to assist him in preventing the contamination of the water of this lake. Drs. Avery and Baker visited Negaunee for this purpose, and from their report the following quotation is taken:

"Midway between the natural outlet and the water-works and on the border of the lake is situated a slaughter-house, where the principal part of the slaughtering for the city is done. A few rods nearer the water-works is a smaller slaughtering-house. Both of these places drain directly into the lake at certain seasons, and through a small quantity of sand at other times. The houses and their surroundings were as filthy as they could well be made. The stench in and around them was simply unbearable. In the larger house there was a great pile of heads, the accumulation of two or three years' killing and in various stages of decomposition. In another corner was a pack of salted hides. On and under the floor there was decomposed and decomposing blood; and outside the building wagon loads of refuse, rotting and stinking."

At the solicitation of these gentlemen, the slaughter-houses were removed. How thoroughly the shores of the lake were cleaned we are not informed, but of one thing we can be quite certain, the large amount of organic matter which was poured into the lake for years was not removed, save as in solution, or as finely suspended matter, it passed through the natural outlet or was pumped into the water-supply, and on this point a further short quotation will be of interest:

"At the time of the visit of your Committee, not more water than would pass through a two-inch pipe, with an incline of one inch to the rod, was running from the outlet, while at the works there was being pumped about 600,000 gallons per day, practically making the outlet of the lake at the water-works."

In regard to the Deerfield water (No. 49), Dr. Yale wrote me the following facts:

"There were seven cases of typhoid fever among those using the water of the well. The water comes up from a four-inch bore 80 or 90 feet into a reservoir 18 feet deep. As the reservoir is not well covered, it is probable that something has fallen into it."

The large amount of salt in this water is of no significance on account of the nearness of the saline deposits to the surface at that place.

The Iron Mountain waters (Nos. 51 to 56) were from shallow wells, and as I have elsewhere[1] gone into detail concerning the condition of the drinking-water of this place, I will not say more on the subject.

The Rankin water (No. 59) was from a drive well 218 feet deep, but the bore is larger than the pipe and surface water could easily pass into the well in this way. There is a barnyard near.

Remarks on the pathogenic microörganisms — *Bacillus* A.—This germ was found in waters 41, 57, 58, and 65. It is a short motile bacillus which does not liquefy gelatin, and its growth on potato presents a white, raised, moist surface. It produces no gas, takes the ordinary stains fairly, and gives a positive result with Gram's method. Of 6 full-grown rabbits each inoculated in the abdominal cavity with sixty drops of a twenty-four hour culture, all died. Of 2 rabbits, each of which were given subcutaneously twenty drops of this culture, neither was affected. Of 33 rats which had twenty drops of this culture, all died within twenty-four hours. Of 2 rats which were inoculated subcutaneously, both died after ten days. Of 8 guinea-pigs inoculated in the abdomen, all died; and a like result followed the subcutaneous inoculation of guinea-pigs. Cultures of this germ were tested along with similar cultures of bacterium coli commune, and the former appeared to be slightly more pathogenic with rats and guinea-pigs and less so with rabbits than the latter.

In every case of death after inoculation with this germ, plate-cultures were made from the spleen, liver, and kidney, and in many instances from the blood of the heart, and without exception the plates showed abundant growths. Therefore, this germ not only produces death, but is capable of living in the rat for ten days.

The post-mortem appearances vary with the time which elapses between the inoculation and death. In cases dying within twenty-four hours the intestines are, as a rule, slightly reddened, the liver, spleen, and kidneys engorged, and the heart has invariably been found in diastole. In cases which survive for several days there may be ulceration of the intestine, the spleen and kidney are enlarged, and the liver dark. In a few instances, all of which, strangely enough, have followed subcutaneous inoculation on the back, a marked peritonitis has been found after death. The same fact has been observed with bacillus B. In no instance has suppuration resulted from an inoculation.

Bacillus B.—This is also a short motile rod, which in cultures from four to six weeks old shows some liquefaction of the gelatin. It is certainly a slowly liquefying germ. It sometimes forms gas along the line of the stick. This occurs, if at all, during the first few days of growth and long before liquefaction begins. It forms a white, raised growth on potato. The ordinary stains are taken readily, and Gram's method yields positive results.

This germ agrees very closely with bacillus A in its pathogenic properties and in the post-mortem appearances induced—so closely, indeed, that it will not be necessary to repeat details. Yet the two germs are wholly distinct morphologically, and, as we shall see later, the symptoms produced by their chemical poisons differ. Moreover, this germ has, in the few instances in which it has been tried, failed to kill rats when inoculated subcutaneously, though it is fatal to guinea-pigs when employed in this manner. The plates prepared from the organs of animals killed with this germ have invariably yielded numerous colonies. The germ is also found in the blood.

Rats were inoculated in the same manner in every particular with bacilli A, B, and Eberth's germ. A and B killed a larger per cent. of the animals than Eberth's germ, but the post-mortem appearances were the same in the three sets of cases.

Bacillus C rapidly liquefies gelatin, the liquefaction beginning at the surface. It forms gas, is stained by the ordinary agents and by Gram's method. It resembles Eberth's germ in the formation of an invisible growth on potato, but in no other respect.

Some 20 rats were killed with this germ. The minimum fatal amount of the twenty-four hours' culture for white rats seemed to be between 10 and 15 drops. One strange observation was made. Cultures nine or ten days old are apparently less virulent than those only twenty-four hours old. Moreover, the germ decreases in virulence as it is grown in the artificial media, until in about the sixth generation it may be employed in four times the quantity first used without any effect.

The post-mortem appearances are quite different from those observed with A and B. The intestines are reddened but the liver and spleen are tarry black. Cultures from these organs show numerous liquefying colonies.

Bacillus D, as has already been noted, is probably not pathogenic, but kills on account of the chemical

[1] THE MEDICAL NEWS, vol. liii. p. 92 et seq.

poisons rapidly developed. Further study of this germ is needed before statements can be made concerning it. I can only say that it does not correspond with any germ given in the tables of Eisenberg.

Bacillus E is non-liquefying. It grows slowly in stick cultures, and forms a scarcely visible growth on potato. It decreases in virulence with artificial cultivation, and while none of the other germs in these waters showed any pathogenic properties in pure cultures, beef-tea inoculated with a drop of the water never failed to kill rabbits and rats, while bacillus E in pure cultures frequently failed to produce death. Moreover, after the death of these animals inoculated with the mixed culture, bacillus E was the only germ found living in the organs. The following quotation from my notes will illustrate this: October 28, 1889, a large rabbit was inoculated with sixty drops of beef-tea, to which one drop of the Negaunee public water had been added. October 29th. Animal found dead at 9 A. M. Post-mortem showed small intestines and mesentery highly inflamed; no other changes observable. Plates made from spleen, liver, and kidney showed pure culture of germ marked "Negaunee."

It is possible that this is Eberth's germ, though of this I am not certain. Unless this be the exception, I have not found Eberth's germ in any of the waters.

The chemical poisons produced by bacilli A *and* B. —Cultures of these germs, after being heated to 100° C. for one hour, lose all their poisonous properties. I concluded from this that their chemical poisons are destroyed at this temperature, and determined upon the following method of isolating them: eight quart flasks of beef-broth were inoculated with each germ and kept in the incubator, at 37° C., for ten days. They were then filtered twice through heavy Swedish filter-paper, and during the last filtration the filtrate was allowed to fall into a large volume of absolute alcohol. A copious flocculent precipitate was produced; the supernatant fluid was decanted and the precipitate repeatedly dissolved in water and reprecipitated with absolute alcohol. Finally, the precipitate was collected in a dish and immediately placed in a desiccator over caustic potash (or over sulphuric acid, though the former seems to prevent decomposition better). After drying, small quantities (about the size of a large pea) were dissolved in water and injected into rats, producing death in about three hours. These poisons are albumins. They are soluble in water, from which they are not precipitated either by heat or nitric acid, singly or combined. They are precipitated by saturating the aqueous solution with ammonium sulphate, and are, therefore, not peptones. They are not precipitated by carbonic acid gas, or by sodium sulphate to saturation, and are, therefore, not globulins. The aqueous solutions respond to the xantho-protein and biuret reactions.

Chemically, I can so far distinguish no difference between the poisonous albumins produced by the two germs, but physiologically there is a great difference. That from bacillus A produces in a few minutes complete paralysis of the voluntary muscles, and the animal lies perfectly limp, with rapid breathing, until death occurs. The proteid of bacillus B is equally poisonous, but it induces no paralysis of the voluntary muscles, and death apparently results from gradual heart failure. After death from these poisons no abnormal appearances could be detected. The heart was found in diastole. Plates were made from the kidney, spleen, and liver, but remained sterile.

It is absolutely necessary in obtaining these poisons that they should be quickly transferred to the desiccator. Only a few minutes' exposure to the air while moist converts them into hard, brown, leathery substances soluble in water only with great difficulty and wholly inert. The further study of these poisons promises to be of interest.

Whether or not any crystalline poisons are formed by these germs I have not yet determined.

I have intentionally refrained from offering any theories, but have simply stated the facts gathered in the study of these waters. There are from 350,000 to 400,000 cases of typhoid fever in the United States yearly. Medical men believe that these are almost wholly due to impure drinking-water. If this be true, it does seem that with all the advances which have been made in methods of chemical and bacteriological study we should be able to detect the harmful agent or agents in these waters.

I conclusion, I desire to thank my able assistant, Dr. F. W. Brewer, and my students, Mr. Churchill, Miss Schryver, and Miss Hinkley, for their valuable assistance, without which the work could not have been done.

A RETROSPECT OF ABDOMINAL SURGERY.[1]

By JOSEPH PRICE, M.D.,
of Philadelphia.

Under this title I wish briefly to call attention to the accomplishments of abdominal and pelvic surgery, together with the influences that have led to such successful results in the handling of diseases of the peritoneum. Among the first of these influences must be considered early operations in the hands of those best able to appreciate the necessity, if the ultimate safety of the patient is to be considered. In the light of proven statements of operative surgeons, physicians in general practice have no longer the right even to question the expe-

[1] Read before the American Medical Association, May 20, 1890.

diency and necessity of referring women afflicted with abdominal growths, small or large, at once to the attention of the skilled surgeon. They have no right to *suppose* in the case at all. They are not and cannot be judges of the situation, and by presuming or pretending to be so they reflect ultimately on their skill as physicians and on their unselfish honor as men. It must be taken as a corollary to the now established propositions of abdominal surgery, that in the large majority of cases the earlier the operation the greater the chance for success. That there may be an occasional exception to the rule is no excuse for delay, for if now and then an exception occurs, it is such as one not skilled in abdominal diagnosis is able to decide upon.

Looking back over the field of abdominal and pelvic surgery, nothing can strike the practical surgeon with greater force than the change that has come over opinion as to what is and what is not a justifiable operation, a question which is of paramount importance in determining the choice of cases. To know what to operate upon and what to refuse as inexpedient, impossible, or useless, is primarily of the greatest importance to the patient, to the physician, and to the surgeon. Up to a period measured scarcely by years it was the custom to bring so-called pelvic "abscesses" to the surface, stitch them there, and leave them to drain away. Extra-uterine pregnancies were not operated upon at all, or most exceptionally. When they were interfered with, it was only in a tentative way, that had nothing exact in its methods, and nothing tangible in its results except the death of the patient. There was preliminary puncture, with subsequent hæmorrhage or peritonitis, or there was injection of morphine into the sac, or a trial of electricity. The last two procedures are still flapping their ghastly wings like vultures over their graveyard records and inviting new victims. Although so prominent a man as Barnes still refers to the possibilities of morphine injections into the extra-uterine sac, by practical surgeons the suggestion must be thrown aside. As to electricity, if it has a place at all it is where it is not needed, and where surgical interference is by all odds the safest and surest method, both of doing no harm and of leaving no post-operative complications. Practical surgery like all other sciences, must leave pure theory behind. A theory may be enticing and brilliant, yet if it is not substantiated by facts and if it does not prove its worth it is left behind. Pure theory looks at facts from the outside, not from experience The theorist has his mind full of ancient pathology, constantly contrasts it with the more modern exposition of the same subjects, and is lost in a maze of bewilderment that the two should be so widely at variance. He may be on the verge of an exact diagnosis, or at the point of urging radical surgery to relieve the patient, when the wraith of defunct pelvic cellulitis rises hazily before him, obscures his mental vision, and drives him back to opium, hot water, and poultices. It is still no unusual occurrence to have inflammatory tubal troubles dubbed "cellulitis," and to have some guiding star sought to point out the difference between a condition that is benign because it does not speedily kill, and the same condition further advanced, yielding only to the knife. It should be strongly impressed upon the general surgeon and the general practitioner, that operative gynecologists do not find pelvic cellulitis. Electricians, experimentalists, and conservative procrastinators have a monopoly of this condition. It is not to be forgotten in connection with this that diagnosis with the latter men is the most exact part of their work. Their refinements are such as are not attained by any other class of operators, and where they can easily establish the existence of microscopic lesions of course they can cure infinitesimal disease, which has its chief exponent in pain. Pain apart from lesion should rarely in gynecology be assumed as a proper cause for operation. And among careful surgeons, the reproach of indiscriminate operation so soon as a woman comes complaining of pain, is unmerited. It is to be remembered here that we deny the right of the word conservative to be misapplied to a set of surgical pretenders, who are not conserving, but only riding on a wave of popular favor, because the word conservative is construed into meaning "careful," and that the conservative surgeon is the safer man to deal with is assumed. Let us see. To a man these "conservative" men are without experience. If they have attempted radical surgery they have failed, and abandoned it on that account. If they are young men they have been dragged into the electrical vortex, and while they would laugh at witches and witchery, they ascribe greater accomplishments and mysteries to the electrical current than was ever done to Aladdin and his wonderful lamp. Electropath, hydropath, homœopath—of the three the greatest humbug is the electropath. What conclusions are we to reach then concerning the wonderful cures attributed to this and that panacea?

Simply this, that the cure rests upon an incorrect or fallacious diagnosis, or that a temporary improvement of a condition which often occurs even without treatment has been misinterpreted a cure, or that after a short term of treatment a cure is presumed because the patient disappears, or that an incorrect report has been given, which unfortunate as it is, is too often the case. Now the whole truth of the matter is that, were half the efficacy attributed to electricity in curing disease in other

parts of the body that is attributed to it in the treatment of the generative organs, it would justly be laughed out of sight at the first hearing. If an ovarian abscess, or a pus collection in the pelvis, is curable by electricity, so is it in any other part of the body. If a fibroid can be dispersed by the same means, let it by all means be tried in bony tumors, or in necrosis of the jaw, or in osteo-myelitis. The mysterious force that can destroy one pathological product, ought not to fail in another which is no worse. The assumed results cannot be taken as real in one set of cases more than in the other. Then again the electrical treatment is set down as only suitable for a certain class of cases. What this class is no one has yet been able to ascertain. If it is fit for one set only, who is to determine when a tumor falls within this class? This is the difficulty that only the electricians are able to solve. They are able to do so, because they have never had actual expetience in dealing by sight and touch with these tumors. No man, however skilful he may be, can say positively what are the peculiarities of an intra-abdominal growth. The same is true of a majority of the mixed pelvic conditions. No lesion is unique, or as a rule simple. Complication is the rule, and where complications exist, conditions are more apt to exist in which experimentation will do harm rather than good.

Even for direct surgical operation discriminating care is to be taken in determining proper cases. It is madness to operate upon dying patients, for the result is only quoted as a failure for the surgeon and a reproach to surgery, and is an alarm to other sufferers. In acute inflammatory troubles, septic or specific, it is sometimes urged to wait until adhesions have formed, or until pre-operative treatment has been applied, to simplify the operation. This has no justification in experience. All the preparatory treatment advisable is that necessary to prepare the patient, so far as her ordinary functions are concerned, to undergo the stress of operation. Stimulation and tonics are at times demanded, as well as measures to quiet an irritable stomach. When lung complications exist, operation is to be deferred until these are held in abeyance. Except in suppurative disease it should also be well assured that the kidneys are not doing defective work. After operation where there is the least suspicion of kidney derangement opium is all the more to be avoided, not only as useless but as harmful. Now while early operation is to be advocated in inflammatory conditions, in evident pathological changes and in neoplasms, it is the more to be urged here, because here there is no hope of effecting resolution, for the trouble is organic from the start. Waiting increases the size of the growth and its adhesions interfere with other organs. There is no better proof of this than the result of present operations, in which it is the rule for tumors to be small at removal, compared with the results of the same class of operations a decade ago. The figures are all on the side of prompt removal when a foreign growth is discovered.

Complications are the chief difficulties of all pelvic and abdominal operations. The removal of a simple cyst, or of a growth, unconnected with other organs, is usually simple, but when there is a general fusion of all the pelvic contents, bladder, uterus, omentum and intestine in one conglomerate mass, the manipulation can be accomplished only by skilled hands made so by experience and study, and by a general knowledge of normal relations, and of those assumed under pathological conditions.

A knowledge of how to deal quickly and safely with adhesions, requires more special abdominal training than can be understood or appreciated by the novice or the prurient thirster after abdominal fame. Men of this sort are rendered more dangerous than rabid animals if they by chance in their first encounter with abdominal or pelvic surgery meet an easy case. They then imagine they have mastered the whole subject, and are accordingly all the more unfit to meet the exigencies of any particularly difficult case, because they underestimate the possibility of complications and overestimate their own ability. Of late there has been a great mass of discussion on the sequelæ of abdominal surgery. This discussion involves both the existence and the causation of the sequelæ. Too often the occurrence of some particular sequel has been explained from a personal not a scientific standpoint. Fistulæ for instance, have been attributed to the use of the drainage-tube, when a close study of the operator's work shows that he does not know how to care of a drainage-tube, and therefore is not competent to either commend or condemn it. To clean a tube once in twenty-fours is to put it where it is not needed, and the same is true of cleaning it every twelve hours. A drainage-tube carefully introduced, carefully kept clean, and early removed, has no more reason to cause a fistula, than has the suture in the uterus after Cæsarean section. Another class of operators trace their fistulæ to ligatures, silk being especially condemned. Now I have never, so far as I know, had a fistula after operating, while I have used silk constantly for the stump and the pedicle. The great points are to have as fine a ligature as is consistent with safe tying, to tie in sound tissue, and to cut the ligatures close. Catgut I regard as more or less unsafe, both from its nature and from its physical properties. In the first place we cannot know that it is really aseptic, and secondly it shrinks on the pedicle. Mann, in a late report of

his work, lays the blame of fistulæ on the silk ligature and then, strangely, reports a case where a gut ligature had given him identical trouble. Such statements only show that the faultiness of certain procedures, more than anything else, lies at the bottom of the occurrence of this complication. As to hernia, I have elsewhere dealt with that subject so fully, both in papers and discussions, that I do not deem it proper to resume it here.

Finally, the results of all these operations depend largely on the experience and training of the operator. Many cases do not necessarily make a skilful operator. Many men of large experience, so far as the number of operations is concerned, do not obtain results such as we would expect. Other men with a comparatively few cases have results that stamp their work as careful and conscientious. Work in order to be successful must be done only for the good of the patient, without thought of self or of grafting original methods or instruments upon a branch of surgery already too much cumbered with names and paraphernalia. The trappings, the adornments, and the cumbersome machinery of the old operating-room and table are all to be set aside; simplicity and directness are to be sought, and above all a learning, receptive spirit, that is not vain or puffed up with its own accomplishments, and that learns from others and by its own failures—for failures we all must have. They should be few, but they nevertheless will occur. Miracles are no more possible in this branch of surgery than in others. Too much must not be promised, and too much will not be expected. No man can have good results who is not content to train himself faithfully, carefully, diligently, and tediously. To fail in these latter days of the art, because we do not know how to tie a ligature or to clean a drainage-tube, or to stitch and resect an intestine, is unjustifiable homicide.

A PLEA FOR THE GENERAL ADOPTION OF THE AXIS-TRACTION FORCEPS.[1]

BY JOSEPH HOFFMAN, M.D.,
OF PHILADELPHIA.

IN presenting any question concerning the forceps I am well aware that I am treading upon hackneyed ground. Without preface I shall hasten to the statement of my argument for the adoption of the axis-traction forceps. First of all, the use of the forceps is to be considered as an obstetric procedure, which before its employment is to be fully justified, both in the interests of the mother and of the child, entirely apart from the convenience or prejudice of the operator. The forceps are to be applied, neither because the mother demands them nor because they are a time-saving convenience for the obstetrician. Their use is strictly a logical one, and they must be indicated or contra-indicated, be differentiated from every fallacy of apparent justification. The question has been asked, Can there be a too frequent use of the obstetric forceps? On the other hand, we frequently hear of the "abuse" of the instrument. Now, if some practising obstetricians are in doubt as to whether they shall use the forceps on every occasion where there is delay or other seeming cause, and if others only occasionally use them, the position of the two is evidently entirely different. If the application is for obstetric good and not for convenience, which must be conceded, they must save either mother or child, or both, from troubles or dangers they would otherwise undergo. Given a normal pelvis and a normal head and presentation, with normal application of forces, the labor has only to produce the dilatation of the maternal soft parts. If such dilatation, both perineal and cervical, is tardy, it is evident that an early application of the forceps must be accompanied with injury to the maternal structures, while the injury to the child must, or should, be small, under skilful application of the instrument. If now, on the other hand, there is free relaxation of all the soft parts and a deviated presentation, or a slight disproportion between the diameters of the fœtal head and those of the pelvis, which uterine contraction and external manipulation have been unable to overcome, thereby prostrating the mother and interfering with the fœtal circulation, the use of the obstetric forceps comes under consideration as a preservative measure, and is directly advantageous, as the instrument can be applied without force or forcible effects upon either mother or child. It is at this point that the general misconception of the use and intention of the forceps arises. Probably it is a teaching fault as well as a learning fault. Once let it be considered that the fœtus in the pelvis is a foreign body like the aching tooth in the jaw, and we have the obstetric forceps and the old tooth-key, as similar instruments of torture, both having force as the foundation of the ends they would attain. This principle, unfortunately, even if not confessed, is that followed out by too many obstetricians and obstetrical teachers, whose lectures must indorse, as a result of their ideas, pressure forceps, blades useful for leverage, and the like. This idea makes the forceps a lever or a tongs, with which to pull or pry by force, and loses sight of the principle that it should be used as the supplement of existing forces and in their lines if they are normal, to restore them if abnormal, and to conserve them or reinforce them if they are weak, and to substitute them if under certain conditions

[1] Read before the American Medical Association, Section of Obstetrics, May 22, 1890.

they are absent. Once accept and apply these principles and the abuse of the forceps ceases, even in cases where otherwise their application would be questionable. So far as the fœtal head is concerned, in what light must the ordinary obstetrical forceps be considered? From a mechanical standpoint we must see that the instrument works at a manifest disadvantage. Its adaptation to the fœtal head is maintained, no matter what the resistance opposed by the maternal structures, by a maximum pressure at the extremity of the long arm of the lever composing the handles. If the resistance is small the pressure is not less, but only shorter, owing to the speedy escape of the head, and expends itself to the disadvantage of the mother, and with damage to the perineal floor. If this pressure is not applied the instrument slips, and damages both the fœtal head and the maternal structures. If the resistance is great, the compressing force must be necessarily great to overcome it, while the contusing force upon the maternal structures is proportionate to the force expended in the axis of the pelvis and that lost against the pubic bones. In the use of the ordinary forceps this must exist; it is a mechanical necessity and must be overcome, if at all, by mechanical principles efficient according as they approach mechanical exactitude. True mechanics teaches us to use force gently, and if this is done better results are reached. Considered from the standpoint of the fœtus the force expended against the pubis is lost; considered from a maternal standpoint the force becomes harmful in its pressure-effects, just as the additional force by direct pressure upon the fœtal head is also harmful. It therefore appears that considered mechanically the ordinary obstetrical forceps is a defective instrument, permitting neither the satisfactory utilization of the force applied, nor its regulation so as to conform with the principles previously suggested. Now, as the pelvic axis is the line in which all forces must act in order to be effective, it follows that the greater the deviation from a normally formed pelvis, the greater must be the resistance to any force acting outside of or at variance with this axis, and that in cases of pelvic malformation the violence must be correspondingly great, both to maternal and fœtal structures.

The problem is accordingly presented as follows: Given a resistance; we must apply a force which shall work along the axis of the pelvis, and at the same time minimize lost energy and maximize the energy exerted in the axis of the pelvis and which alone is efficient in the expulsion or delivery of the fœtal head. The more nearly this problem is solved the more direct will be the traction, the less will be the force required, and the more natural will be the artificial delivery, or, as has been suggested above, the two will supplement each other. To fulfil the above indications numerous modifications of the common forceps have been invented, among which are those of Hermann, Hubert, Hartmann, Morales, and these, I think, we may justly say, finally culminated in those of Tarnier. The latter have been essentially modified by Poullet and others. The latest German idea, that of Breus, I regret not to be able to present. It is ably advocated by Winckel, though perhaps too much to the exclusion of Tarnier's forceps.

The conformity of the pelvis is such that when occupied by the fœtal head the problem is to bring an ovoid body through a circular canal in which a curved axis is presented. Now, to accomplish this it is evident that the force should be applied to the centre of the head or fœtal ball, and should act in the centre of the cylindrical passage, the vagina, at the same time varying the position of the application of the force as the head descends in the pelvic curve.

The ordinary objection urged against the Tarnier forceps is the danger of rupturing the perineum by the traction apparatus. This is entirely theoretical, as the rods are to be kept parallel with the forceps handle, and when this is done they practically fall within the blades, and can do no damage that would not otherwise occur. With both Tarnier's forceps and Poullet's modification some of the blunders yet common with some practitioners cannot be perpetrated. I refer more particularly to the so-called pendulum or lever motion of the forceps, and to the rotatory motion advocated by Osiander. These manipulations, while proper in the ruder arts, have no place in obstetrics, and can result only disastrously to the maternal tissues. It will be also seen that the direction taken by the head as it engages, must be in the path of the least resistance, inasmuch as the traction exerted does not guide, but only applies a force which is directed by the handle, which indicates lateral variations in the descent upon the perineum. These lateral deviations are the foundation of the excuse for the pendulum movements, which are only experimental manœuvres to determine in what direction the head will move most easily.

A brief epitome of the specific positions in which axis traction is especially advisable is all that can be here set down. First of all, in high operations in which it is desirable to make traction in the pelvic axis and not against the brim, a careful analysis of cases will show that the axis-traction principle offers better results so far as the mortality of the child and the effects on the maternal structures are concerned than pressure forceps.

As was before remarked, in deformed pelves the results must be even more notable. In occipito-

posterior positions any tendency of the head to rotate is not interfered with, but is allowed to take place freely. In my hands I have noticed a complete revolution of the blades and, of course, of the head in their grasp. In other occipito-posterior positions, in which the perineum usually suffers severe laceration, the lifting effect of these forceps —which, while bringing the head downward and outward, nevertheless raises it toward the pubes—is peculiar, and cannot be imitated by any other procedure. The rotary motion of Osiander, while essentially the same in its intent, cannot be compared in its accomplishment.

In the low operation, in which the short forceps are commonly applied, the same effect can be justly claimed. The short forceps, as such, in my estimation have no place in obstetrics; I have no doubt that of all instruments they inflict the most damage to both mother and child. If, when the head is on the floor of the pelvis, there is any need for the application of forceps, the axis-traction principle is the one that fulfils all the indications, expediting labor and at the same time saving the perineum by lifting, not dragging, the head through.

The final argument for the general adoption of the axis-traction principle is, that by it the force is applied at the centre of or near the centre of the fenestration, and that hence the leverage effect which must be exerted upon the structures within the grasp of the blades must cause less direct violence.

THE CONTINUED FEVERS OF THE SOUTH.[1]

BY W. W. JOHNSTON, M.D.,
OF WASHINGTON, D. C.

THE opportunity of discussing the subject of the "Continued Fevers of the South" with men who are constantly and carefully observing them is one which I appreciate, for at the present moment there is no subject in the whole field of medical pathology which seems to me so interesting and in the study of which so much is to be learned and so great an advance to be made. The places in pathology of the prevailing continued fevers of certain parts of the country have been more or less definitely fixed within the last decade; but in the South—including under that term the Southern Atlantic States, the States of the Gulf Coast, and the Southwestern States—the difficulties in classification are much greater than in the Eastern, Middle, and Western States.

In the Southern country the conditions of climate and soil have impressed such modifications upon the prevailing forms of fever, or have created such varieties, that definition and differentiation are attended with more difficulties than elsewhere. Moreover, the continued fevers of the South are, in great part, mild in type and have a low mortality, so that, in those fevers which are most difficult to classify, the opportunity is not often afforded to study their lesions and thus to discover their true nature.

The questions to be considered, in order to reach clear views as to the nature of the Southern fevers, are these:

I. To what extent does typical enteric fever prevail throughout the South?

II. To what class do the negative, atypical forms of fever belong?

III. Has continued malarial fever or malarial fever of remittent type a very general prevalence?

IV. Is the enteric fever of the South modified by malarial infection, giving rise to a hybrid disease—typho-malarial fever?

I. In answer to the question as to whether the enteric fever of the South conforms in its type to the form of enteric fever as originally described by Louis, it may be said that among the physicians of the South the prevailing opinion is that typical enteric fever is a disease of rare occurrence, as compared with other continued fevers, and I might quote here statements of many physicians scattered throughout this region to show that "text-book typhoid" is in some places unknown, in others rarely seen. This is more true of the Gulf Coast and Southwestern regions than of the States of the Southern Atlantic Coast, where the typical form is more commonly observed. In the Gulf States the actual prevalence is less, and the death-rate lower, than elsewhere; in Texas, Arkansas, Kansas, lower Missouri, Kentucky, and Tennessee, while there are differences of opinion as to what degree of typical manifestation justifies the diagnosis of typhoid fever, yet the preponderating opinion is that the combination of true typhoid symptoms is not frequently observed. I have not been able to learn how far the present belief agrees with that of twenty-five or more years ago, but many physicians of the South assert that enteric fever is assuming a milder type and that it is becoming a rarer disease than formerly. Whether the disease is disappearing or is only putting on a new dress it is of importance to know. The latter is what my own experience teaches me is the case, for while the more virulent forms are less numerous than formerly, the disease under a milder and less fatal form is becoming our endemic summer and autumn fever, with a wide prevalence and low mortality. There are geographical differences in enteric fever, and there are also historical differences; and just as malarial fevers give place to enteric fever as cities are built and sewered, and as areas of country are more carefully cultivated and drained, so enteric fever is modified in time by changes in the soil and

[1] Read before the American Medical Association, May 21, 1890.

in other conditions of environment under which its germs grow and are disseminated.

II. To what class do the *atypical* forms of fever belong—those which do not have the typical symptoms of malarial nor of typhoid fever? This category does not include those cases of mild enteric fever which have at least one of the more characteristic symptoms of the disease in addition to the more or less typical fever curve, but only those cases which have neither rose-spots, delirium, tympanites, nor diarrhœa, but in which a continued fever of moderate elevation, with diurnal remissions and exacerbations, lasts for from two to four weeks or longer, usually ending in recovery, but terminating sometimes fatally by intestinal perforation or hæmorrhage. These fevers have often a sudden onset, with a chill, and in the initial stages the symptoms have some malarial features, but they are not shortened nor markedly influenced by quinine.

There is a growing belief that such negative forms of continued fever belong to the same class as the more typical enteric disease, the reasons for this conclusion being based upon the study of large groups of cases, which show a gradual diminution in intensity and in the number of associated symptoms, until a continued fever, more or less conforming to the type of enteric fever, is the only symptom left. The occasional death by perforation or hæmorrhage and the finding of the typical lesions in the most negative cases have gone far toward confirming this conclusion.

We recognize in the whole class of infectious disease the greatest differences in intensity of manifestation. Some cases of scarlet fever and diphtheria escape observation altogether until dropsy or paralysis makes clear the nature of a preceding, almost unnoticed illness. And so it is not strange that enteric fever should sometimes be so mild as to be difficult of recognition. The question to be answered is this: Is it more probable that these mild forms of fever are "simple continued fever," "gastric fever," or "catarrhal fever," or are they mild manifestations of typhoid infection? The latter doctrine is the safer one in practice, and will, if adopted, avert that rude awakening to the fact that what was thought a slight illness is accompanied with a specific intestinal ulceration and all its attendant dangers.

III. Has the continued malarial fever or malarial remittent fever a very general prevalence in the South?

I include under this question all those forms of continued fever which are supposed to be due to malarial influence and variously denominated "malarial continued," "bilious remittent," "malarial remittent," or "remittent" fever.

There can be no doubt, if the large amount of testimony on this point is taken as a basis for a conclusion, that there is a form of fever prevailing in the South, which lasts from five days to two weeks, which begins with a chill, followed by rapid rise of temperature, by thirst, nausea, vomiting, frontal headache, and lumbar or other pains. A remission follows in from six to twelve hours, with relief to headache and other symptoms. If not promptly treated by quinine there is a recurrence of the rigors, fever, etc., these phenomena being repeated during five, seven, nine to twelve days. Quinine in these cases has a beneficial and curative effect. The existence of such a fever may be assumed and its malarial nature accepted.

But is there an adynamic malarial fever, or a malarial or remittent fever with typhoid symptoms? After a close reading of the descriptions given of the essential symptoms of this form it has seemed to me that there is no symptom which clearly establishes its malarial origin, but much in the history of the subject to show that very many such cases are really cases of typhoid fever. The records of cases in which the diagnosis of remittent fever was made in the early stages, but changed later to that of enteric fever, when some one characteristic symptom appeared, or cases which were called "remittent" or "malarial" until death resulted from perforation or intestinal hæmorrhage, or until an autopsy revealed the lesions of enteric fever and compelled a change in diagnosis, are scattered through hospital reports, army and navy reports of Great Britain and of the United States, and in the journals for many years. I will not be so bold as to say that there is no continued malarial fever or remittent fever, closely resembling enteric fever, in the South, but there is not a shadow of doubt that many so-called cases of "bilious fever," "remittent fever," or "continued malarial fever" are, in reality, cases of enteric fever which lack most of the typical symptoms of that disease. The change of view on this subject has been very decided in the last ten years in the cities of Boston, New York, Philadelphia, Baltimore, and Washington. Here "remittent fever" and "continued malarial fever" were at one time as generally recognized forms of prevailing disease as in Nashville, Memphis, or Mobile; but at the present time few in these former cities would venture to call a continued fever lasting over ten days "malarial continued" or "remittent," no matter how great the morning remissions might be.

IV. Is the enteric fever of the South modified by malarial influence, producing a hybrid disease—the so-called typho-malarial fever?

I approach this part of the subject with much hesitation, knowing how difficulties crowd the road to its solution; but while waiting for the time when the microscopist will decide whether the microör-

ganisms of the two diseases are or are not coincident, much may be done by clinical observation to determine it. The great diversity of opinion alone serves to throw the gravest doubt on this belief.

The term "typho-malarial fever" has five distinct meanings in the minds of those who employ it. It means: (1) A continued malarial fever with typhoid symptoms which is not influenced by specific (quinine) treatment; or, (2) an enteric fever, with intermittent or remittent phenomena in the beginning or at the end of its course; or, (3) a continued fever, with gastro-hepatic disturbance; or, (4) a prolonged fever, of a certain gravity, without the typical symptoms of enteric fever, and not influenced by quinine; or, (5) a fever of a negative and mild character, without the characteristic symptoms either of malarial or of typhoid fever.

The strongest arguments for the theory of the union of the two diseases in one individual are the presence of supposed well-defined malarial symptoms in typical enteric fevers and the beneficent effects of quinine in such cases. To the first of these arguments it may be answered that the occurrence of chills in the onset or during the course of enteric fever, marked remissions in the fever-curve, gastric irritability, the vomiting of bile, icterus, and hepatic tenderness are not necessarily due to malarial infection, and may and do occur in the course of the enteric fever of localities where malaria is unknown. The most severe chills are seen in the course of enteric fever in Washington; they are probably septic in nature, and are not prevented by quinine treatment.

It is not wise to be too dogmatic on this point, but as many writers of the South have advanced such strong assertions in denial of the existence of typho-malarial fever, I feel more assurance in expressing my own adhesion to the same view. In no instance have I seen a fever which seemed to require such an interpretation, and in view of the fact that twenty-five years have passed since the hybrid name and theory were suggested by Dr. Woodward, a very large mass of testimony ought to be forthcoming in its support, and yet the medical world has not accepted the doctrine as an essential article of faith. Among those who do accept it there is such a contrariety of opinion as to what typho-malarial fever is that we may even hesitate to believe that there is any truth in the doctrine or any well-founded arguments to support it. What is needed on this question is an authoritative collective investigation, and the American Medical Association could do no better work than to order such an investigation by a competent commission which shall sift the truth out of the mass of uncertainty and give some simplicity and definiteness to our knowledge. There is no uncertainty in the facts—it is in our interpretation of them only, and a properly constituted body of investigators may be trusted to act without prejudice and to formulate conclusions which will carry great weight to all impartial minds.

The following conclusions embody the main statements in the above remarks:

1. Enteric fever is a rare disease in the South in a typical or intense form.

2. There is a probable change going on in the type of enteric fever; it is losing its typical character and is assuming a less typical and milder form.

3. Many cases of mild continued fever, which have no well-defined or characteristic symptoms, are cases of mild enteric fever.

4. While malarial continued fevers are found in the South, many so-called cases of "adynamic malarial fever," "remittent fever," etc., are in reality cases of enteric fever.

5. There is no good reason to believe that there is such a disease as typho-malarial fever.

CLINICAL MEMORANDA.

OBSTETRICAL.

Detachment and Expulsion of the Vaginal Portion of the Cervix during Labor.—This rare accident recently happened to a patient in the Maternity Hospital:

A. S., V.-para, aged thirty-four, had a history of difficulty in previous labors, which, with one exception, had been instrumental, partly on account of a slightly contracted pelvis, but mainly because of unusually large children. Labor began by rupture of the membranes; vigorous uterine contractions soon followed; but little progress was made in spite of energetic abdominal action which the woman persisted in exerting with almost every pain. The os dilated unevenly, the anterior lip, nipped between the head and symphysis, remained thick, firm,

Vaginal portion of the cervix detached and expelled during labor.

and unyielding, but was not œdematous. After more than twelve hours of ineffectual uterine and abdominal contraction a fleshy mass was discovered protruding from the vagina; it proved to be the vaginal portion of

the cervix, lacking a small piece posteriorly. On examination the head was found well down in the pelvic cavity, surrounded by the vaginal walls. The expulsive forces then failing, the child was extracted by forceps. Twenty-four hours after labor a vaginal examination was made. No trace of a cervix could be felt except posteriorly, where a tongue of cervical tissue, about the breadth of a finger and one and a half inches long, projected into the vagina. There was no hæmorrhage during labor nor afterward, and the puerperium has been uncomplicated except for a slight cystitis. At the present time, three weeks *post partum*, the tongue of cervical tissue projects from the median line posteriorly, the entrance to the womb is reduced to its ordinary calibre by cicatricial puckering in the centre of the vaginal vault, and the involution of the uterus has progressed normally.

The dilatation of the os was, no doubt, prevented in in this case by cicatricial infiltration, the result of injuries in former labors. The absence of serious symptoms after an injury of this gravity is remarkable. It speaks well for the asepsis obtained in the Maternity Hospital.

BARTON COOKE HIRST, M.D.,
Professor of Obstetrics in the University of Pennsylvania.

An Anencephalous Twin.—Mrs. H., on May 8th, gave birth to male twins. The first born was well formed, vigorous and healthy, weighing at birth seven pounds. The second was anencephalic, with almost entire absence of the occipital and parietal bones. The hemispheres of the brain were only partially developed and were apparently covered by dura mater.

Both children presented by the vertex and were in separate sacs; their placentæ were united by the edges. The monster was the larger of the two, and, with the exception of the head, was well formed, weighing eight and one-half pounds. The mother ceased to feel motion upon the right side about the beginning of the ninth month of gestation, and the fœtus probably perished about this time. The funis was shrunken and small, and the surface of the body was easily denuded of cuticle. No post-mortem was made, as I desire to present the specimen intact to the Lexington and Fayette Medical Society.

By palpation, at the beginning of labor, both children could be distinctly outlined. By auscultation the fœtal circulation could be heard upon the left side only. The abdomen presented a broad and flat appearance.

Antisepsis was carefully practised in this case, and both the patient and the living infant are doing well. This was the woman's seventh confinement and her first twin labor. Upon the subject of maternal impressions I made particular inquiries, and learned that about the beginning of the fourth month of gestation the patient had been frightened by the attempt of an intoxicated man to enter her bed-chamber. For several days after this she suffered from nervous prostration. But if the shock thus received was the cause of the abnormal development in the one fœtus, why was not some impression made upon the other? F. M. GREENE, M.D.

GREENE DALE, KY.

MEDICAL PROGRESS.

Antiseptic Paste.—SOCIN recommends the following paste to be used in place of other antiseptic dressings on regions where it is difficult to apply a bandage (*Medicinische-chirurgische Rundschau*, May 15, 1890):

R.—Zinc oxide	. . .	12½ drachms.
Zinc chloride	. . .	75 grains.
Distilled water	. . .	12½ drachms.—M.

This paste should, if possible, be used when fresh. It dries quickly, forming a strong crust which can be still further strengthened by incorporating a small amount of cotton-wool with the paste.

The Treatment of Chronic Bronchitis.—In an instructive lecture upon bronchitis (*Lancet*, May 24, 1890) HARRIS gives the following advice on the treatment of the chronic form:

The inhalation of steam alone night and morning helps the expectoration, but the addition of compound tincture of benzoin, creasote, eucalyptus or carbolic acid in small amounts, adds considerably to the value of this method of treatment. If one drug seems too irritating, another may be tried. The patient must be induced to give this plan a fair trial, but must be directed not to employ the inhalation too long at one time, as faintness may be induced. Here should be mentioned the sprays of various medicaments recommended by Drs. Ringer and Murrell, and used by them with such success. The drug most frequently employed is ipecacuanha wine, either pure or diluted with once or twice its bulk of water. Simple spray apparatus may be used with the ipecacuanha wine, and the patients should be directed to inhale the spray as given off. At first there may be some involuntary resistance to the entrance of the drug into the lungs; but, as the patient gains confidence, it no doubt enters freely into the air vesicles. Instead of the ordinary spray apparatus a steam atomizer may be used. Dr. Murrell claims that with a few sittings, at each of which two drachms or more of ipecacuanha wine are used, the patients are greatly relieved, the shortness of breath and cough are diminished, and good rest at night is obtained. The number of inhalations required in most cases of chronic bronchitis ranges from four to eighteen, and they should be given daily. The effect of ipecacuanha is said to be increase of the secretion. In small doses it depresses blood pressure but little, while it stimulates ciliary action and that of the respiratory centres. Tartar emetic spray (one grain to an ounce of water) has also been used; it produces the same effect as the ipecacuanha wine, but is less satisfactory. Lobelia spray is sometimes employed, especially when there is much spasm. Iodide of potassium spray (two per cent. solution) is also of much use.

Counter-irritants seem to be of great value in chronic bronchitis, and the author has great faith in the linimentum terebinthinæ aceticum (B. P.) well rubbed into the chest night and morning. Others use linimentum iodii, with the idea that it is not only an active counter-irritant, but that it also does good when inhaled, iodine having been strongly recommended as an inhalation in bronchitis.

As regards expectorant and other drugs in the treatment of chronic bronchitis Harris gives the preference to carbonate of ammonium, five grains of the salt with infusion of senega or serpentaria, or with aromatic spirit of ammonia, ipecacuanha wine and compound tincture

of camphor. Chloride of ammonium is also of much service. Terebene, in the author's experience, gives relief at first, but he has not found it of as much value as carbonate of ammonium. Emetics are often very serviceable in cases with excessive secretion which is not easily expectorated.

Treatment of Profuse Menstruation.—The following prescription for cases of profuse menstruation is quoted by the *American Practitioner and News*:

R.—Dialyzed ergotin	. . .	10 drachms.
Glycerin	. . . .	5 "
Salicylic acid	. . .	30 grains.
Distilled water	. . .	2½ ounces.—M.

One teaspoonful diluted with three teaspoonfuls of water to be injected into the rectum after stool once daily.

Bougies Weighted with Mercury.—DR. LEOPOLD CASPER uses elastic bougies filled with mercury which he thinks have decided advantages over both metallic and ordinary gum bougies. The weight of the mercury causes them to slip into the bladder with great ease and they possess all the safety of the unweighted elastic bougies.—*Therapeutische Monatshefte*, May, 1890.

The Treatment of Local and of General Peritonitis.—DR. W. E. B. DAVIS, of Birmingham, Alabama, considers that the following facts in reference to peritonitis are definitely settled:

1. Simple peritonitis, when caused by a sufficient quantity of chemical irritant, will produce death by the extent of the inflammation.

2. Simple inflammation may terminate in septic peritonitis, by producing a weakened condition of the walls of the intestines, which permit the passage of septic germs from the intestinal canal into the peritoneal cavity.

3. While pathological germs in small quantity may be absorbed by the healthy peritoneum, without producing a peritonitis, the same quantity combined with a chemical irritant may produce a violent inflammation—the irritant having prevented the absorption of the germs and caused the exudation of a nutrient fluid for their multiplication.

4. Large quantities of septic fluids and microbes always produce suppurative peritonitis; yet, a small quantity of either may be absorbed and destroyed, unless the peritoneum has been weakened by antecedent pathological changes.

5. A septic fluid may gravitate into dependent parts of the peritoneum, and become shut up, either by plastic inflammation, or by a coil of intestine, and thus be prevented from producing diffuse peritonitis, but after a time this may rupture and produce death from general peritonitis.

6. The germs of septic peritonitis will be found in the kidneys and other organs of the body, and in quantities proportionate to the extent and duration of the inflammation.

7. The condition of the peritoneum, and the nature and quantity of the product, will determine the rapidity of the inflammation, which usually ends in from forty-eight hours to six days, but death may be produced from shock in a few hours. Tubercular inflammation is always slow in its progress.

The foregoing principles indicate the following rules of treatment:

(*a*) Promote absorption of the inflammatory products of simple peritonitis as rapidly as possible, and thus relieve the inflammation and prevent the possibility of septic peritonitis.

(*b*) In the early stages of peritonitis, whether simple or septic, where the cause cannot be determined, hasten the absorption of inflammatory products, etc., with purgatives.

(*c*) When medical treatment fails to give relief, septic fluids should be removed by operative procedure.

(*d*) In localized peritonitis, with circumscribed pus formation, the pus should be removed and the abscess cavity drained.

(*e*) In acute septic peritonitis, operative procedure must be adopted early, or there will be no chance of recovery offered by the operation, as the inflammation will become more extensive the longer it continues; and, too, there will be so great a quantity of septic germs absorbed into the system that death will result from toxæmia, even though the local inflammation should be remedied by a late operation.—*Virginia Medical Monthly*, May, 1890.

Ammonium Bromide Fumes in Asthma.—The value of the fumes of ammonium chloride in some varieties of bronchial and naso-pharyngeal catarrh suggested to DR. THEODORE MAXWELL the use of ammonium bromide fumes in the same diseases when complicated with spasm, as is seen in asthma (*Lancet*, May 10, 1890). The ordinary solutions of hydrobromic acid were found useless for the purpose and Dr. Maxwell was obliged to use a strong acid with a specific gravity of 1.7. This, with solution of ammonia, gave abundant fumes. In several patients suffering from asthma a few whiffs relieved the dyspnœa at once. In some cases when used early the inhalations aborted the paroxysms.

As some difficulty in obtaining absolutely neutral fumes with the usual inhalers was experienced, an apparatus was finally adopted in which the ammonium bromide is simply vaporized by heat and drawn through a wash-bottle before being inhaled.

The Treatment of Dysentery in Children.—VEILLARD recommends the following mixture in the dysentery of children:

R.—Powdered ipecacuanha . . 25 grains.

Boil for five minutes in 3½ ounces of water. Filter and add:

Tincture of opium, from	2 to 4 drops.
Cinnamon water . . .	3 drachms.
Syrup of orange flowers . .	6 " —M.

Dose, for a three-year-old child, one dessertspoonful every hour, or at longer intervals if nausea is produced. To quiet tenesmus enemata containing tincture of opium, or enemata of infusion of chamomile or of eucalyptus flowers, should be used.—*Annals of Gynæcology and Pediatry*, May, 1890.

Pilocarpine in Deafness.—MR. GEORGE P. FIELD reports a series of eighteen cases, diagnosed as labyrinthine

deafness, treated with pilocarpin. In all of these cases the improvement was marked. The cases which derived the greatest benefit from the treatment were those in which bone conduction was the least. A few cases of middle-ear deafness were also somewhat improved.

The author states that the pilocarpine was given hypodermically but does not state the dose nor the frequency of its administration.

Prescription for the Expulsion of Lumbricoid Worms.—According to the *Annals of Gynæcology and Pædiatry* the following is DUJARDIN-BEAUMETZ'S prescription for the treatment of lumbricoid worms:

R.—Tincture of kameela . . 1½ drachms.
Syrup of orange-peel . . ½ ounce.
Water, sufficient to make . 4 ounces.—M.

This should be taken in small doses at short intervals until all has been used. If the worms are not expelled within two hours after taking the last dose castor oil should be administered.

Formulæ for the Administration of Condurango.—KRAUS, of Vienna, who uses condurango as a stomachic gives it in the following combinations:

R.—Extract of condurango . . 30 minims.
Chloral . . . . . 15 grains.
Syrup of orange . . . 5 drachms.
Distilled water . . . 4½ ounces—M.

Dose, from three to six tablespoonfuls daily.

Or,

Condurango bark . . 5 ounces.
Hydrochloric acid . . 15 minims.
Elixir of orange . . . 2½ drachms.
Syrup . . . . . 5 ounces.—M.

One tablespoonful every two hours.—*Internationale klinische Rundschau.*

Quadrangular Sounds for the Treatment of Urethral Stricture.—DR. HAL C. WYMAN has devised a four-sided bougie, with a groove between each angle, which he thinks has several points of superiority over the ordinary instrument (*American Lancet*, May, 1890). A round bougie in passing a tight stricture often severely stretches the urethra longitudinally and not infrequently causes laceration, whereas the quadrangular bougie, presenting less surface for friction, slips through more easily, at the same time dilating the stricture. The grooves between the angles insure the presence of the lubricant where it is most needed, and, moreover, by means of them medicaments can be applied to the urethra.

Asepsis of Urethral Instruments.—PICARD (*Gazette des Hôpitaux*, No. 28, 1890) writes that a clean aseptic bougie or catheter, no matter how often employed, never occasions cystitis, urethritis, orchitis, urethral abscess, or urinary fever. To this should be added—provided the urinary tract be not previously infected.

Respecting the means to be employed to secure asepsis, the author confines himself to those easily adopted by the general practitioner. Metallic instruments are most easily disinfected. Boiling in simple water or in salt water is regarded as giving practically the necessary guarantees. Boiling in strong carbolized water is preferable, but often impracticable. Soft or semi-soft instruments require greater care. The soft, red, Nélaton catheter is easily disinfected by dipping for a few seconds into boiling water, or it may be kept in a strong antiseptic solution, such as a five per cent. carbolic acid or a 1-to-1000 sublimate solution. It is recommended to wash the instrument either in boiling water or boric acid solution before using. After boiling, the instrument may be taken up with clean forceps and placed in a jar containing a saturated solution of boric acid. A thread previously fastened to the end of the sound is slipped into a slit in the cork, and the sound thus suspended can be readily withdrawn without handling when needed. Semi-soft catheters and bougies are not so easily sterilized. They should be placed in tubes closed with absorbent cotton. The tube is then placed in boiling water and allowed to remain for half an hour. During this time this heat will sufficiently sterilize the tubes. It will be more prudent to repeat this process several times at intervals of twenty-four hours, for while this temperature destroys bacteria it is without effect upon the spores.

Before passing a bougie or catheter the hands of the physician should be thoroughly cleansed and rendered aseptic. The meatus and glans penis of the patient should be washed with a sublimate solution or with hot water. If the urethra is already infected it should be washed out with a saturated solution of boric acid. For lack of these precautions a more or less acute cystitis has been again and again set up.—*Journal of Cutaneous and Genito-urinary Diseases*, May, 1890.

Drainage Water from Cemeteries.—DR. E. VON ESMARCH (*Zeitschrift für Hygiene*) has examined the question of the dangers of contagion through the drainage from cemeteries. His experiments show that where bodies are placed in water or buried, the earth or water surrounding the bodies does not become contaminated with germs. He finds that in the case of death from anthrax the bacilli in the body very quickly die. He concludes, with several other German observers, that the proximity of cemeteries and the drainage water from them have no influence in the spread of epidemic or contagious diseases. He unfortunately does not tell us whether the typhoid bacillus meets with the same fate as that of anthrax.—*Brooklyn Medical Journal*, June, 1890.

Filaria Sanguinis Hominis.—At a recent Intercolonial Medical Congress of Australia DR. BANCROFT announced some of the results of his studies of filaria. He thinks that probably all filaria, whose embryos circulate in the blood, require for their distribution the intervention of some blood-sucking animal, such as the mosquito, sand fly, louse or flea, all of which should be studied. The larva of filaria immitis are often found in dogs, and the embryos are found in the lice infesting such dog.

Dr. Bancroft was the first to discover filaria sanguinis hominis in Australia (1876). The filariæ were found in an abscess of the arm in a butcher's boy, embryos being found in the blood. Since then other cases have been observed. The author thinks that one of the modes in which the parasite may prove injurious is by invading the heart and causing thrombosis. They may also produce emboli.—*Medical Chronicle*, June, 1890.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author.

THE INFLUENCE OF MATERNAL HÆMORRHAGES UPON THE VITALITY OF THE FŒTUS.

MANY investigators have studied the effect of certain maternal conditions upon the life of the fœtus, and both experiments and clinical observations have established some facts of great practical importance. Thus, it has been shown that a sudden elevation of temperature to 105°–106° is usually fatal to fœtal life, while even 108° gradually reached has been apparently harmless. The ill effects of emotion and maternal impressions have often been disputed, but an interesting paper by Fordyce Barker would seem to establish the fact that profound maternal impressions in some way influence the growth and development of the fœtus. The danger to fœtal life of poisons in the maternal blood has been carefully investigated, and no one denies that eclampsia, lead-poisoning, the saturation of the blood with bile salts, and infectious diseases in the mother frequently cause the death of the fœtus. It is also well known that death of the fœtus is very probable when the mother is affected with any chronic disease rendering her nutrition so defective as to induce a condition of marked anæmia. It is in this way that the pernicious vomiting of pregnancy destroys the vitality of the fœtus.

At a recent meeting of the Société de Biologie, MM. CHARPENTIER and BUTTE reported the result of a series of experiments made to determine the effect of hæmorrhage of the mother upon the vitality of the fœtus. Gravid rabbits, near term, were immersed in a six-tenths of one per cent. saline solution, the abdomen and uterus being opened in such a way that the condition of the fœtus and the umbilical circulation could be observed. The rabbits were then bled, and the results led to the following conclusions: When the hæmorrhage is sudden and profuse enough quickly to cause the death of the mother the fœtus will survive if it is immediately extracted. If the loss of blood is gradual, yet sufficiently great to cause death eventually, the fœtus will die a short time before the mother. Finally, if the mother survive a severe hæmorrhage the fœtus will die about an hour after the appearance of the hæmorrhage.

These observers attribute the death of the fœtus before that of the mother to the disappearance of a part of the oxygen of the maternal blood, to the diminution of the total amount of oxy-hæmoglobin, and also to the diminished blood-pressure which impairs the umbilical circulation. The supply of oxygen to the fœtal structure is thus insufficient for the purpose of carrying on the functions. These experiments are of practical value and offer suggestions which may be applied to cases not infrequently met with, and will, no doubt, lead to the saving of life. Examples of serious hæmatemesis, hæmoptysis, and epistaxis in the latter months of pregnancy are by no means rare, and the further history of such cases is the birth some weeks later of a macerated fœtus which has evidently been dead for some time. It would seem from these experiments that the death of the fœtus in such cases is directly dependent upon the hæmorrhage of the mother. If this be the case in obstetric practice the indication is plain to induce labor as soon as such a hæmorrhage makes its appearance, with the purpose of saving the child's life. Since the introduction of incubation and *gavage* in the management of premature infants, and the happy results of their employment—twenty-two per cent. of the infants saved at six months, eighty-nine per cent. at eight months—this plan of extracting the child when a severe hæmorrhage has occurred after the sixth month would appear both desirable and justifiable.

THE MICRO-BIOLOGY OF RHEUMATISM.

IN *La Médecine Moderne* of May 21, 1890, is a communication by DR. BORDAS upon some micro-biological researches on acute articular rheumatism,

which while they cannot be considered absolutely conclusive are nevertheless exceedingly interesting as an earnest of what further investigation in this line may bring forth. It is but a few years since malarial fever was a reproach to the practical physician in that he could not state the manner in which this disease was cured by quinine. Through the discovery of the malarial germ of Laveran and the additional knowledge that quinine exercises a germicidal effect upon this organism, this stain upon the fair name of rational medicine has been removed, and the contribution of Bordas is important as forming what may perhaps be a prelude to the removal of the other reproach to medicine, viz., the cause of rheumatism and the manner in which salicylic acid does good in this disease. This is not the place to detail all the experiments of the investigator whom we have named, and we can do no more than give his conclusions, which are as follows:

He asserts that the bacillus which he has isolated, when injected into the carotid artery of a rabbit, produces endocarditis with vegetations upon the valves.

That acute articular rheumatism with its complications may be considered as a disease produced by microbes analogous in their production, for example, to the micrococcus pyogenes.

This investigator is also certain that the germ which he has isolated is a specific one. The research was carried out under the directions of Professor Germain-Sée, and if further studies confirm the ones just quoted, another advance in the study of disease will have been made.

REVIEWS.

REPORT OF MEDICAL EDUCATION, MEDICAL COLLEGES, AND THE REGULATION OF THE PRACTICE OF MEDICINE IN THE UNITED STATES AND CANADA, 1765 to 1890. By JOHN H. RAUCH, Secretary of the Illinois State Board of Health. Springfield, Illinois, 1890.

WE are glad to notice in the columns of THE MEDICAL NEWS the appearance once more of the publication issued by the Illinois State Board of Health upon this most important subject. Elsewhere the writer of this review has alluded in terms of the highest praise to the work which Dr. Rauch and the rest of his Committee are constantly performing.

Although we are, as a nation, proud of the boast that one State can have but little influence upon the United States, we have in this report an evidence that by proper legislation one State can influence the educational centres not only of the United States but also of Canada.

The enormous amount of labor required in the compilation of the statistics given us by the distinguished statistician who edits these reports, can be conceived of by no one who does not thoroughly examine its contents. The State of Illinois puts into the hands of every regular practitioner of medicine the means by which he can stop the practice of any illegal practitioner at any time through the discovery of the standing of the school from which he claims to be a graduate, and puts every man, woman, and child under a debt of gratitude for its influence upon medical education on this continent.

CORRESPONDENCE.

LONDON.

The Recent Epidemic of Influenza. The Relation of Salicylic Acid to Uric Acid and Acute Rheumatism. The London Post-graduate Course.

To the Editor of THE MEDICAL NEWS,

SIR: The epidemic of influenza being now virtually at an end, it may not be uninteresting to glance briefly at some of the facts in connection with it. The main effects of the outbreak were felt during the first two weeks in January, but the disease was in full swing during the entire month as well as during the first week in February. It is quite impossible to obtain acurate statistics for the whole metropolis, but some idea of the number attacked may be gained by reference to the statistics of St. Bartholomew's Hospital; I must premise, however, that there is some reason for thinking that more cases were met with in this hospital than in others, possibly owing to its situation. During the first two weeks of January the number of medical patients was 3612 and 3397 respectively, and the weekly average for the whole month was 2682, the average of the preceding five years being 1530; it was estimated that about two patients out of three, or at least considerably more than one-half, were suffering from influenza. It was also estimated that during the three weeks of prevalence over 6000 cases were treated at this hospital. On the other hand, at the Hospital for Sick Children, Great Ormond Street, which is only about a mile distant, not half a dozen cases occurred amongst the in-patients, and only an inappreciable number amongst the out-patients.

In the General Post-office, where some 13,000 persons are employed, and where the average daily sick list is 250, on one day in January there were no less than 2000 absentees, and this would not necessarily represent every case of the disease, as those who suffered from the milder forms doubtless continued at work. It has been roughly estimated that in London alone no less than 400,000 persons were attacked, an estimate which certainly has not erred on the side of exaggeration.

During the first five weeks of the year the deaths in London exceeded the average number by over 2000, and 378 deaths were directly ascribed to influenza, respiratory diseases being credited with nearly the whole of the remaining excess. Of course in calculations of this kind no account is taken of the minor, but not necessarily trifling effects of influenza, and the number of those who have been left with permanently impaired health must be very considerable. After all, the death-rate in London has remained considerably below that of

the other principal cities of Europe, so we have not much to complain of.

Dr. Alexander Haig, who has already done much good work in regard to uric acid, has just read a paper before the Royal Medical and Chirurgical Society on the relative effects of salicin and salicylate of sodium in the excretion of uric acid and their value in acute rheumatism. He finds that salicylate of sodium has about thirteen times the excretive power of salicin, and that their action in disease appears to correspond roughly with their action on uric acid secretion. According to him, all methods of treatment that are of any value in acute rheumatism cause an increased excretion of uric acid, and salicin and the salicylates are useful in this disease in exact proportion to their power of producing elimination of this substance. He then proceeds to give reasons for thinking that acute rheumatism is due to uric acid, and he expresses his belief that the uric acid is driven out of the blood by high acidity and precipitated in the joints, and that such precipitation and non-destruction of the uric acid afford the true explanation of the effects of the inflammation and fever of rheumatism. He maintains that owing to the rise of temperature the acidity is greater and the precipitation of uric acid, in the joints is, therefore, more complete in rheumatism than in gout. Other causes that raise the acidity and therefore predispose to an attack of rheumatism are chilling and suppressed perspiration, ingestion of acids and acid-forming foods, and tonsillitis or other local inflammation. He says that high arterial tension at the end of an attack points to an excess of uric acid in the blood, and anything that raises the acidity at this time will cause a relapse.

The second London post-graduate course commenced recently, and like the last will consist of about seventy lectures and demonstrations at the leading special hospitals. To the list of the hospitals which were used in the last course there must be added Bethlehem Hospital, the best known lunatic asylum in London, and one of the Poor-law Infirmaries, where it has been arranged that Mr. Hutchinson will give a series of demonstrations which no doubt will constitute a most valuable addition to the course. I suppose these lectures have not become very widely known yet, for only twenty-nine men joined for the last course, a very small number considering the amount of instruction and material offered to the class.

The Charing Cross Hospital Medical School has been extensively enlarged and will be well equipped now in the way of laboratories and lecture theatres. It is not nine years since the school buildings were erected, and the necessity for such extensive alterations in so short a time speaks well for the prosperity of the school. Nearly all the metropolitan schools, however, in the last ten or twelve years have had to double their accommodations.

NEW YORK.

To the Editor of THE MEDICAL NEWS.

SIR: The rapid advances in the surgery of the brain which are now being made are but the natural outcome of the elaborate and painstaking experiments which have been made by Ferrier and others in endeavoring to penetrate the darkness and solve the mysteries of this wonderful region of the human anatomy. Dr. E. D. Fisher recently added his mite to the physiology of this subject, by presenting to the New York Academy of Medicine some of the results of a series of experiments which he had made upon animals to determine the functions of the cerebellum. He trephined several days prior to the removal of portions of the cerebellum, in order to eliminate errors which might arise from the irritation caused by the trephining itself. He found that superficial lesions did not cause any symptoms, and that when these lesions were sufficiently extensive to cause incoördination, the animals apparently tried to overcome these disordered movements. He exhibited a monkey which dragged the leg on the side corresponding to the lesion, and which held the arm most of the time in a semi-flexed position. The experiments seemed to prove that there was a peculiar cerebellar incoördination.

Dr. W. Gilman Thompson said that he had witnessed many of the experiments, and had sometimes observed extraordinary movements in animals, following simple trephining. One of the great stumbling-blocks in the study of cerebral localization is the way in which recovery takes place after serious injury to the brain; and this is well shown in the present series of experiments. Dr. Thompson said that three varieties of coördination are to be distinguished, viz.: 1. A lower form, controlled by the spinal cord; 2. A higher one, controlled by the cerebellum; and, 3. A still higher variety, due to education, and controlled by certain parts of the cerebral hemispheres, which have not yet been definitely located. When one of these three divisions is injured, it is possible for the other parts of either the brain or cord to be educated to do the work of the injured portion. This does not seem surprising, when we remember that children have to learn first the simple movements of co-ordination, and proceed gradually to the most complicated ones. Recovery after injury takes place in the same order, beginning with the simpler movements.

In a discussion on the "Complications of Laparotomy," at a meeting of the Clinical Society of the Post-graduate School, the question of the propriety of using drainage-tubes received a good deal of attention. Dr. A. Palmer Dudley was most emphatic in denouncing their use after laparotomy unless pus is found in the abdominal cavity. He thinks the dangers of the use of the drainage-tube are tenfold greater than those arising from an ordinary oozing of blood into the abdominal cavity, and that the tube is not necessary to show the occurrence of a secondary hæmorrhage, as this is more quickly indicated by the condition of the patient. Neither could Dr. Robert T. Morris see any necessity for the use of drainage-tubes, for Nature has provided the large intestine as an efficient drainage-tube, which runs directly through the middle of the "cess-pool." He said that the ordinary drainage-tube requires careful and skilled attention; but by the administration of a hydragogue cathartic, Nature's drainage-tube can be made to remove rapidly, by osmosis, the noxious material. Certain German experimenters have shown that large quantities of fermenting liquids may be absorbed by the great lymph-sac—the peritoneum—which are eliminated by the kidneys and intestinal glands. Dr. Charles C. Lee expressed the general opinion of those present when he said that drainage-tubes are oc-

casionally extremely useful, if not indispensable, but that the progress of the profession in laparotomy has shown that they are rarely necessary, and certainly did harm if indiscriminately or extensively used. Dr. J. R. Nilsen called attention to the difficulty sometimes experienced in finding the linea alba, owing to its deviating an inch or more from the median line; and he advised making a careful examination with reference to this point, prior to the operation. When dealing with intestinal adhesions, which do not yield to gentle manipulation, his rule is to enlarge the incision and to work by sight. This, he said, greatly simplifies the operation and yields better results.

A paper by Dr. C. L. Dana, entitled "A Study of Alcoholism in the Bellevue Cells," excited a general discussion among the alumni of Bellevue Hospital, which was also participated in by several neurologists and alienists. The paper stated that, annually, three thousand cases were confined in the "Bellevue cells," and that three-fourths of this number were males varying in age from twelve to seventy years. Fully one-half of these unfortunates are of Irish birth, and the preponderance of Irish parentage among the native-born is very great. These facts, he thinks, are especially serious in view of the well-known fecundity of the Irish race. The period when delirium develops is usually about twenty-four hours after admission, and is due to the withdrawal of the accustomed stimulant and to general starvation of the nervous tissues. It usually lasts only a day or two; but when it continues for two or three days, about five per cent. of the cases die of exhaustion. A glance at the annual number of deaths for the past four years shows that it has increased nearly seventy per cent., while the annual number of cases has only increased from three thousand to thirty-six hundred. The great mortality this year is partly due to the epidemic of influenza, and its complicating pneumonia. Appalling as these figures are, they could be much improved if we could prevent the sale of cheap liquor and abolish the "treating" and credit system. Cheap whiskey is freshly distilled, and contains much amylic alcohol, which is eight times more poisonous than ethylic alcohol.

Dr. Matthew D. Field then read a paper on "Inebriety." He believes that the present treatment of inebriates is radically wrong, and that dipsomania is a physical disease; hence the treatment, to be successful, should be in conformity with this view. He incidentally touched upon a social problem of much interest when he referred to the effect of poor ventilation in predisposing to drunkenness, and he cited, in support of this statement, the experience in England with a certain class of trades-people who were notoriously intemperate until their lodgings and workshops were put in a more healthy condition, when drunkenness was notably decreased. Imprisonment of the inebriate does not cure him, as is well shown in the case of a certain woman who was sent to the workhouse twenty-eight times in twenty-five months. In discussing this paper, Dr. J. West Roosevelt thought that the increased annual number of cases of alcoholism can be explained by the more than proportionate increase in the population. It is, he said, very difficult to regulate the quality of liquor sold, although there is much need for reform in this direction. He has seen many cases of alcoholism, especially the febrile ones, which simulated poisoning by the essential oils.

Mr. Clark Bell, President of the Medico-legal Society, in discussion, said that owing to the peculiar laws with reference to drunkenness in Boston, that city has the largest number of criminals in proportion to its population of any city in the world; and as a similar state of affairs exists in New York, it partially accounts for the large number of cases cited by Dr. Dana. At the present time, both the medical and the legal professions are pretty generally agreed that there is a disease called inebriety, which causes one to lose control of his conduct.

Dr. F. H. Ingram reported a collection of statistics which embraced information gathered from every nation. These statistics show, among other things, that apple brandy, or "Jersey lightning," is the most potent of all alcoholic beverages in producing mental derangement; next in order comes hard cider; then brandy and whiskey; then white wines; and, lastly, the red wines.

CURIOSITIES OF HOMŒOPATHIC PHARMACY.

To the Editor of THE MEDICAL NEWS,

SIR: Having recently obtained a copy of the circular and price-list issued by a dealer in high potencies residing in New York City, I desire to impart to the profession some of the information therein contained. This document is a printed pamphlet of thirty-two pages, and is entitled "Catalogue of Morbific Products, Nosodes, and other Remedies in High Potencies." These remedies are for sale by Samuel Swan, M.D., at No. 13 W. 38th Street, N. Y.

Glancing over the catalogue, we were struck, on page 16, by one article of the materia medica kept for sale, and called "Luna, or Moonlight." How in the world is this obtained, and what are its properties? Astronomers have long disputed whether the rays of the moon possessed any heating power, but why need they any longer be in doubt, when moonlight may be bought by the vial-full, and can be seen and tasted by ordinary mortals.

On page 20 we find three species of pediculi on the list of remedies to be dispensed, namely, the pediculis pubis, pediculis capitis, and pediculis corporis. These minute insects we only expect to find on uncleanly persons, and the idea of swallowing them, or a preparation made from them, no matter how dilute, is rather startling to the uninitiated. The pediculis corporis, by the way, has a note in brackets stating that this special lot came from Boston. The inquiry, then, arises in our minds, Why is this? Are the Boston pediculi more voracious, or of larger size than those of other cities? What is the cause of their superiority? Unfortunately, the vender of these delectable preparations does not condescend to inform us upon these points, so we are compelled to remain in ignorance.

On page 1 we find on the list the name "acarus scabies" translated "lice insect." As the acarus mentioned is the one found in the disease known in common parlance as the itch, and is not the pediculis, there seems to be a (H)itch in the Latin; but such trifles need never daunt the swallower of preparations like these.

There is on the first page one familiar remedy, viz.:

adeps anserina—goose-grease. How well do we remember the vile odor of this substance when applied externally to the neck in our youthful days. Never did we imagine we should see it prepared in "high potencies," and given in granules.

On page 15, "lachryma filia" are defined as "tears from a young girl in great grief and suffering." In ancient Rome small crystal or glass flasks have been found called lachrymalia, which are said to have contained the tears of mourners. Were these lachryma filia obtained from such sources, or are they the tears of some modern damsel; mourning, perhaps, like Miss Flora McFlimsey, because she had nothing to wear, or in utter desperation from the lack of a spring bonnet; or, it may be, crossed in hopeless love?

The explanation of "flavus irides," on page 11, is "yellow ray of the spectrum." Here is bottled sunshine with a vengeance! Photographers have long desired to fix the fleeting rays of the sun, and to make their pictures glow with the colors of nature, and here we have the rays prepared and fit for internal medication. Would that we knew the secret of this preparation! One thing is certain, if we *must* swallow globules it would be much pleasanter to think of swallowing bottled sunshine than a preparation of pediculis corporis, even though it came from Boston.

On page 6 we find "carbunculus on neck (Swan); very severe." We are not told whether the carbuncle was very severe upon the swan, or whether the pus obtained from it is very severe upon the unlucky patient who takes it—perhaps both statements may be true.

"Fel gryllus Americana" (page 11), or "Brazilian cricket," is said to be beneficial for "suppression of urine with or without pain," and this important fact is also stated, that "a boy who had chills and fever swallowed a live cricket, and never had a chill afterward."

On the first page several dainties are provided for lovers of preparations of the high potencies. One is "adenia," or "glands from a person suffering from Hodgkin's disease," a little further on is the "ailanthus bug," an insect found on the odorous though unfragrant ailanthus tree. On the same page "albuminuria" is defined as "renal albumin," or, in other words, the putrid and disgusting products of the decomposition of the human body, as found in diseased urine.

On page 2, "anthracin" is said to be "pus from a carbuncle." On page 4 is "burboin syphilitica," or "pus from syphilitic buboes." On page 5 are a number of preparations of "calcarea" from different parts of the body, as "calcarea renalis," or "stone of the kidney," and "calcarea from the lungs and bladder." On page 6 we have three preparations to choose from, made from different varieties of catarrh, namely: "catarrh of the intestines," "catarrh of the bladder," and "catarrh of the nose."

Page 7 gives us a little hope that we may not be called upon to swallow any more such vile compounds, for there we find "cerulia irides" defined as "blue ray of the spectrum," but, as if to dash our newly found hopes to the ground, immediately beneath is given a preparation made from the "chancre of syphilis."

Page 8 gives a remedy for constipation in newly born infants, viz., "colostrom, found in their intestines previous to and after birth." Page 9 gives preparations of two varieties of poisonous snakes, viz., crotalus horridus (rattlesnake) and crotalus cascavella. On the same page is "crusta lactea," commonly called "milk crust," and found on the heads of sickly or uncleanly babies. Further down, on the same page, are preparations of diabetes mellitus, and also of the serum found in cases of dropsy.

Pages 10 and 11 give us preparations entitled "electricitas, or electricity," and "galvanismus, or galvanism." It has been said of our countryman Franklin that he brought down lightning from heaven for the service of man, but our homœopathic brethren can do more, they can make it edible and drinkable for ordinary mortals.

But time fails me, and I can only enumerate a few of the choice morsels obtainable in the high potencies: "hippozinine," a preparation from glanders; "lyssin," from hydrophobic patients; "osteo-necrosis," from necrosed or dead bone; "pus from abscess of rectum," from "caries of heel," and from septic abscess.

Page 22 gives us "rubrum irides, or red ray of the spectrum," completing the list of rays of light used in the manufacture of these globules. On page 23 we find four varieties of cancer served up to us, viz., cancer of the breast, uterus, bowel, and face.

Page 25 seems to show that Dr. Brown-Séquard's so-called Elixir has been anticipated, for we there find two preparations: one "testiculo gallinæ," or "testicles of the fowl," and "testiculo muliebris sinistra," from the left ovary of a woman.

Many other preparations might be given, but I will conclude by giving an extract from the note after page 30. Dr. Swan says that the plan of sending grafts has been adopted, viz., "If a graft is put into a vial filled with unmedicated pellets, and corked, the whole mass will be medicated in half an hour." Further down, on the same page, he says: "When a vial of medicine is nearly emptied, fill it with unmedicated pellets, and you will not have to purchase the remedy a second time."

"Can the farce of humbug further go?"

ROBERT REYBURN, M.D.,
Professor of Physiology and Clinical Surgery in the Medical Department of Howard University.
WASHINGTON, D. C.

GYNECOLOGICAL ELECTRO-THERAPEUTICS.

To the Editor of THE MEDICAL NEWS,

SIR: In the issue of THE MEDICAL NEWS for May 10, 1890, I find an article on "Gynecological Electro-therapeutics," by Horatio R. Bigelow, M.D., in which he refers extensively to an article of my own, on "Electricity in Chronic Pelvic Inflammatory Diseases," which appeared in your issue of March 22, 1890. The vital points I made in my paper were that electricity never actually cured chronic pelvic troubles, and that the most it could do was to relieve the symptoms temporarily and leave the diseased tissue, which at some future time would again develop acute symptoms. My object in again burdening your readers with this subject is to call attention to how thoroughly Dr. Bigelow corroborates my statements as made on that and other occasions, although his paper is an apparent criticism of my position; or, at least was meant to be such. Dr. Bigelow

has now been in constant attendance at Apostoli's clinic for about one year, and in speaking he gives not only his own opinions, gained from his personal observation, but reflects the opinions of Apostoli—opinions based on an experience in gynecological electro-therapeutics second to none in the world. Dr. Bigelow says, "I have *never* seen a pyo- or a hydro-salpinx anatomically cured. There are many of these cases which should never be electrically handled. Dr. Apostoli, my master, has never claimed in his writings that he cured these cases anatomically." And again, "some conditions of salpingo-ovaritis may be *symptomatically* cured."

This is exactly what I have claimed, and nothing more.

Now, in spite of this personal experience, Dr. Bigelow, in speaking of those gentlemen who claim to cure these diseases *anatomically* with electricity, thinks that "the word of any professional brother who has carved out for himself recognized standing must be accepted without the shadow of a doubt." He further observes, "If Dr. Goelet says that he has dissipated these adhesions, I cannot conceive why we should not accept his statement, although clothed in poetic language. The science must go forward or backward, it cannot stand still, and improvements will be made upon Apostoli's plan by his disciples as experience and knowledge increase, so that you will have more extended results in America than here. . . . I have not seen a case of chronic adhesions absolutely cured anatomically, but I am quite ready to believe that it is possible." In this, as in many other articles lately written, those of us who do not believe that electricity will *cure* these diseases, are reproached for throwing discredit on the honesty of our opponents. This is not true, however, and is simply begging the whole question. We give all due credit to their honesty and know full well that they believe what they say about this remedy and the results of its use. There is room for a great difference of honest opinions on most medical subjects, and this is no exception to the rule. The difficulties of accurate diagnosis in pelvic inflammatory diseases are so great that we claim little in that direction which we do not grant to our opponents. It is here that we think these gentlemen are at fault and where they go astray, and this could easily be proven by numbers of individual cases were it necessary. Now, if Apostoli and Bigelow fail to obtain the cures claimed by their disciples and I also fail after repeated and prolonged trials, is it reasonable to suppose that I will accept without question the statement of other men when they say they have obtained these cures, especially when I go to some of these same men and ask to see a case cured by them, and when after several years of constant observation they fail to show me a single cure, although in the meantime they are constantly talking of the cures they have made? I repeat, are we not bound under these circumstances, in the interest of science, to refuse to accept their results unless accompanied with the most convincing proof? I can say, with Dr. Bigelow, "I have not seen a case of chronic adhesions absolutely cured anatomically," but there he and I must part company on this road, for in spite of all the claims made by others, I am thoroughly convinced that it is impossible to cure them with electricity.

J. M. BALDY, M.D.

330 SOUTH SEVENTEENTH ST., PHILADELPHIA.

SHORT-WEIGHT QUININE CAPSULES.

To the Editor of THE MEDICAL NEWS,

SIR: In your issue of May 3d there appeared a letter from Professor V. C. Vaughan, of Ann Arbor, on "Short-weight Quinine Capsules." In this letter a detailed description of our tin boxes of 100 filled capsules, labels, etc., is given, together with an analysis of contents of four boxes (of formula No. 106: Quinine sulphate 3 grs., capsicum ½ gr.), to which *his attention had been called*, showing shortages in the capsules. Dr. Vaughan's analyses indicate that boxes 1 and 2 contained no capsicum, a defect not noticeable in boxes 3 and 4. Our tins of 100 Elastic Filled Capsules are sealed with tinfoil before leaving our house, and we have direct knowledge that the first two boxes which were submitted to Dr. Vaughan were *not intact*. The Detroit jobber to whom these goods were sold finds it inconvenient to furnish us with the name of the purchaser, and Dr. Vaughan is disinclined to give any information, except such as relates directly to his analysis.

As the formula in question is not frequently called for it was fortunately a matter of no difficulty for us to trace the date of manufacture of this particular order, which was prepared during the rush of the grippe season by additional help specially employed for such work. As it happened, the identical employé who filled the goods in question was soon after detected in shortage work. Whether this shortage work was due to intentional carelessness is a question we reserve for discussion at a later date and in another place. But we do not reserve mention of the use which has been made of Professor Vaughan's letter. Hardly had it appeared in your columns before our Chicago agent apprised us of the fact that one of our competitors located in Detroit was distributing with liberal hand a circular containing an extract of the article above mentioned, and was using it against us. The fact bears its own comment. If they believe that this sort of tactics will do them any good they are welcome to the profit and the honor that are in it. Let them make the most of the above-outlined occurrence. We content ourselves with calling attention to their proceeding, and we give them fair warning that we shall hold them strictly accountable for any inference they may attempt to cast on our goods, outside of the capital they can make out of the aforesaid occurrence, which fortunately we are able to trace and account for.

We can state that our trade on filled capsules has been increasing most rapidly, especially so since we have recently placed our capsules directly before the medical profession through our representatives or by means of direct correspondence, and this has doubtlessly raised the ire of our competitors, who no doubt think that they alone should have the undivided attention of the profession. We make over 125 standard formulæ of filled capsules. Of these there are only seven which contain medicine in dry form. The rest, containing fluids, are filled by a machine invented by us and especially designed to secure as absolute exactness in filling as is possible. However, our professional friends require no assurance that our goods are all that is claimed for them and we are content to leave our friends to determine in the present criticism just where the shoe pinches.

Respectfully,

DETROIT, May 28, 1890. THE MERZ CAPSULE CO.

A DEFENCE.

To the Editor of THE MEDICAL NEWS,

SIR: Your representative has called our attention to Dr. Austin Flint's letter, published in the issue of your journal of May 3d, and, although our intention was to pay no attention whatever to such plausibly malicious attacks, based on private motives, we address you at the special urgence of a number of our friends in the medical profession, and trust you will kindly give space to our reply.

In referring to members of the alumni of Bellevue Hospital and other medical colleges, it should be clearly understood that each physician referred to by us as endorsing "Vin Mariani" has given us full authority to do so. Upward of 7000 letters bearing physicians' signatures can be seen any time at this office, having been purposely and kindly given us to aid in the further introduction of "Vin Mariani," it being well known that such advertisements are confined exclusively to those channels recognized and approved of by the severest code of ethics, and a method which we are justly proud to boast has, during thirty years, won for "Vin Mariani" the most thorough approbation and appreciation of the entire medical profession.

We are to infer from Dr. Austin Flint's letter that, owing to our recent publication, he intends to discontinue the use of "Vin Mariani;" this he is, of course, at perfect liberty to do; but we positively assert, both himself and his eminent father have for years ordered "Vin Mariani" for use in their own family, as well as very largely for their patients, and this we can and will attest by prescriptions and letters bearing the name, "Austin Flint, M.D.," which we hold subject to inspection. We doubt that any reputable practitioner would, from a personal motive, withhold from his patient a preparation which he has prescribed in the past, and which practical testing for years has proved to be a valuable therapeutic agent, and we may be permitted to state that no recognized medicinal preparation has received stronger endorsement at the hands of the medical profession than "Vin Mariani." Incidentally we call attention to an article published on the same date as was Dr. Flint's letter, in *The Journal of the American Medical Association*, by Dr. Charles E. Sajous, in which "Vin Mariani" receives the highest commendation (see page 645).

Respectfully yours,

MARIANI & CO.

NEWS ITEMS.

Myopia of Schools.—Dr. Kirchner, of Berlin, has investigated the causation of myopia as shown by the pupils at two of the largest gymnasia in the city. One of these schools is old, badly constructed, and poorly lighted. The other is a new building designed with special reference to good illumination. Dr. Kirchner found that, at the old school, short-sightedness increased progressively from the lowest class up to the highest, whereas in the new building it did not begin to increase until the middle classes were reached.

Medicine in Siam.—A new medical mission has been opened at Rathboree, Siam, the third city in importance in the kingdom. The former Prime Minister has presented a large brick station, well built and very conveniently located.

The Chair of History of Medicine.—Dr. A. B. Lyman has been elected to fill the newly created Chair of History of Medicine in the University School of Medicine at Baltimore.

Medical Education of Women in Austria.—A petition has recently been presented to the Austrian House of Deputies, asking for the admission of women to the philosophical and medical faculties of the universities of the empire. It is stated that the petition was signed by 4812 people, including many leading representatives of literature, art, and science.

Progress of Cremation.—The new cremation furnace of Paris at the cemetery of Père la Chaise, has been used 735 times in its first four months of operation. Of this number, 35 only were at the request of surviving relatives; by far the greater number were unclaimed bodies of those who had been drowned, and stillborn children.

The Senate of Hamburg has authorized the construction of a furnace, with columbarium, at a cost of $19,000. The funds will be collected by a local society which has been in existence for several years and working quietly in favor of cremation.

The cost of cremation appears to have undergone a marked reduction. The Paris correspondent of the *British Medical Journal* writes that at the new crematorium, above referred to, the expense for each firing is placed at three francs instead of thirty-five francs as in the case of the older establishment. Coke is the fuel employed at the new furnace.

Medical Missions.—The Edinburgh Medical Missionary Society will celebrate its jubilee anniversary in 1891 All of its orginal board of directors save one are dead. At home it controls the Livingstone Dispensary and Training Institution, caring for 10,000 patients yearly. Abroad, it has branch institutions or missions in India and Palestine, with more than sixty physicians and surgeons. In 1860 there were only 14 qualified medical men in the foreign field; now there are 280, of whom 37 are female physicians. In China there are 82 medical missionaries, a majority of whom are from the United States There are mission hospitals and dispensaries in several of the principal cities, and they get a considerable portion of their financial support from the better classes of the Chinese, who highly appreciate the work, or at least the medical side of it. The Hangchow Mission, in its last annual report, shows that it ministered to 9,000 patients with 24,000 treatments; the number of in-patients was 550.

Artificial Musk.—The *Journal of Pharmacy* of Alsace-Lorraine states that a very powerful musk has been made artificially by a distillation of toluol with the chlorides of aluminium and butyl. So far as the use of musk in perfumery is concerned, it is stated that the natural article will sooner or later be supplanted by the artificial. As to the medical employment of musk, at the present time it is very restricted, and, indeed, hardly exists. If the

natural musk shall become a cheaper and less adulterated commodity, it may again be used in medicine, especially in adynamic diphtheria, for which Dr. Jacobi has found it sometimes valuable.

Bayonne, New Jersey, Hospital.—A new hospital has been established at Bayonne, New Jersey, having a capacity of forty beds. It has been furnished with all the new and most approved appliances that can be made available in a small hospital.

Physiology at Vienna.—After the retirement of Professor Ernst von Brücke from the chair of physiology in the University of Vienna, which will take place at the end of the present scholastic year, there will be two professorships provided for this branch of instruction. According to the *British Medical Journal*, this new departure has been rendered necessary by the fact that the classes have become too large to be satisfactorily managed by one professor.

Medical Progress in the East.—A medical college has been established at Antananarivo, the capital of Madagascar, in connection with a Norwegian missionary enterprise. There have already been graduated a number of well-trained native physicians, whose lives will be spent in distant provinces which European missionaries have not yet been able to reach. A new hospital, at the college, will soon be added to the advantages of the Norwegian station. The Society of Friends, of England, has, at the same city, an extensive medical mission under the supervision of Drs. Fenn and Moss.

"Doctor Pascal."—It is stated that the last book of Emile Zola, entitled *Doctor Pascal*, was in part founded on the unfortunate family history of the celebrated physiologist, Claude Bernard, who said of himself that he was "the martyr of marriage."

The Delta Sign in Prescribing.—The *Western Druggist* notices a tendency on the part of certain physicians to employ the Greek delta as a symbol for the drachm in prescriptions.

Obituary. — Dr. Samuel Rush Haven, formerly of Chicago, died, in his sixty-fourth year, at Joliet, at the house of his brother, Professor Dwight Haven, on May 5th. He was eminent in surgery, and in the late war was staff surgeon to Generals Hancock and Grant. He was a native of Sheridan, N. Y., and was an alumnus of the Rush Medical College, from which he was graduated in 1850.

Corrigendum.

ASEPTIC MIDWIFERY.

In THE MEDICAL NEWS, May 24th, page 577, it was incorrectly reported that Dr. T. B. Greenley advocates antiseptic douches during and after labor. Dr. Greenley discountenances the use of vaginal douches in labor and during the puerperium.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JUNE 3 TO JUNE 9, 1890.

DIETZ, WILLIAM D., *Captain and Assistant Surgeon.*—Is granted leave of absence for one month.—Par. 4, *S. O. 131, A. G. O., Washington, D. C.*, June 5, 1890.

By direction of the Secretary of War, WILLIAM D. DIETZ, *Captain and Assistant Surgeon*, having completed at New York City the duties assigned him in Special Order No. 29, April 30, 1890, Division of the Pacific, will return to his station in that Division.—Par. 5, *S. O. 129, A. G. O., Washington, D. C.*, June 3, 1890.

By direction of the Acting Secretary of War, leave of absence for seven days, to take effect upon the final adjournment of the Army Medical Examining Board, is granted HENRY MCELDERRY, *Major and Surgeon*—Par. 7, *S. O. 127, A. G. O., Washington, D. C.*, May 31, 1890.

By direction of the Secretary of War, leave of absence for six months, on surgeon's certificate of disability, is granted PETER J. A. CLEARY, *Major and Surgeon.*—Par. 4, *S. O. 127, A. G. O., Washington, D. C.*, May 31, 1890.

With the approval of the Secretary of War, leave of absence for ten days is granted CHARLES WILLCOX, *First Lieutenant and Assistant Surgeon.*—Par. 16, *S. O. 126, A. G. O., Washington, D. C.*, May 29, 1890.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING JUNE 7, 1890.

KITE, I. W., *Passed Assistant Surgeon.*—Detached from Naval Hospital, Pensacola, and ordered to Hospital, New York.

CRAIG, THOMAS C., *Passed Assistant Surgeon.*—Detached from Naval Hospital, New York, and ordered to the U. S. S. "Vesuvius."

ANDERSON, FRANK, *Passed Assistant Surgeon.*—Granted leave of absence for the month of June.

OGDEN, F. N., *Assistant Surgeon.*—Ordered for examination preliminary to promotion.

WHITE, S. S., *Assistant Surgeon.*—Ordered for examination preliminary to promotion.

BEYER, HENRY G., *Passed Assistant Surgeon.*—Ordered to duty on the U. S. S. "Yantic."

SIMONS, MANLY H., *Surgeon.*—Detached from Widow's Island Hospital, and placed on waiting orders.

HAWKE, J. A., *Surgeon.*—Ordered to Widow's Island Hospital and attending officers of Navy and Marine Corps at Portsmouth, N. H.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FROM MAY 11 TO MAY 31, 1890.

PURVIANCE, GEORGE, *Surgeon.*—Detailed as Chairman of Board of Examiners, May 31, 1890.

LONG, W. H., *Surgeon.*—Granted leave of absence for three days, May 19, 1890.

GODFREY, JOHN, *Surgeon.*—Detailed as a member of Board of Examiners, May 31, 1890.

FAIRFAX, IRWIN, *Surgeon.*—Detailed as Recorder of Board of Examiners, May 31, 1890

CARTER, H. R., *Passed Assistant Surgeon.*—Ordered to examination for promotion, May 31, 1890.

BANKS, C. E., *Passed Assistant Surgeon.*—To proceed to Boston, Mass., on special duty, May 2, 1890.

PECKHAM, C. T., *Passed Assistant Surgeon.*—Granted leave of absence for eight days, May 14, 1890.

AMES, R. P. M., *Passed Assistant Surgeon.*—To proceed to Memphis, Tenn., for temporary duty, May 14, 1890. To proceed to Gulf Quarantine Station for temporary duty, May 31, 1890.

PERRY, T. B., *Assistant Surgeon.*—Ordered to examination for promotion, May 31, 1890.

CONDICT, A. W., *Assistant Surgeon.*—Granted leave of absence for twenty-two days, May 24, 1890.

ORIGINAL LECTURES.

ON PRIMARY PROGRESSIVE MYOPATHY.

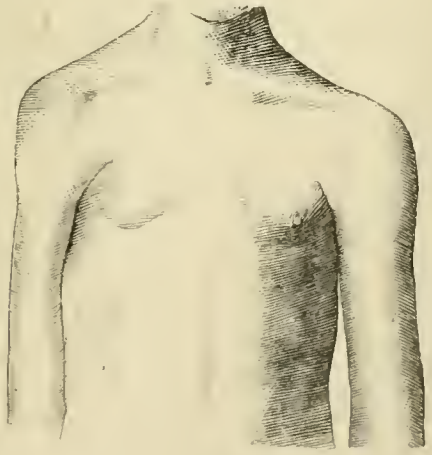
A Clinical Lecture
delivered at the New York Polyclinic, April 29, 1890.

BY B. SACHS, M.D.,

PROFESSOR OF MENTAL AND NERVOUS DISEASES IN THE NEW YORK POLYCLINIC.

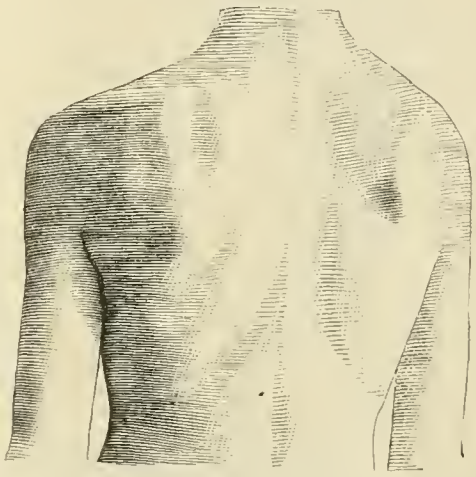
GENTLEMEN: It is a rather rare experience to find a single case that has an important bearing upon some medical theory, or that can be said to decide some mooted point. Such a case I present to you to-day. The patient before you is a youth aged twenty years. His history is entirely negative, except that at the age of seven or eight years he had a tooth extracted, and since that time has noticed a certain peculiarity about his face. He was not able to whistle as well as other boys, and, as long as he can remember, his face appeared twisted to one side, at least while speaking. It was not until one year ago that he was aware of any further trouble. At that time he fell upon his shoulder, and since then has noticed a weakness of both upper extremities. He was employed by a surgical instrument-maker and had to lift heavy boxes, but this he is no longer able to do. The extraction of the tooth and the fall upon the shoulder are landmarks in the boy's history; they served to call attention to his trouble, but surely they do not stand to the latter in the relation of cause to effect.

FIG. 1.



The most superficial inspection of the patient shows us that some of his muscles appear unusually small, others unusually massive; there is atrophy of some muscles and hypertrophy, or apparent hypertrophy, of others. Proceeding from below upward, you will please note that the anterior surfaces of the legs are much flattened, the calves, however, are unusually large and firm to the touch, the left being larger than the right; the patient is very positive *that they are smaller now than they were a few years ago.* It is fair, therefore, to say that the calves of this patient are in a condition of pseudo-hypertrophy. The thigh muscles are a little below the normal volume, and the right is smaller than the left. The gluteal muscles are well preserved. The muscles of the abdomen and lower portion of the back present no abnormalities, and the greatest changes are evidently in the chest and shoulder muscles (see Figs. 1 and 2).

FIG. 2.



I ask you to note the deviation of both scapulæ from the median line, the right scapula being rotated upward and inward, the left chiefly outward and downward; the hand can be easily passed between the scapula and the wall of the thorax. If I ask the patient to raise his right arm, you will observe that he can bring the arm to the horizontal position easily enough, but that he cannot bring it into the vertical position; showing, therefore, good action on the part of the deltoid, but deficient action on the part of the serratus.[1] The left arm he can raise a little better than the right, but not altogether freely. If he is put on the floor, you will notice that he can rise with great ease. I ask him, furthermore, to whistle—he cannot do it; I ask him to keep his eyelids tightly pinched, you see I can open them without any difficulty.

The muscular abnormalities are so numerous that it will be well for us to examine them *seriatim* and to note which muscles are wasted, which hypertrophied, and which have remained normal.

[1] The photographs do not bring out the winged appearance distinctly.

Wasted. — Both pectorals, major and minor; both serrati, right more than left; both latissimi dorsi, left more than right; levator anguli scapulæ, right more than left; rhomboids, left more than right; both trapezii (middle and lower third), left more than right; both biceps muscles and both brachiales antici; both triceps, right more than left; supinator longus, right more than left; anterior thigh and leg muscles, left more than right; posterior thigh muscles (thin); orbicularis palpebrarum of each side, and the orbicularis oris.

Normal.—Back muscles, forearm and hand muscles, gluteal muscles, and small muscles of feet.

Hypertrophied.—Deltoids, infra-spinati, supra-spinati, and calf muscles, but the right calf is beginning to waste.

After this detailed examination it remains for me to add that there are no fibrillary contractions in any of the affected muscles. This slight quivering, which we observe for a few seconds, is simply due to exposure of the bared skin. Another fact of some diagnostic importance we gain by an examination with galvanic and faradic currents. The result of this electrical examination is, that all muscles, including those wasted and those hypertrophied, respond to both currents in proportion to the quantity of normal contractile fibres that each muscle retains. In other words, although there may be a feeble response, there is no reaction of degeneration of any muscle. Lastly, let us note that the knee-jerks are present, that there is no ataxia, no disturbance of sensation, and that there is not a single symptom pointing to an involvement of the central nervous system.

The absence of the reaction of degeneration and of the fibrillary contractions, particularly of the former, is the point which I wish to impress upon you. By these negative symptoms and by the occurrence of distinct pseudo-hypertrophies we can distinguish this case before us from cases of progressive muscular atrophy of spinal origin. But if we are convinced that this is a purely muscular trouble, a primary myopathy, the question arises, To which one of the many subdivisions shall we relegate the case? Reviewing the symptoms, there would be some reason to class it among the pseudo-hypertrophies; from the appearance of the shoulder girdle and the thinness of the upper arm we might rank it with Erb's juvenile form, and if we take the face into consideration, we must classify it with the Landouzy-Déjérine type of progressive muscular atrophy.

We cannot call it a case of pseudo-hypertrophy pure and simple, for, although the shoulder muscles are sometimes involved in such cases, it is very exceptional to have both shoulder and face muscles affected. Westphal reported one case of pseudo-hypertrophy in which the face muscles were affected, but there was no involvement of shoulder muscles. From Erb's form it is distinguished by the involvement of the face muscles; although, as I pointed out in an article on muscular dystrophies published in the *New York Medical Journal*, December, 1888, it is possible that the face is more frequently involved than Erb was willing to believe. From the ordinary cases of the Landouzy-Déjérine type this case is distinguished by the additional involvement of the calves. You will not do the boy the injustice to suppose that he is affected with three different diseases. The symptoms in his case simply prove the point I raised in the paper referred to above, that the mere localization of atrophies and hypertrophies does not constitute a sufficient distinction between the various forms of progressive muscular troubles. At that time I had already endeavored to simplify matters by dividing the primary myopathies into cases of Erb's juvenile form and cases of pseudo-hypertrophy. This patient, however, convinces me that even these two forms are closely related, and, as you see, occur in one and the same individual. Instead of making a diagnosis of three different forms of progressive muscular atrophy, let us say that this young man is afflicted with a progressive primary myopathy involving the legs, the shoulder muscles, and the face.

CASE II.—This case is of special interest when considered in connection with the preceding one. We elicit from the father, who has brought the patient to the clinic, the following history: The boy is eight years of age. There have been eight children in the family, four of whom are dead, four living. None of the other children were affected like this boy. Our little patient did not begin to walk until three years of age, and he has never been able to walk or run as well as other children. As he stands before you, the boy keeps his mouth open and there is a stupid grin on the face, which is in accord with the somewhat demented state of his mind. He drools, as many of these children do. The patient walks in a waddling way, carefully and with a broad base to avoid falling. He is unsteady on his legs.

You will notice, on superficial inspection, the winged appearance of his scapulæ, the case being in this respect similar to the preceding. This patient can, however, raise both his arms with considerable ease. We note also a marked lordosis of the spinal column, due to the wasting of the long and deep muscles of the back. If I attempt to lift up this boy by the arms, you will observe that I cannot get a firm hold, that there is no resistance on the part of the shoulder-joint, and that I can lift him only by grasping the walls of the thorax. Note, however, that there is no hypertrophy of any of the muscles about the shoulder-joint. The muscles in the lower part of this child's body are extremely well developed—the glutei are large, the thighs are fully of normal volume, and the calves are large and unusually hard to the touch. There is no evidence of atrophy below the waist.

If I place the boy upon the floor and ask him to rise, he cannot do it. If we give him a little assistance, he can get into the erect position by climbing up upon himself. The knee-jerk is absent on both sides; there are no fibrillary twitchings, either in the hypertrophied muscles of the lower extremities, or in the atrophied muscles of the upper extremities. The atrophy of the upper extremities is chiefly confined to the shoulders and arms, while the muscles of the palms and forearms are fairly well developed. The most marked atrophy is in the serratus anticus, and, in contrast to what we found in the other case, in the supra- and infra-spinati. The deltoids are smaller than usual, the rhomboids are considerably atrophied, while the pectorals are not markedly so. The electrical tests show that the hypertrophied and atrophied muscles respond as did those of the preceding case—that is, in proportion to the quantity of normal fibres. If you had seen the first case at the age of this little boy, the difference between the two would, possibly,

not have been very great. No one would deny that this second case is a typical pseudo-hypertrophy, yet the hypertrophied condition of a few muscles in the first case constitutes the only real distinction between the two.

I do not intend to speak to-day of the future course or of the treatment of this disease. I feel confident that you will receive the same impression which I have formed, that these two cases bear a strong resemblance to one another, and that they are both types of a widespread nutritive disturbance of the entire muscular system.

ORIGINAL ARTICLES.

THE VALUE OF THE LEITER INCANDESCENT-LAMP URETHROSCOPE IN THE DIAGNOSIS AND TREATMENT OF CHRONIC URETHRAL DISCHARGES.[1]

By JOHN B. DEAVER, M.D.,

DEMONSTRATOR OF ANATOMY AND LECTURER UPON SURGICAL ANATOMY IN THE UNIVERSITY OF PENNSYLVANIA; ATTENDING SURGEON TO THE PHILADELPHIA, GERMAN, ST. MARY'S AND ST. AGNES'S HOSPITALS.

Having used the Leiter incandescent-lamp urethroscope for some time with most gratifying results, both in the diagnosis and the treatment of chronic urethral discharges, I have felt that it would be of interest to present my views upon the advantages offered by this instrument, at the same time illustrating my remarks by the citation of a few of the many cases I have recorded in my case-book.

The incandescent-lamp urethroscope made by Leiter, of Vienna, consists of three pieces: the handle, the lantern, and the urethral canulæ or tubes. The handle is made of vulcanized rubber and has upon its upper end a small incandescent lamp, which is connected with the two binding-screws projecting from its lower end.

The light steel spring on the side is the key by which the current is connected and broken. The handle fits into the bottom of the lantern.

The lantern is a gutter-shaped box, roofless, having at one end, which I will call the ocular end, an obliquely placed concave mirror for the purpose of reflecting the light of the lamp along the urethral canula or tube, also a movable lens intended for either long- or short-sighted observers. At the other end is a nozzle for fitting on the tubes. In addition to this are also noticed small perforations in the floor of the lantern immediately around the lamp, which are intended to carry off the heat. The urethral tubes are of different sizes, intended, of course, to be used in different sized urethræ. The larger the tube used the more satisfactory will be the examination, and, if necessary, I do not hesitate to enlarge the meatus, which in most cases we find contracted, and this simple division will, in some instances, relieve the patient of the trouble which we are trying to learn the nature of by the urethroscopic examination. The nearer the size of the tube approaches the normal calibre of the urethra, the less likely are we to overlook a fold which may be the seat of a small patch of disease. The mirror is to be so adjusted as to reflect the light along the tube.

Fig. 1.

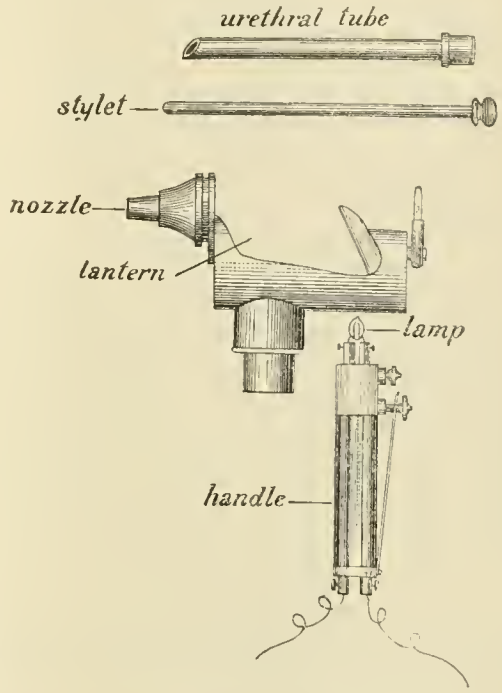


Fig. 2.

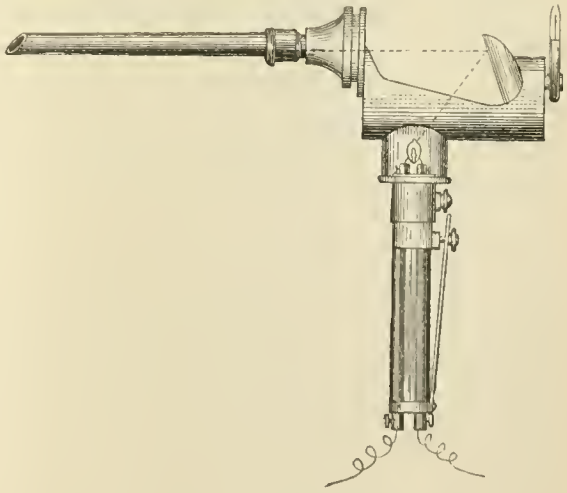


Urethroscope ready for use.

The construction of this instrument is so simple that it very seldom gets out of order. The most delicate part is the lamp, which after being used some time requires changing, as it is apt to become

[1] Read before the American Medical Association, Section of Surgery, May 21, 1890.

blackened. Changing is done by simply removing the handle and loosening the two small screws holding the lamp in place, when the lamp is lifted out and replaced by another, care being taken to secure it by tightening the screws. The handle is then replaced and fixed. In adjusting the lamp care must be taken to have it at a proper level, otherwise there will be insufficient illumination. To avoid all annoyance it is best, when inserting the handle into the lantern, to light the lamp and test the amount of illumination by placing the end of the urethral tube, adjusted on the nozzle, against a dark surface, when by elevating or depressing the handle the proper level can be obtained.

The two forms of batteries used by me in lighting the urethroscope, are the Julian storage system and the Grenet or plunge battery.

The Grenet or plunge battery, which I prefer, is made by Mr. Flemming, of Philadelphia, and consists of a box containing two equal compartments, the first of which is occupied by a series of rubber cells, one-half filled with the following solution: potassium bichromate, 6 ounces; sulphuric acid, 5 fluidounces; water, 3 pints. This solution must be removed every two or four weeks, according to usage. The second compartment contains one large cell, the object of which is to catch the drip from the plates after their removal from the bichromate bath, and also to protect them.

These two compartments are covered by a bed, the under surface of which is divided into two equal parts, one half being covered by a sheet of rubber, to close the cells when not in use, and the other half occupied by a number of sets of plates. Each set is composed of two carbon and one zinc plate, which are fastened to the bed in the usual manner, and so connected as to have independent action, the number of cells being thrown into circuit as required. After using the battery and wishing to discontinue the current it is merely necessary to lift out the plates, change sides, and deposit them in the one large compartment.

Upon the upper surface of the bed are a number of binding-posts corresponding to the number of cells employed, and by attaching the cords in a proper manner the number of cells desired can be brought into circuit. On this surface there is also a rheostat, consisting of a rubber plate wrapped with silver wire, connected with the cells and having a swinging arm which can be moved to any part of the plate; the object of the rheostat I will speak of later.

The other form of battery used by me is made by Waite & Bartlett, of New York, and consists of a carrier or box, containing four large storage-cells, each of which is composed of a rubber cup, a series of carbon and lead plates not in contact with each other, and contains a dilute solution of sulphuric acid which must be replenished from time to time. The materials used to connect these cells are narrow plates of lead, which are not acted upon by the sulphuric acid solution. The cells each measure two volts, and on increasing the voltage it is necessary to use a rheostat for reasons mentioned below.

There are two objections to the general use of the storage system. First, it must be charged from a dynamo, and second its weight (from 90 to 100 pounds) renders it inconvenient to carry.

The objects of using a rheostat are to govern the current, to prevent burning out of the lamp, and to measure the exact resistance of the lamp. It is a well-known fact that the carbons vary greatly in different lamps. In some the resistance is high, and such only burn when the rheostat is at its minimum; in others the resistance is so low that the lamps will not burn with a white light unless when the rheostat is at its maximum.

Manner of Using the Instrument.—In using the instrument the position of the patient which I have found most satisfactory is the recumbent one, on a table or couch of considerable height with the knees bent over the edges and slightly separated. The largest tube which the meatus will admit is now introduced, and passed gently through the urethra to the bulbo-membranous junction; unless obstruction is met with, when the stylet is withdrawn, the urethroscope adjusted, and the obstructing point examined. Great care is to be exercised in passing the tube, as it may induce bleeding, thus obstructing the field of vision. Where we are dealing with a much inflamed urethra, we will necessarily be annoyed more or less by a few drops of blood, and when this occurs it can be gently removed by a pledget of cotton carried down the tube by the applicator. In case the pendulous urethra is found normal I carry the tube into the membranous urethra by depressing the proximal end, and in this way examine the deep urethra.

Normal Appearance of the Urethra.—When at rest the walls of the urethra are closely approximated and the lumen varies in shape at different parts of the canal.

Commencing at the bulb and extending to within an inch of the meatus, the lumen is transversely slightly oval; in the remaining portion it is either vertical or triangular, and at the meatus vertical. The color of the mucous membranes varies from a pale grayish or pale bluish-pink to a full, bright pink; generally it is very similar to the buccal and labial mucous membrane in the same individual. The brilliancy resembles that of the mouth. On slowly withdrawing the urethroscopic tube the walls of the urethra will be seen to contract behind it. One of the most important characteristics of the

healthiness of the spongy urethra is the evenness with which its walls contract behind the retiring tube, or expand when it is advanced. A limited thickening in a small area will cause them to approximate irregularly. A scanty secretion of pus will destroy the lustre of the mucous membrane.

The lumen of the membranous urethra at the site of the anterior layer of the triangular ligament is triangular, which is due to the walls being less elastic than in the spongy portion; elsewhere it is oval. Owing to the presence of the urethral crest (veru montanum) the lumen of the prostatic urethra is crescent-shaped.

All chronic discharges of the male urethra have been from time immemorial, and still are, known by the name "gleet." The opinions advanced as to the pathological conditions present in gleet in the absence of a well-marked stricture have been various, and not until recently has the proper aspect been given to these cases. The proper understanding of these conditions is solely due to the use of the urethroscope, which has been so perfected as to make the examination of the urethra, particularly the pendulous, membranous, and terminal portion of the prostatic, as satisfactory, and in every sense as reliable as is the examination of the eye-ground with the ophthalmoscope.

I believe, as does Professor Otis, that in the great majority of cases of gleet, one, and in some instances more than one stricture is present, which when situated in the pendulous urethra, the usual site, can be most satisfactorily demonstrated by the urethra-meter, and that the removal of the stricture by dilating internal urethrotomy will cure the greater number of such cases. I also believe that the minority of cases are not the result of stricture, and can be correctly diagnosed, and consequently successfully treated, by the use of the urethroscope. It has been my experience to see a few cases, where, after a complete dilating internal urethrotomy, the discharge continued, though not to as marked a degree as before the operation, and where cure has promptly followed a few applications made to the affected portion of the urethra through the urethroscopic tube; also in cases where internal urethrotomy is practised I am able to hasten the cure by local applications.

What are the varieties of gleet (meaning any chronic urethral discharge) met with and clearly demonstrated by those who practise urethroscopy?

In my experience with the use of this instrument I have been able to demonstrate the following varieties of chronic urethritis:

1st. Simple chronic urethritis consisting of three different forms; one where the surface of the urethra is uniformly livid and moist; a second where, in addition to the above, are circumscribed areas involving the deeper portion of the urethra (the submucosa), resulting in the formation of nodular masses, slight, yet easily demonstrated by the absence of the normal elasticity of the urethra; and a third where there are circumscribed areas presenting a granular surface, covered, in many instances, with adherent pus and readily bleeding at the slightest touch, which is most probably that variety of urethritis described by some authors as granular.

2d. Follicular urethritis, where the inflammatory process is confined to the simple follicles, or the lacuna magna, and in some cases to the ducts of Cowper's glands.

3d. Ulcerative urethritis, never present except when associated with stricture, the treatment of which calls for division of the stricture (dilating internal urethrotomy), and local applications to the ulcer or ulcers made through the urethroscopic tube.

It is not uncommon to meet with two or more of the above conditions in the same case.

In the absence of the urethroscope, to ascertain the exact pathological condition which is keeping up the discharge is, in a large number of these cases at least, impossible. I have made the statement that, in my judgment, by far the greater number of such cases are the result of stricture; but, even so, a urethroscopic examination properly made tells us the actual condition of the urethra, both behind and at the strictured portion. The cases which I will now cite demonstrate the advantage of the instrument in the way of treatment.

CASE I.—J. D., aged thirty-eight years, was admitted to the surgical wards of the Philadelphia Hospital, in February, 1890, with a purulent discharge from the urethra, and pain upon micturition. History of gonorrhœa for four years, followed by stricture. Was operated on in the winter of 1889, at Bellevue Hospital, by Dr. Keyes. Urethroscopic examination revealed a small ulcer, one-eighth of an inch in diameter, on the floor of the pendulous urethra immediately in advance of the bulbo-membranous junction. A solution of silver nitrate, 10 grains to the ounce, was applied through the urethroscopic tube by means of the applicator. Two more applications, at intervals of three days, were made, when the ulcer was entirely healed, resulting in the relief of all symptoms. The patient was kept under observation for one month, when he was discharged cured. This ulcer was evidently the result of the stricture, but, unlike it, was not cured by the internal urethrotomy, which, I believe, would often be found to be the case were a careful urethroscopic examination made in many of those cases where the discharge is still present.

CASE II.—C. D.; private patient; came under my care some months since, with a history of gleet of two years' standing. During this time, he says, he had several attacks of gonorrhœa immediately following connection; these were evidently not attacks of true gonorrhœa, but simply aggravations of the existing urethritis, the result of the venereal

act. Examination of the deep urethra with the *bougie-à-boule* and of the pendulous urethra with the urethra-meter revealed the absence of stricture. This examination was followed by some bleeding. Urethroscopic examination revealed chronic urethritis, with three distinct granular points on the floor of the pendulous urethra, 2½ inches anterior to the bulbo-membranous junction. The granular patch nearest the meatus bled freely when touched.

Four applications of a 20-grain solution of silver nitrate were made at intervals of five days. In addition to the application of silver solution, the patient used the following injection four times daily: sulphocarbolate of zinc, 12 grains; sulphate of morphine, 4 grains; distilled water, 4 ounces. At the end of three weeks, all symptoms having subsided, treatment was suspended. The patient reported two weeks later, when a urethroscopic examination showed the urethra to be normal.

Case III.—W. H.: private patient; came to me suffering from a chronic urethral discharge of four years' standing, as a result of a very severe attack of gonorrhœa. Three years ago he was examined by a genito-urinary specialist, who found a stricture of large calibre in the pendulous urethra. This specialist cut the stricture by dilating internal urethrotomy, since which time the patient has been passing, at stated intervals, a No. 36 (French scale) bougie. During the past three years, the patient states, he has had several attacks of gonorrhœa of a mild type, but these were evidently attacks of so-called bastard gonorrhœa. Examination for stricture showed the urethra to be normal throughout. Urethroscopic examination of pendulous urethra was negative, except at the point which had been the seat of the stricture; here there was an absence of the normal elasticity, particularly well marked on the floor. Examination of the membranous urethra showed the mucous membrane of the anterior part of the floor to be dark-red and presenting a distinctly granular area, bleeding upon the slightest touch. In the light of this examination I made instillations, of 5 minims each, of a 20-grain solution of silver nitrate, six in all, into the deep urethra with the Ultzman drop-catheter, at intervals of three days. This treatment not proving satisfactory, I brought into the field of vision the granular area, and made two applications through the urethroscopic tube, this sufficing to accomplish the desired end. Some weeks since the patient wrote me that he was well.

Case IV.—G. G.; private patient; contracted his first attack of gonorrhœa in 1883. It ran through the three stages, and had all the characteristic symptoms of genuine acute urethritis. The treatment consisted of balsam of copaiba internally and various injections; it lasted four months. In 1884 he contracted a second attack, which did not differ from the first, excepting that it lasted six months.

In 1886 he contracted a third attack, which was by no means as pronounced as either of the previous. He had merely a discharge which differed from that of the other attacks in being thinner and whiter. The treatment was internal only, and consisted of paste of the balsam of copaiba and of cubebs, for two weeks.

He did not have connection nor did he drink any spirituous liquors for one month after the discharge stopped; when having transgressed from the path of virtue, upon the day following he had a return of the discharge. There was neither pain nor discomfort other than that occasioned by the presence of the discharge. He was again treated by balsam of copaiba internally and by injections, but not improving as rapidly as his medical attendant thought he should, the systematic passage of steel bougies in connection with the above treatment was begun. The medication was continued until the patient's stomach would no longer tolerate the balsam, when it was omitted, the bougieing and injections being persisted in. Three months from the institution of the treatment, the patient remaining abstemious, there was still enough discharge to make him despair as well as seek other advice.

In July 1888, I was consulted, and examination then showed a slight gleety discharge. Calibre of urethra 36 millimetres. Stricture 3½ inches within the meatus, calibre 34 millimetres. At this time, not having a urethroscope with which to make an examination of the urethra, I believed the discharge was caused by the stricture of large calibre present. I advised the passage of solid bougies and injection *brou* (French formula), hoping in this way to restore the normal condition of the urethra. This treatment was used faithfully for five months. In December there being no longer any discharge I stopped passing bougies and discontinued the injection, which had been changed from injection *brou*, several different formulæ having been used. I advised that a No. 35 solid bougie be procured and passed once a week for some time.

In August, 1889, I was again consulted for an epididymitis of left testicle, following the passage of the bougie. This attack of epididymitis confined the patient to house for one week, when the discharge again returned. As soon as the epididymitis had cleared up I examined the urethra with urethrameter, finding it trespassed upon to a little less than one millimetre at site of original stricture. Examination of urine showed presence of a few pus corpuscles and some shreds of mucus. Examination of prostate through rectum was negative. Believing the cause of the trouble to be chronic inflammation of the deep urethra, I used instillations of solution of silver nitrate, varying in strength from 10 to 20 grains to the ounce, using the Gross instrument.

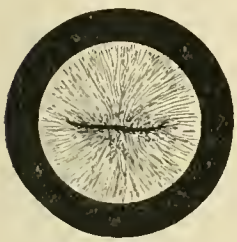
In a very short time the discharge disappeared, only to reappear after taking a glass or two of beer. In the fall of 1889, a urethroscopic examination showed the cause of the trouble to be chronic urethritis with granular areas in the membranous urethra. Treatment like that I have detailed proved in a short time entirely satisfactory.

The citation of these four cases, I think, is sufficient to support what I have intended to convey by the title of this paper.

In addition to the value of this instrument in the diagnosis and treatment of chronic urethral discharges, I desire to call attention to what, by its

use, I believe I have demonstrated to be a cause of failure in obtaining cure in a certain number of cases of stricture operated upon by divulsion, and which I think is an argument in favor of dilating internal urethrotomy (the operation I strongly advocate where it is feasible), as the cause of failure cannot result from the cutting operation, if properly done. I refer to tabs or teats of mucous membrane which have been separated at the time of the divulsion; and by bougieing, the usual after-treatment instituted in these cases, the union of these tabs to the surface from which they were torn has been prevented. In two cases coming under my care recently, I have found the following conditions as here shown in the diagrams.

FIG. 3.

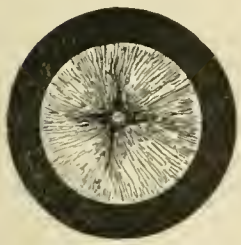


Normal ureter.

FIG. 4.

Teat-like prominence of urethral mucous membrane.

FIG. 5.



Same as Fig. 4. Point of prominence showing in the centre.

FIG. 6.

Multiple projections of mucous membrane into the urethra.

FIG. 7.

Multiple small projections into the urethra. Same as Fig. 6; tube partly withdrawn.

This condition, in my judgment, granting that all of the strictured area has been removed, is quite sufficient to keep up a discharge.

The routine treatment of cases of chronic urethral discharge is by injections, soluble bougies, the systematic passage of solid bougies, and internally by the administration of stimulating blennorrhagics, until the patient's stomach will no longer tolerate them, and with, in many cases, little or no effect. It is evident to all that this form of treatment will no doubt modify the condition, and will cure a few cases. The advantage offered by the method advocated in this paper is, that we are with certainty able to deal with the diseased point or points, it being necessary only in a very few to trespass upon the prostatic urethra proper, which is always done in the ordinary routine practice of introducing the bougie into the bladder, thereby exposing the prostate gland to injury, as well as endangering the patient to an attack of epididymitis.

ON THE MANAGEMENT OF OBSTINATE DROPSIES.[1]

BY JAMES TYSON, M.D.,
PROFESSOR OF CLINICAL MEDICINE IN THE UNIVERSITY OF PENNSYLVANIA.

A SUCCESS greatly beyond what I expected in the management of certain cases of obstinate dropsy, mainly instances of incurable kidney disease, but even better calculated to succeed in cardiac disease with renal sufficiency relatively maintained, has led me to wish to announce the method pursued, although it involves the use of no drugs that are new or other measures that are novel. My paper will be illustrated by three cases; indeed, may be said to consist of these with comments. All three may be said to have been water-logged in the highest degree, and there was large abdominal dropsy requiring tapping from one to five times. All had been treated with the usual diuretics and purgatives to no purpose; indeed, the symptoms kept on increasing:

The first patient was a man, aged forty years, who had been, for several years, superintendent of an Indian school in Arizona. Until June 16, 1889, he regarded himself in good health. About this time he took a long tiresome wagon journey with General Armstrong, and on his return noticed some swelling in his feet. This rapidly increased until the anasarca became general despite all treatment, and he came East. I first saw him August 15th, with Dr. G. C. Laws, of Paulsboro, N. J. There was general anasarca and large abdominal dropsy, and I at once drew off a gallon of water from the peritoneal sac. Examination of the urine revealed much albumin, numerous dark, granular casts, and compound granular cells. There was evident chronic parenchymatous nephritis. He was sent to his home in a neighboring town, digitalis being ordered in full doses. He bore the journey of thirteen miles well. He was put to bed between blankets, which produced copious sweating. There was, however, no improvement, and in a few days the abdomen had refilled. Desiring to make use of some treat-

[1] Read before the Medical Society of the State of Pennsylvania at its meeting in Pittsburg, June, 1890.

ment totally different from what he had pursued, I then ordered him to be placed upon a pure skimmed-milk diet, directing that he should have two ounces every two hours throughout the day, from 7 A. M. to 9 P. M. All drugs were discontinued, but he was permitted to have some whiskey, if needed, as he felt very weak. This was on the second day of September, and I did not hear from him until October 25th, when Dr. Laws reported that Mr. G. had greatly improved under the skimmed-milk diet. More recently, however, he thought that improvement had ceased, and that liquid was again accumulating in the abdominal cavity as well as in the subcutaneous connective tissue generally. He was passing, however, three pints of urine in twenty-four hours, and the albumin had greatly diminished. I then added to the milk diet spartein in doses of one-fourth of a grain three times a day. On the 2d of November I was much surprised to see Mr. G. walking into my office, having come from his home that morning in that train. He was then without dropsy, but reported that his legs became swollen toward evening, and that he was up all day. Under the use of spartein and milk the urine had increased to sixty-five and seventy-five ounces in the twenty-four hours. Careful examination failed to discover casts, although the urine still contained one-seventh its bulk of albumin. He was directed to continue the spartein in one-third grain doses as required to keep up the flow of urine; also to continue the milk a while longer until the dropsy had completely disappeared, after which he was to be permitted a diet a little more liberal.

Exactly one month later he called again, looking and feeling well. He was passing from two to three quarts of urine daily, and living largely on milk, but he occasionally took a baked potato and a boiled onion. He had tried oatmeal, and was under the impression that it increased the amount of albumin in the urine. He had been taking one-third of a grain of spartein three times a day with occasional interruptions. He was then on his way to Florida, where he was to spend the remainder of the winter.

The patient called again on the 15th of April apparently in perfect health, having just returned from Florida. He had taken no medicine, but had kept pretty closely to skimmed milk, having, however, occasionally taken a baked potato and a soft-boiled egg. The urine still contained a small quantity of albumin, but no casts were found.

The next case was a more intractable one, and ultimately proved fatal, although his life was prolonged long after it had been despaired of, illustrating what may be accomplished by treatment.

H. H., a man, aged forty-three years, was admitted to my wards in the Philadelphia Hospital on the 13th of April, 1889, with the primary diagnosis of acute bronchitis. He had been in the English army in India, and came to this country in 1872. Since his arrival here he has been working as a carriage-finisher. He has been dissipated, often going on sprees for three or four days at a time. It was discovered very soon after his admission that he had albuminuria, but his salient symptoms were those of an obstinate bronchitis, to which was soon added a pleurisy. He gradually recovered from his cough, but œdema of the extremities soon set in, and gradually ascended. Simultaneously the albuminuria increased, while granular and hyaline casts were found in his urine. The anasarca became general, and the effusion invaded the pleural sacs and abdominal cavity. He was treated actively by cupping and blistering, the use of digitalis, strophanthus, spartein, pilocarpin, and purgatives, by Hay's treatment with concentrated solution of magnesium sulphate in connection with limited ingestion of fluids, and by hot-air baths. Paracentesis of the chest was performed several times. Paracentesis abdominis was attempted, but failed, because of the thickness of the abdominal walls, which were in a state of myxœdema. Notwithstanding these decided measures, no advance was made; indeed, he was slowly losing. He was orthopnœic and the picture of distress. About the 1st of August paracentesis thoracis was repeated, and I left for my vacation, never expecting to see him again. I, however, directed, before leaving, that he should be placed on a skimmed-milk diet. I resumed my wards on the 11th of September, and was greatly astonished to find him not only alive, but greatly improved in his condition; there was still swelling in the arms and legs, but they were much better. He was passing about 40 ounces of urine. He had been under skimmed milk throughout. He had, however, every three or four days been also sweated by a method not novel, but which I have found very satisfactory. Large bottles—wine bottles are of the best size and shape—are filled with hot water, surrounded with cloths wrung out in hot water, and applied to the surface of the body wherever possible. I now, September 8th, added to his treatment spartein in doses of ½ grain three times a day. It will be remembered that this drug had previously been given without effect, not, however, in connection with an exclusive milk diet, which was continued in the quantity of about 42 ounces daily. It again appeared without effect, and on the 14th was substituted by the infusion of digitalis. The quantity of urine ranged from 32 ounces to 44 until the 25th, when it rose to 55 ounces, and continued to rise with fluctuations until 69 ounces were reached. Then there was some diminution, but the quantity continued free until about the 1st of November, when it began again to decline until November 15th, when but 20 ounces were passed. Spartein was then again resorted to, and at once the urine rose rapidly and remarkably. Thus, on the 16th there were 20 ounces; on the 17th, 33; on the 18th, 40; on the 19th, 50; on the 20th, 70; on the 21st, 128; on the 22d, 169; on the 23d, 155; on the 24th, 114; on the 25th, 148; on the 26th, 149. On the 26th the drug was discontinued, when at once there began a gradual fall, the quantity being, however, still free. On the 5th of December, the quantity being 121 ounces, the infusion of digitalis was again commenced; the urine remained over 100 ounces until December 30th. During this time he ingested not more than 45 ounces of milk. Of course, the dropsy gradually diminished, and his general condition

greatly improved. His legs, which had become ulcerated from the excoriating effect of the leakage from the burst tissues, gradually healed, although the skin remained very hard. He was up almost the whole day, moving all over the wards in a wheel-chair. A drawback occurred about the middle of November, when he had a severe chill, and there developed some cerebral symptoms which suggested uræmia. This was the day before the urine reached the low point referred to of 20 ounces, and on the day of the chill there were but 40 ounces. Purgatives and vapor baths were given for a couple of days with the spartein, and as the urine increased the uræmic symptoms rapidly subsided, and by the 23d they had disappeared. The fluid persisted most stubbornly in the pleural sacs, and he was again aspirated on December 22d.

On the 30th of December I ceased my service in the hospital, and although the notes, which were placed at my disposal, indicate a free discharge of urine up to the middle of January, he died about this time.

Necropsy.—The post-mortem examination was interesting. The notes state that he was a man of extremely large size, weighing about 250 pounds. The abdomen was much distended, and upon being opened was found to contain many quarts of serous fluid. The right pleural cavity was almost filled with bloody fluid—about 2½ quarts—the lung being collapsed to the size of a man's fist. The left pleural sac contained a small amount of fluid. The pericardium contained but little fluid, and the heart was much hypertrophied, weighing 20 ounces. The kidneys are noted as slightly enlarged, but as each weighed only 6½ ounces they cannot be regarded as enlarged. I should consider them rather below the normal size for a man of that weight. The capsule was but slightly adherent. The description on section is not definite. The note says, "Kidney substance was much wasted, only about ¾ of an inch left." Presumably this refers to the cortex, and if this is the case ¾ of an inch of cortex cannot be regarded as wasted. It is full width. I was informed, in fact, by one of the resident physicians present at the autopsy that there was quite a discussion as to whether the cortex was actually reduced or not. Nothing is said as to color, or, indeed, as to any appearance. Nor was any microscopic examination made. The probabilities are that the case was one of chronic parenchymatous nephritis in the stage of beginning contraction, and illustrates, what is so often seen in renal disease, an apparent disproportion between the gravity of symptoms and the degree of lesion.

The third case, also a desperate one, was that of a young man, twenty-eight years old, admitted to the Hospital of the University of Pennsylvania February 3, 1890. He was a stone-mason, and had regarded himself as in perfect health until Nov. 14, 1889, when, after a drive of eight miles, he ate his dinner and lay down for a nap. On rising he noticed that his face was swollen. The day was chilly, but he was well protected, and was not aware that he had taken cold. He had, however, also been working for a week previous to this drive in a damp cellar. The swelling extended rapidly, and in a few days he was anasarcous. He consulted a physician, who said the dropsy was due to kidney disease, but allowed him to be up and about for a month. He then put him to bed, where he remained until admitted to my wards.

On admission there was extreme general anasarca and large abdominal effusion. His face was so swollen that his eyes were almost closed and his hands and arms were like cushions. His legs, thighs, and abdominal walls were similarly infiltrated, and the first were marked with cicatrices left from scarifications which had been made to allow the serum to drain off. His scrotum was as large as a child's head. The secretion of urine was very scanty, only fourteen ounces being secreted the first day after admission. He was first placed on Hay's treatment, with concentrated salines and restricted fluids. Digitalis had been used before admission in such quantities that the smallest dose sickened him, and it was impossible to use it. His abdomen was tapped and a gallon of water drawn off. A hot vapor bath was given without effect, and pilocarpin hypodermically, in one-third and one-quarter grain doses, with like result.

On the 16th of February he was placed on skimmed milk—four ounces every two hours, increased to six ounces in the second twenty-four hours, and subsequently to eight—in lieu of all other food and medicine, except such as was required to keep his bowels open. Under this treatment his urine increased from an average amount of twenty-five to thirty ounces, but never became large. The dropsy, however, rapidly diminished, and soon had entirely disappeared from his arms, face, and trunk and almost entirely from the lower extremities. On the 28th of February he was permitted to have, in addition to the milk, four oysters, to his intense satisfaction. He was also allowed small doses of Basham's mixture, with strychnine. The abdominal effusion gradually re-accumulated, and he was again relieved of a gallon of fluid, on March 10th. During this time the bowels were kept freely acting with magnesium sulphate, but, as stated, the quantity of urine did not increase above thirty ounces and remained for the most part at about twenty-five. With a view to increasing this secretion spartein was ordered in one-quarter grain doses, three times a day, and increased until two grains a day were taken without any effect. Caffein was then ordered (March 20th) in doses of three grains, three times a day, without materially increasing the quantity of urine, but with an unexpected effect on the bowels, which were moved from seven to thirteen times in a day. Notwithstanding this, he felt perfectly well, and the dropsy had almost entirely disappeared, even from his feet, although he was up many times on account of his bowels. On the 27th his temperature, which had been either normal or subnormal since his admission, suddenly rose, simultaneously with that of every other patient in the ward. He acquired a stubborn cough, his breathing became embarrassed, and he seemed very ill. Then his dropsy rapidly increased, and in a few days he was as bad as ever. He became discouraged and left the hospital. The acute illness which was responsible for this relapse

was probably influenza, as all the patients in the ward were suddenly attacked by it.

These cases represent a class in which the usual measures fail to accomplish any results, and it is certain that if they had been left alone the patients would have perished. In all a turn in the tide took place after milk began to be administered at regular intervals and in fixed doses. In two the opportune addition to this treatment of spartein in full doses was followed by free increase in the secretion of urine, with continued improvement, while in one this drug failed. On the other hand, in that case caffein proved a valuable remedy, though not by its action on the kidneys so much as by its effect on the bowels. This effect of caffein, scarcely referred to by therapeutists, I have found a frequent one, by which its efficiency as a diuretic is greatly increased. Although there is reason to believe that sugar of milk is a diuretic, it is evident, from a review of these three cases, that the substitution of all food by milk was not followed by diuresis, and yet improvement set in, and when it flagged and diuretics were used the physiological effect of this class of remedies promptly appeared in two instances, while in the third a purgative effect was equally efficient.

In looking about for an explanation of this happy effect I have been forced to conclude that it was really the result of the small amount of solid and liquid nutriment ingested. It will be remembered that the method was to permit but four ounces every two hours for the first day from 6 A. M. to 8 P. M., or thirty-two ounces in the twenty-four hours, in lieu of all other solids and liquids, and in the second twenty-four hours but sixteen ounces more. Now, even with the urine unincreased and the action of the skin, lungs, and bowels maintained, there is a large drain upon the liquids, intra- and extra-vascular, so that the latter are bound to be sucked up, with the effect of gradually diminishing the œdema.

The effect is similar to that which is produced by blood-letting upon absorption. It is well known, for instance, that when a drug, as digitalis, is being administered without effect, and, for any reason, even a small quantity of blood is drawn, the physiological effect promptly asserts itself because of its prompt absorption. The limited ingestion of food in the shape of milk acts similarly, while it facilitates for the same reason the action of drugs, as shown in its effect upon the action of the spartein and caffein in my cases. The same effect on dropsies might be expected if blood be taken from a vessel, and I can conceive of a case where such a course would be justified, but it has the disadvantage of withdrawing nutriment, while the milk keeps it up sufficiently. On the other hand, I regard the hunger as an important adjuvant, and it is the demand of the blood for food which contributes to the drawing up of the dropsical fluid. It is similar, too, to the action of Hay's treatment, which has for its principle the minimum ingestion of water along with the action of hydragogue cathartics, and there is no doubt that this treatment is often an efficient one in removing dropsies, even when invading the great serous sacs like the pleuræ and peritoneum. It has the disadvantage, however, of presenting food in a more unmanageable shape, especially in connection with limited water ingestion, than the milk, which is given skimmed simply because it is more assimilable in this shape. Buttermilk may be substituted, being equally well assimilated, often more agreeable to the stomach, and often diuretic. Further, milk may be made even more assimilable by being peptonized.

There is, of course, no direct curative effect upon the altered organs, whether kidneys or heart, but when it is remembered how much of the inconvenience of the patient is due to dropsy, and how the circulation is interfered with by these enormous accumulations of liquid in the great serous sacs, as well as in the subcutaneous connective tissue, it is evident that the relief afforded by their removal must be extreme. It is true, also, that the movement of blood through the kidneys is further interfered with by the dropsical effusion around it, and with the removal of that effusion the engorgement is relieved, and thus a tendency toward cure results; whence may be explained, on the one hand, the long immunity from recurrence often enjoyed by such cases, and on the other, the rapid aggravation which follows exposure to cold or other cause of congestion, as instanced in the case of the young stonemason related. Such is also another very similar case of a young actor in whom there was dropsy equally aggravated, which after months of treatment had totally disappeared so that he was walking about apparently well, when the irresistible attraction of a base-ball match on a cold April day furnished the exposure which produced a recurrence of symptoms, this time irremediable.

In conclusion I desire to emphasize the class of cases in which this treatment is indicated. It is not in acute or subacute nephritis, where there remains an integrity of structure and function which permits the free transudation of water into the Malpighian capsules, but where, as has been stated, there is a complete saturation of all the tissues, including the kidney itself, with transuded serum, and where there is no movement in the lymph spaces and lymph vessels. In such cases to administer diluents is only to increase the difficulty, because it results in a further interstitial accumulation of fluid. The indication is to get rid of liquid, and to do this more must be taken out than is taken in, and as the kidneys have, for the time being, lost their power

of removing—and it is to be remembered that this loss of power may be but temporary—ingestion must be restricted until the balance is restored. Hence we must watch and measure and limit the ingestion and watch and measure the outflow, and until the latter exceeds the former no improvement can result. It is needless to say that tapping the great cavities and even as a *dernier ressort* the tissues, is an aid to our efforts in this respect.

ON THE EMPLOYMENT OF THE CATAPHORIC ACTION OF THE GALVANIC CURRENT FOR THE REMOVAL OF SYPHILITIC NEW-GROWTHS.

A Contribution to the Medical Treatment of Tumors.[1]

BY FRANK WOODBURY, A.M., M.D.,
FELLOW OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA; HONORARY PROFESSOR OF CLINICAL MEDICINE IN THE MEDICO-CHIRURGICAL COLLEGE, ETC.

MR. X., married, thirty-three years of age, a travelling salesman, contracted the primary lesion of syphilis in May, 1885. He at once put himself under my charge, and I gave him the usual treatment, varying the form of mercurial from time to time, but relying principally upon gray powder, two grains three times a day. Secondary symptoms were moderately severe; there was not much sore-throat, but there were "milk spots" and ulcers in the mouth, falling-out of hair, and eruptions on the skin, especially psoriasis of hands and feet. The usual treatment was kept up almost continuously for about two years. One year and a half ago, he presented himself with a tubercular eruption over the left eyebrow, and in the course of about a month this had appeared upon the left side of the nose and from there soon spread over the entire lower half of the organ. Isolated tubercular lesions appeared upon the upper and lower lips and upon the chin. The masses were flattened, and showed a tendency to run together. The surface was slightly reddened, but not markedly congested. The orifices of the sebaceous glands were prominent, and large plugs of sebaceous material could be expressed by moderate pressure. The course of these lesions was indolent, and seemed very little influenced by treatment, either local or systemic. The patient was much annoyed by the appearance of his face and the comments excited by it among his friends, and very faithfully carried out the means advised for his relief. Wet dressings and dry, plasters and ointments (including resorcin and ichthyol), were resorted to, and iodides and *Sirop Gibert* were given, but with little apparent effect, except to prevent the further progress of the syphilide. Finally, while continuing the specific treatment by potassium iodide and bichloride of mercury, about three months ago I concluded to try cataphoresis, using a solution of iodide of lithium (five per cent.).[2] The applications were made upon absorbent cotton, applying the anode over the new-growth and the kathode at a distance. The anode being quite small, it was found that a current of from two to three milliampères was as much as the patient could bear without actual pain. The applications were made with moderate pressure, lasting from five to fifteen minutes, at first every second day, and subsequently twice a week. The improvement was evident; though slow at first, it has been very marked since this method was adopted, although due credit must be given to the internal treatment, which has been steadily continued. One fact illustrating the influence of treatment should be mentioned. Within the last year he has had the pleasant addition to his family of a girl, who is the picture of a healthy baby, and is without apparent blemish.

Remarks.—It is a source of gratification to the patient that there was no ulceration following the extensive infiltration of the deeper layers of the skin, thus avoiding cicatrization or scarring, which in this situation would have been very disfiguring. It may be assumed that the treatment exercised a decided influence over the course of the disease, especially as the patient was under excellent hygienic conditions and possessed a good constitution. I was led to the adoption of cataphoresis by the slow effects from systemic treatment, and by revolving in my mind the problem of how to carry the remedies to the cell-groups more directly and in greater quantity than through the ordinary channels, more especially because he did not bear potassium iodide well and always was attacked by coryza after he had taken it for a few days, requiring frequent interruptions of the treatment, I believed that the iodine was the principal or active agent in causing the absorption and disintegration of syphilitic new-growths, and the thought occurred to me that the cataphoric action of the galvanic current was just what was required to solve the problem. Of the various iodides, I selected the lithium compound because of its solubility, and because the lithium might assist in carrying off nitrogenized waste; probably the potassium salt, which is cheaper, might answer quite as well, except where there is a decided lithæmic or gouty condition.

By cataphoresis, or electrical osmosis, is meant the movements of liquids or solutions from one electrode toward the other, through animal tissues, under the influence of a galvanic current. Munk,[1] nearly twenty years ago, demonstrated the transmission of a solution of sulphate of quinine through the skin when electrodes were moistened by it, and detected quinine in the urine twelve hours after the passage of the current. Von Bruns proved that potassium iodide could be passed through the body, whether

[1] Read before the College of Physicians of Philadelphia, May 7, 1890.

[2] The current was obtained from six to eight cells of a Waite & Bartlett twenty-cell battery, measured with a W. B. dead-beat milliampèremeter.

[1] Archiv. für Anat. u. Physiologie, H. 5, 1873.

alive or dead, in a similar manner. In the same way strychnine, cocaine, and bichloride of mercury have been made to traverse the tissues, or technically, have been driven through the skin. Adamkiewicz has employed chloroform in this manner in the treatment of neuralgia, and claims extraordinary success with it, in many cases giving immediate relief.

Where it is desired to introduce a considerable quantity of a medicament, the method of Munk should be followed. He took two of Dubois's conducting tubes, stopped with plugs of clay. Both the tubes were filled with a saturated solution of the substance to be introduced, and the plugs were moistened with it. These were then applied to the body, and currents of moderate strength passed through the parts in the same situation. Their direction was reversed every five or six minutes, because it was found that the activity of the process diminishes with the continuance of any one current. For the same reason it is necessary to charge both electrodes with the substance used. Erb[1] states that in this manner it is possible to introduce a considerable quantity within the system in a period varying from fifteen to forty-five minutes. Strychnine cramps have been produced in the rabbit, and in man traces of potassium iodide and of quinine administered thus have been found in the urine hours afterward.

With regard to the treatment of new-growths by electrolysis, we are familiar with the treatment of hypertrophied scars and keloid, and the removal of similar inflammatory deposits giving rise to stricture of the urethra, rectum, etc. In the same connection, I might also cite Apostoli's treatment of uterine fibroids, which in many cases has obviated the necessity of a resort to the knife. Dr. Garrett, of Boston, reported last year the successful treatment of 157 cases of tumors of the breast by the aid of galvanism. It seems to me that the combination of the two methods, cataphoresis and electrolysis, opens an inviting field for exploration for both physician and surgeon.[2] Possibly we may hope for the eventual successful treatment of malignant growths by this combined method. It certainly offers a more promising outlook than any surgical procedure with which I am acquainted.

218 S. Sixteenth St., Philadelphia.

[2] By placing the electrodes moistened with iodide of lithium in starch-water, the iodine reaction is quickly manifested at the positive pole, with a current of from two to five milliampères. It is possible that where morbid growths are superficial or merely subcutaneous, and the skin thoroughly wet with the iodide solution, electrolysis may take place directly among the cell-groups, and thus expose them to the action of nascent iodine, with results not to be obtained in any other way. It is within the limits of possibility that we may soon discover the chemical agent—chlorine, bromine, arsenic, acetic acid—which is especially obnoxious to the abnormal cell-growths of carcinoma, which Formad claims is a kind of inflammation. When this occurs medicine will achieve a triumph over surgery.

HERPES ZOSTER OF THE MOUTH AND GUMS.

By A. C. HUGENSCHMIDT, M.D.,
of Paris, France.

Herpes zoster, which is a rare affection in other parts of the body, is not more often met with in the mouth. In a period of ten years I have encountered only two cases, which, however, presented all the classical clinical signs of this disease. In one case the lesion was found on the mucous surface of the cheek, in the other on the gums. The following are the histories:

Case I.—In 1884, a lady, fifty years of age, came to me complaining of an intense neuralgia of the right side of the face, involving all the ramifications of the fifth nerve, but the patient pointed to the region of the superior maxillary, as being much more painful. The disease had begun three days before with very high fever and neuralgia of the right side of the face; it was only on the fourth day that the pain became more particularly localized in the region of the superior maxillary nerve.

On examining the mouth the teeth of the superior maxilla were found in a perfect state, excepting a few very small gold fillings. When, however, I tried to separate the cheek from the gum, the patient uttered a loud cry, saying "There is all the pain." The gum was not at all inflamed, but on the internal surface of the right cheek, at the hypersensitive point, I found a lesion quite sufficient to explain the pain. On a line about one and one-half inches long and one-half inch broad, there existed a series of agglomerations of small herpetic vesicles regularly disposed in an antero-posterior direction, parallel to the upper molar teeth. These small vesicles in their form as well as in their regular disposition resembled the vesicles met with in intercostal herpes zoster, or zona. The severe pain in this case was probably not due to neuralgia of the superior maxillary nerve, but of the buccal branch of the inferior maxillary. The pain and eruption persisted for about one month, the only treatment used being the insertion of a little pad of cotton covered with a morphinated ointment between the the surface of the cheek and teeth.

Case II.—In May, 1889, the patient, a woman, twenty-two years of age, came to me suffering from intense neuralgia of the right side of the head, which had localized itself on that day in the region of the inferior maxillary nerve. On examining the mouth the upper and lower teeth of the right side were found in good condition, the lower sixth-year molar having been extracted. My attention was immediately attracted to the gums of the inferior maxilla, where I found a long line of herpetic vesicles disposed in small groups and parallel to the alveolar border, beginning at the inferior canine of the right side and terminating at the posterior

aspect of the second molar. These vesicles were on an inflamed mucous membrane. As in the preceding case this patient presented marked febrile and other general symptoms during the three days which preceded the eruption. The patient being very anæmic was put on arseniate of iron, and, to combat the pain, antipyrine. Locally a pad of cotton covered with a morphine and cocaine ointment was placed between the cheek and gums. The pain persisted for three weeks, the fever remained, and, strange to say, as soon as the eruption disappeared the patient was taken with a severe pneumonia, which passed into chronic pneumonia and general tuberculosis, with an evening temperature of from 102° to 104° F. The patient is now (May 1, 1890) in a dying condition.

From these two observations one might conclude that herpes zoster of the buccal cavity presents itself with all the symptoms of a general disease. It is an inflammatory affection involving *one side only* of the buccal cavity, characterized by an eruption of herpetic vesicles disposed in groups and regularly distributed, which eruption is preceded by and accompanied with a neuralgic pain of the fifth nerve.

The development of the disease can be divided into two periods: the period of invasion and the period of eruption. The period of invasion comprises an elevation of temperature in the evening sufficient to be recognized by the patient, and general symptoms, such as headache, etc. There is also intense neuralgia of the fifth nerve of one side. The marked fever lasts about three days and is followed by the period of eruption. At the beginning of the eruptive period the invaded part becomes excessively painful to the touch, the mucous membrane is red and presents a series of small vesicles the size of a pin's head. A few vesicles are blended together and are regularly disposed in a straight line and on one side only of the buccal cavity. No irregularly disseminated vesicles are found. The neuralgia, which during the first three days extends throughout the fifth nerve, localizes itself in the eruption and becomes still more painful.

From an etiological point of view, herpes zoster has the form and development of an infectious disease, as has been indicated by Professor Kaposi, of Vienna, who remarks that this variety of herpes appears in an epidemic form at a certain period of the year, when pneumonia and erysipelas are also most frequently observed.

In Unna's clinic at Hamburg an epidemic of zoster was observed after the admission of a patient suffering from the disease, four patients in the ward presenting the general and the characteristic local symptoms.

In my second case the eruptive and painful manifestations of the disease disappeared at the end of three weeks, but the patient was then taken with a severe pneumonia and later with pulmonary tuberculosis, which corroborates Professor Kaposi's observations on the relation between herpes zoster and pneumonia.

The local lesions are attributed to trophic changes, due to a neuritis of the nerve distributed to the invaded part.

As to the diagnosis of the disease, if all the symptoms are marked, as they were in my two cases, no difficulty will be encountered. In irregular cases it could be mistaken only for herpetic stomatitis or for aphthous stomatitis.

Herpetic stomatitis is rarely met with alone, and is usually associated with herpetic angina. It is distinguished from zona by the irregular dissemination of herpetic vesicles on the surface of the buccal cavity, moreover neuralgia of the fifth nerve is not present. As to the general symptoms, those which precede herpetic angina are much more violent than those which announce the appearance of zona.

Aphthous stomatitis is also an infectious disease, presenting general symptoms with local pain before the eruption, but the pain has not the neuralgic type; it is a lancinating pain situated at the points where the lesions will appear.

The treatment should consist of protecting the painful part against rubbing and applying on a pad of cotton an ointment, such as the following, which I have used with benefit:

℞.—Muriate of cocaine } of each 2 grains.
Muriate of morphine }
Borate of sodium . . . 1½ drachms.
Honey . . . . . 1 ounce.—M.
Use a portion the size of a pea, several times a day.

CLINICAL MEMORANDA.

MEDICAL.

A Case of Intermittent Fever, Complicated by Acute Gastritis, Dysentery, and Leucorrhœa.—Mrs. M., aged fifty-five years, well nourished and slightly inclined to *embonpoint*. Family history good. Has had the various diseases of childhood, but her health has been otherwise excellent. Is the mother of two strong adult male children. Labors normal. I was called to the patient on the morning of October 1st. For some days she had been troubled with indigestion, anorexia, and dizziness, but these symptoms had passed away before I saw her.

She was then suffering acutely from a "cold," with severe frontal headache, and complained of feeling chilly and weak. She had no fever; tongue slightly coated; bowels regular.

I prescribed a mixture containing equal parts of spirit of nitrous ether, paregoric, syrup of ipecac, and syrup of squill, one teaspoonful to be taken every four hours in water. Also ten grains of sulphate of quinine at bedtime.

October 2. Her coryza was somewhat improved, but on the previous afternoon she had had a slight chill, followed by rise in temperature (at the time of my visit

she had no fever). Tongue was heavily coated with a yellowish-white fur, mouth pasty, and breath foul and heavy. Prescribed five grains of calomel, divided in five powders, one powder to be taken every hour. I ordered, in addition, ten grains of quinine daily, in doses of two grains each ; the last dose to be given three hours before the expected paroxysm.

3d. Patient had a very severe chill in the afternoon about 3 o'clock, followed by a temperature of 103.4°. She had had a copious movement from the bowels but was suffering intensely from indigestion. I ordered an absolute milk diet and gave:

R.—Pepsin (Jensen's) . . . 4 grains.
Lactic acid . . . . 8 minims.
Dilute muriatic acid } of each . 1 drachm.
Glycerin }
Water, sufficient to make . . 2 ounces.
One teaspoonful, in water, before each meal.

4th. During the night she had frequent spells of vomiting accompanied by extreme nausea and retching. Everything was rejected by the stomach as soon as swallowed. Stopped both quinine and pepsin mixture, and prescribed:

R.—Bismuth subnitrate . . . 15 grains.
Carbolic acid . . . . 3 "
Peppermint water . . . 5 drachms.
Water, sufficient to make . . 1 ounce:—M.
One teaspoonful, in water, every three hours.

5th. The nausea and vomiting had increased, and were aggravated by the medicine. Severe pain in stomach and in epigastric and right and left hypochondriac regions. Bowels had not been moved since October 3d. Had a slight chill in the afternoon, followed by a temperature of 102°.

As the medicine seemed to irritate the stomach, I stopped it, and substituted the following:

R.—Calomel . . . . . 1 grain.
Sodium bicarbonate . . . 5 grains.
Sugar . . . . . 3 "
Divided into 12 powders, of which one was given every two hours, dry, on the tongue.

In addition, I ordered brandy to be given with cracked ice at frequent intervals; an enema of hot water, soap, and glycerin was administered, and was followed by a very free evacuation.

6th. Nausea and vomiting lessened in frequency. Patient passed a comfortable night, but early in the morning was attacked simultaneously with symptoms of dysentery and leucorrhœa. Tormina and tenesmus were very marked. The desire to go to stool was almost constant. The passages were composed of blood and mucus, with a small amount of scybala, and had a most offensive odor.

The leucorrhœal discharge was dark-colored and very profuse. Temperature remained during the day at 102.1° F.

I prescribed:

R.—Fowler's solution . . 8 minims.
Tincture of opium . . 1 drachm.
Water, sufficient to make 1 ounce.—M.
One teaspoonful in water every three hours.

For the leucorrhœa she was ordered a saturated solution of boric acid, of which one ounce was added to eight ounces of hot water, and used as an injection every four hours.

7th. A slight chill early in the day—otherwise no change. Continued treatment as before, and ordered quinine again in two-grain doses every two hours until ten grains were taken.

9th. Leucorrhœa much improved. A chill in the afternoon.

11th. The leucorrhœa had almost disappeared. Dysentery improved. No chill. Stomach rejected everything but brandy and ice. Ordered half an ounce of cold milk every three hours, and prescribed:

R.—Bismuth, subnitrate . 8 grains.
Pepsin (Jensen's) . . 15 "
Dilute muriatic acid . 35 minims.
Glycerin . . . 1 drachm.
Peppermint water . . 4 drachms.
Water, sufficient to make 2 ounces.—M.
One teaspoonful in cold water before taking milk.

12th. Vomiting lessened in intensity and frequency. Slight chill in the afternoon.

From this time on the gastric trouble steadily improved. But as it grew better the intermittent fever increased, the chills appeared regularly about four o'clock on each alternate day, and they were followed by high fever. Both chills and fever became more and more intense until October 25th, when the disease seemed to reach its acme. During all this time I still continued to use the prescription containing pepsin and bismuth, and also full doses of quinine.

Each succeeding day showed marked improvement in the patient until November 6th, when she was again attacked by nausea, which was caused by indiscretion in eating. By judicious employment of milk and proper food the stomach recovered its normal tone.

I kept her for several weeks on low diet, and gave simple tonics. Later, as she lived in what is commonly known as a malarious district, I gave the following prescription, which is highly recommended by Dr. Samuel Bemiss as a prophylactic:

R.—Reduced iron . . 40 grains.
Arsenious acid . . 1 grain.
Sulphate of quinine . 40 grains.
Oleoresin of pepper . 10 minims.—M.

Make into twenty pills, of which one should be taken three times daily.

Martin W. Barr, M.D.,
Resident Physician in the Pennsylvania Institution for Feeble-minded Children.
Elwyn, Pa.

SURGICAL.

Ligation of the Subclavian Artery.—This operation, like many others which before the days of Listerism were so fatal, has lost some of its most dreaded consequences, and future statistics will undoubtedly show a decrease in the mortality of the operation. The following case was admitted to the Jefferson County Almshouse April 5, 1890:

Henry B., colored, aged twenty-two years, of small stature. In a brawl six weeks before admission he had

been stabbed several times and in different parts of the body, the wound giving rise to the aneurism being in front of the left shoulder, the knife entering opposite to the acromion process. From this wound he bled profusely, and stated that he thought he would bleed to death. The bleeding stopped spontaneously and everything went well for two weeks, when he noticed a small tumor at the seat of the injury, and burning pain along the inner side of the arm and forearm.

The swelling and pain increased until, on admission, there was a tumor the size of a large orange in front of the shoulder-joint, and the pain was so severe that the patient carried his arm supported at right angles to the body by the other hand. The tumor was easily diagnosed as an axillary aneurism. The subclavian artery was ligated in its third portion with strong catgut, April 8, 1890.

Pulsation immediately ceased in the tumor as well as in the radial artery. The arm was wrapped in cotton and hot-water bags were constantly applied. The patient immediately began to improve, and he complained very little of the former pain in the arm. Feeble and irregular pulsation was detected in the radial artery on the third day after the operation. The tumor slowly became smaller and when he was dismissed, May 6, 1890, had almost entirely subsided. The radial pulse at this time had been reëstablished, but was not so full as in the other forearm. The patient was able to resume his occupation as a laborer.

CUNNINGHAM WILSON, M.D.
BIRMINGHAM, ALABAMA.

HOSPITAL NOTES.

MEDIAN LITHOTOMY. SARCOMA OF THIGH. RESECTION OF KNEE.

Abstract of a Clinical Lecture delivered at the Roosevelt Hospital, New York.

BY CHARLES McBURNEY, M.D.,
ATTENDING SURGEON.

CASE I.—Dr. McBurney first presented a little boy, four years old, who two years ago began to have trouble with urination. An examination had revealed the presence of a small calculus. The operation had been postponed for three weeks on account of an attack of measles. The usual method of performing median lithotomy, including digital dilatation of the perineal wound, the operator thought, was a procedure of considerable gravity in a young child, if the stone were large. But, in this patient the stone appeared to be only about the size of a small bean, and Dr. McBurney modified the operation by making use of a new instrument, which he had originally devised for the purpose of introducing perineal drainage-tubes after deep internal urethrotomy. The instrument consists of a grooved director, carrying a concealed knife, the end of which can be projected or withdrawn. According to the usual method of operating an incision is made down to the staff, and the knife having been removed a grooved director is substituted; but in doing this the director often catches in some fold of tissue, and with difficulty is made to reach the staff. With the new instrument this difficulty cannot arise, for as soon as the knife reaches the staff its point is withdrawn without removing the director from the groove in the staff.

It was found necessary to slightly enlarge the boy's meatus before introducing the staff. Having made a very small incision in the perineum, the director was made to reach first the staff, and then, after withdrawing the knife, it was passed on into the bladder. Small forceps being inserted into the bladder along the director, the stone was seized and removed. A drainage-tube was then introduced into the viscus in order to secure drainage for the first two days. The bladder, wound, and adjacent parts were well irrigated with boro-salicylic solution, the wound was dusted with iodoform, and the external opening of the drainage-tube was covered with a mass of moist antiseptic gauze.

CASE II.—This patient, a boy of seventeen years, had been in good health until ten weeks ago. He received at that time a strain of the right knee while playing football. Swelling and other inflammatory changes rapidly supervened, and the limb was placed for some time upon a splint. On admission to the hospital ten days ago, swelling, redness, and tenderness were found over the inner condyle of the right thigh, apparently with indications of superficial suppuration Incision did not reveal pus, but a mass of soft tissue, containing cartilaginous material; and the finger in the wound could feel the bare surface of the femur. The new growth was evidently a rapidly developing sarcoma, and immediate amputation was urgently indicated. But the patient was of a very delicate and nervous organization, and the examination produced such a profound impression upon him that the operation was postponed. His condition at present is only slightly improved, but further delay in a sarcoma of such rapid growth was not deemed advisable. The general condition of the patient was so poor that the idea of amputation at the hip-joint could not be entertained. It would be almost certainly fatal. If the disease had infiltrated the shaft of the femur the only chance of cure would be, of course, in an amputation at this point. Dr. McBurney considered that the best interest of the patient was subserved by an amputation a little above the middle of the thigh, with a long anterior flap. Amputation at this point gave, in his opinion, the best results, excepting amputation through the extreme upper portion. The broad base of the flap—two-thirds of the circumference of the limb—was one of its good features. The flap was made wedge-shaped, its base being composed of all the soft parts at the front of the thigh. A very short posterior flap, from two to two and a-half inches long, was also made, simply to allow for the retraction of the muscles. The cicatrix would be sufficiently far back to escape pressure, and the end of the bone would be covered with a thick pad of tissue. The flaps were united by interrupted catgut sutures, rubber drainage-tubes were inserted at the angles, and the usual antiseptic dressing was applied to the stump.

CASE III.—This case, also a young man, apparently in robust health, presented a tumor which had been growing upon the inner side of the left thigh for the past seventeen years, and was about the size of a pea when first noticed. Although the tumor had reached a diameter of nearly seven inches, and was pendulous, it had given him comparatively little inconvenience. It was,

probably, a lipoma. Slight traumatisms had occasionally caused an increase in its size, probably from interstitial hæmorrhage. As the patient was strongly opposed to taking ether, cocaine anæsthesia was employed, the solution being introduced subcutaneously at a number of points around the periphery of the tumor. The growth was removed by an elliptical incision, and the wound stitched with interrupted silk sutures. A rubber drainage-tube was inserted, the wound dressed antiseptically, and the limb bandaged to a lateral wire splint.

Dr. McBurney said he did not favor the use of cocaine in large operations, for local anæsthesia was not sufficient in case of unexpected hæmorrhage or other accident which might at any time arise; and, beside this, the agent was very uncertain in its action. Quite recently he had given a patient in his office an injection of ten minims of a four per cent. solution of cocaine, and the patient had been made very ill by it for several hours; while the patient just operated upon had received nearly three times this quantity of the drug and had experienced no inconvenience.

On cutting into the tumor after removal it was found to be a pure, small spindle-cell sarcoma. Dr. McBurney said that he did not remember ever having seen a sarcomatous tumor with a history of such long duration, and with such an innocent appearance. The interest of the case was still further enhanced by a comparison with the preceding one, which had existed only ten weeks, and yet had extensively invaded the surrounding structures, and demanded amputation.

CASE IV.—The next patient, a woman, aged twenty-nine years, had received an injury near the knee, when at about her seventh year. This was quickly followed by periostitis, requiring incision for the evacuation of pus. Sinuses remained for some time, and sequestra of considerable size were discharged from time to time. Soon after the injury flexion of the leg began, and for over twenty years it had been flexed at nearly a right angle, and permitted only slight motion. There was considerable atrophy, and a shortening of five and one-half inches. She used crutches, and the limb projecting out behind was not only useless but inconvenient.

The choice of operation lay between an excision of the knee, with the removal of a wedge of bone sufficiently large to allow extension of the leg, and an amputation. The latter was preferable, but the patient would not consent to it. On account of the extensive displacement of the leg backward it would be necessary to remove a large wedge of bone, and this would probably result in a shortening of six and one-half inches. Besides this, success was by no means certain on account of atrophy of the tibia and femur, which made it highly probable that great changes had taken place in the bones.

A free incision was made just below the patella, and the joint opened. As there was no advantage in saving the patella or the lateral portion of the capsule, these were removed. After a sufficiently large wedge of bone had been excised to permit proper alignment, a nail was driven from below upwards into the bones so as to secure greater stability. Ordinarily two nails are employed; but in this case the small size of the bones precluded the safe use of more than one. The wound was united by interrupted catgut sutures, and as it was very desirable that the dressings should not be disturbed for two weeks, two absorbable-bone drainage-tubes were used instead of rubber. A plaster-of-Paris splint, strengthened with narrow strips of thin wood, was applied over the usual antiseptic dressing.

ECZEMA FROM EXTERNAL IRRITANTS. SEBORRHŒIC ECZEMA. SYPHILIS AND PREGNANCY. OTHER CASES.

Abstract of a Clinical Lecture delivered at the New York Post-Graduate Medical School.

BY ROBERT W. TAYLOR, M.D.,
PROFESSOR OF DERMATOLOGY AND SYPHILOGRAPHY.

CASE I.—A boy, nineteen years of age, having had an eruption for the past month, presented himself for treatment, and gave the following history: He had had no previous eruption, except from ivy poisoning, which he said had returned again one year after the first attack, this second attack lasting about four weeks, the face being swollen and covered with crusts. His occupation requires him to handle dyes and cosmetics in the form of liquids and powders. The present eruption, beginning on the hands, had now spread to the neck, hands, arms, and knees, and consisted of small patches of thickened, inflamed, scaly, and fissured tissue, and had the appearance of having been caused by an external irritant. The "relapse" after the poisoning was very probably an erythematous or eczematous eruption. It is not uncommon for such an eruption to follow an attack of severe dermatitis, arising from any cause.

Treatment.—Dr. Taylor said that the first essential to successful treatment was that the patient should either give up his occupation or else protect the hands most carefully from contact with these irritants; and for this purpose, an old kid glove was the most suituble. A rubber glove was useful in a chronic scaly eczema, but in the present condition the poulticing caused by such a glove would probably greatly aggravate the disease. The hands should be freely anointed with the following:

℞.—Balsam of Peru . . . 1 drachm.
Diachylon ointment } of each 1 ounce.—M.
Oxide of zinc ointment }

It would be well also for the patient to wear turn-down collars and soft linen around the neck. If he should wear woolen clothes next to the skin he would be liable to have a return of the eruption.

CASE II.—A young woman, having a chronic and painful ulcer of the leg, was the next patient. The ulcer was indolent and unhealthy, and a few enlarged veins in the popliteal region still further complicated the case. The ulcer was surrounded by a discolored zone of skin, showing an area in which there was a condition of blood-stasis.

Treatment.—In the first place, it was necessary to secure rest, with the limb elevated so as to favor the return circulation. The ulcer should then be dusted with iodoform and cold compresses wet with the following lotion kept upon the parts:

℞.—Solution of subacetate of lead . 2 drachms.
Tincture of opium . . . ½ ounce.
Carbolic acid solution (2 per cent.), sufficient to make . 1 ounce.—M.

When the acute symptoms have subsided careful bandaging will complete the cure and an elastic stocking will provide against relapse.

CASE III.—The next case, a man twenty-five years of age, was interesting on account of the uncertainty that has until recently surrounded the classification of the disease. Dr. Unna, of Hamburg, deserves great credit for his extensive and painstaking observation upon this subject, which has resulted in a simpler and more accurate classification. Dr. Taylor said the case was a typical illustration of seborrhœic eczema, a disease which begins as a patch of seborrhœa. According to Unna, Brooks of Manchester, and some others, the disease begins most commonly about the head, and is probably caused by microörganisms which invade the sweat- and hair-follicles and are then transferred to other parts of the body. When this patient was a child there was a scurfy condition of the scalp, and later he suffered from eczema. Three months ago a patch appeared upon the penis, which is now much encrusted. At present the whole scalp is covered with yellowish, uneven, hillocky incrustation, with here and there fissures extending down to the corium. The yellowish crusts bear some resemblance to favus, but there is no cupping such as one sees in the latter disease. The eruption terminates abruptly on the forehead, about one inch beyond the margin of the hair, which is a very characteristic feature of the disease. Other patches are found behind the ears, on the neck, between the shoulders, and elsewhere; and everywhere they are oozing, greasy, and of a dirty yellow color.

Treatment.—The general condition of the patient is very important, but it must be remembered that there is no diathesis to combat. An occasional powder of ten grains each of calomel and bicarbonate of sodium at night, followed in the morning by a draught of Hunyadi water was advised. Acetate of potassium in daily doses of thirty grains acts as an aperient and a diuretic, and will relieve the irritation of the skin. Formerly, tarry applications were usually employed locally, but Unna's researches have shown that the best topical remedies are sulphur and resorcin. The patches should be thoroughly rubbed and kept thoroughly moistened with the following ointment:

℞.—Camphor . . . . . 10 grains.
Washed sulphur . . . . 1 drachm.
Petroleum ointment . . 1 ounce.—M.

The scales should be removed as frequently as possible without injuring the skin. In about two weeks the patient should be considerably improved. If, as sometimes happens, the sulphur should prove ineffectual, from twenty grains to one drachm of resorcin will be substituted for the sulphur in the ointment. Twenty grains is usually sufficient.

CASE IV.—The next case was one of great practical interest. The patient, a woman, twenty-three years of age, about eight and a half months advanced in pregnancy, had entered Charity Hospital a few days before. She had a typical hard chancre of the fourchette in the form known as a chancrous erosion, and the inguinal glands were decidedly enlarged. She was probably infected at about seven and a half months of pregnancy, and the outburst of general syphilitic manifestations would be expected about six weeks later. The child might escape infection if born before the appearance of general syphilis, but Dr. Taylor thought that there was a likelihood that the syphilitic fever, if it came on, would induce premature labor, as is often seen with smallpox, typhoid fever, and similar conditions. There is no communication between the mother and child through the utero-placental circulation, so that it is possible for the child to be born perfectly healthy, although there is great risk of infection by the genitals of the mother during its birth. The mother is extremely liable to have a severe perineal laceration, owing to the situation of the chancre. This woman came into the hospital to be cured of syphilis and to be delivered of her child. It was her intention later on to go out as a wet-nurse and, perhaps, to care for her own baby also. Should she do this she would then be in the early and infectious stage of syphilis, and very liable to infect the child she nurses. Being comely and well built, she may present a good appearance, and to the lay eye appear healthy. These facts show how careful we should be in the selection and examination of nurses.

Treatment.—In such cases immediate mercurial treatment is indicated—mercurial ointment to the fourchette, with thorough irrigation of the parts, and mercurials internally, in order to produce a speedy resolution of the syphilitic new-growth.

CASE V.—A man was next exhibited, having more advanced syphilitic lesions than those which had hitherto been shown. The patient had a chancre in October, 1888, and in February, 1889, sore-throat and a general eruption, which in May of that year became papular and pustular. From October, 1889, until the beginning of the present year he was free from these symptoms, as a result of treatment. Dr. Taylor said that the occurrence of a tubercular syphilide fifteen months after infection was not uncommon. About the nose, and on the cheeks, neck, and arms were tubercular patches, showing a tendency to form rings. There were ulcerating syphilides on the legs. The tubercular patches caused some elevation of the skin, were of a somewhat coppery color, and on pinching up a fold of the skin, it was evident that the nodule involved the whole thickness. There was a nodule on the upper lip. If the only lesion were the patch at the side of the nose, one might at first sight take it to be lupus. Just below the lower lip, in the mental furrow, there was a large tubercle about the size of a silver quarter. The surface was warty and elevated at least one-fourth of an inch above the surrounding skin. Owing to the presence of a number of sebaceous glands, and as a result of the chronic inflammation and irritation, the tubercle had become converted into this papillomatous growth known as the "vegetating syphilide." It looks not unlike the dermatitis tuberosa which appears during the administration of potassium iodide, and even resembles slightly inflammatory ringworm, or a large flat "seed wart."

Treatment.—The treatment should be very active. The patches should first be washed with a five per cent. solution of carbolic acid, after which mercurial plaster should be constantly applied to them. Internally the following was advised:

℞.—Bin iodide of mercury . . . 2 grains.
Potassium iodide . . . . 6 drachms.
Water . . . . . 6 "
Compound tincture of cinchona, sufficient to make . . . 4 ounces—M.

Three teaspoonfuls daily, gradually increasing to six teaspoonfuls.

This is the "strong mixed treatment," the ordinary formula containing one grain of the biniodide, and four drachms of the potassium iodide. It is important to remember that if mental or physical depression supervene during the administration of potassium iodide, it is an indication to discontinue the drug immediately.

CASE VI.—The next case was an excellent illustration of the appearance of a small miliary papular syphilide occuring in the negro. The lesions presented a typical conical appearance and were copiously and universally scattered over the whole body. He had iritis, which is a frequent concomitant of this form of syphilide, and the inguinal glands were enlarged. Negroes very commonly exhibit extreme enlargement of the ganglia.

Treatment.—The eye should be protected from light, and a solution of atropine—four grains to the ounce—dropped into it every three or four hours. Inunctions of thirty grains of mercurial ointment were ordered, observing the precautions already mentioned in several previous lectures. Internally tonics should be taken, together with good food.

MEDICAL PROGRESS.

Prescription for Bronchitis.—For cases of acute bronchitis with "tight" breathing DR. ENGLE advises the application of from sixteen to twenty-four dry cups, and the administration of the following mixture:

R.—Tartar emetic	6 grains.
Spirit of Mindererus . . .	3 ounces.
Fluid extract of glycyrrhiza .	6 drachms.
Compound glycyrrhiza mixture (filtered) sufficient to make .	9 ounces.

Two teaspoonfuls of this in half a glassful of water should be taken every two hours, the meals being so arranged that they fall halfway between two doses of the medicine.—*Medical Summary*, June, 1890.

Prescription for Irritable Bladder.—DR. E. L. TUNSTALL recommends the following mixture in cases of irritable bladder:

R.—Potassium citrate	4 drachms.
Fluid extract of triticum repens . . } of each	1 ounce,
Tincture of hyoscyamus }	
Fluid extract of buchu . . .	½ "
Water sufficient to make . .	3 ounces.

One teaspoonful in a wineglassful of water three or four times daily.—*Medical Summary*, June, 1890.

Acute Œdema of the Glottis following the Administration of Potassium Iodide.—Having observed four cases of œdema of the glottis following the use of potassium iodide, DR. A. GROENOUW offers the following conclusions (*Monatshefte für praktische Dermatologie*, May 15, 1890):

1. In a few cases after the administration of potassium iodide œdema of the glottis, with dyspnœa, suddenly supervenes, and demands immediate tracheotomy.

2. This symptom is not produced only by the administration of large doses or by the long duration of its use; on the contrary, the dyspnœa may appear after a relatively small dose, and even within a few hours after the administration.

3. Other symptoms of iodism are often absent.

4. This œdema is probably due to an idiosyncrasy of the individual, and not to impurities in the drug.

The Treatment of Chlorosis.—DR. WILLIAM AINSLIE HOLLIS (*British Medical Journal*, May 31, 1890) writes that in the treatment of chlorosis (or, as he terms the disease, chloræmia) no drug has given such good results as the carbonate or the freshly powdered saccharate of iron. He advises the large doses of one drachm of either preparation given after meals. Under this treatment he has repeatedly observed the hæmoglobin increase 20 per cent. and more in the course of a week. If the stomach is irritable, these large amounts may, at first, produce nausea, which, however, usually subsides. If it does not, it is advisable to give the powder in an effervescent mixture. With this treatment the smaller the percentage of hæmoglobin the more rapidly is the iron absorbed. After the first week the increase of hæmoglobin takes place more slowly, and in all the cases under Dr. Hollis's observation it was impossible to increase the hæmoglobin more than 80 per cent. In most cases these large amounts of iron regulate the bowels, so that laxatives are not necessary. If constipation should occur, it can be overcome with cascara sagrada better than with any other drug.

Coincidently with the improvement in the amount of hæmoglobin there is a slight increase in the number of red blood-corpuscles.

The Treatment of Placenta Prævia.—DR. ALDERSON considers separation and removal of as much of the placenta as possible the most satisfactory method of treating the majority of cases of placenta prævia. The mere irritation of the operation is sufficient, in many cases, to stimulute the uterus to contraction, and thus to check hemorrhage.

If the membranes are ruptured, and the os dilated sufficiently to permit the safe introduction of the hand, and if the woman is not already exhausted by flooding, version is perhaps the safest, and certainly is the most rapid way of terminating labor. But if there has been much loss of blood, or if the patient is prostrated, delivery with forceps is safer, separating the entire placenta, if within easy reach.—*Provincial Medical Journal*, June, 1890.

Mixture for Chapped Hands.—According to the *Times and Register*, the following is a useful application for chapped hands:

R.—Menthol	12 grains.
Salol	30 "
Olive oil	30 minims.
Lanolin	1½ ounces.—M.

Apply twice daily.

Resection of Intestine at Three Points for Cancer of Sigmoid Flexure.—DR. THEODORE KOCHER, of Berne, reports a case of cancer of the sigmoid flexure in which the involvement of several loops of the intestine made it neces-

sary to resect the bowel at three places (*Correspondenz-blatt f. Schweizer Aerzte*, April 1, 1890). After exposing the cancerous mass one loop of the small intestine was clamped, cleansed, and divided. The mesentery was then cut through, and the divided ends of the bowel were united with a continuous suture. The second intestinal loop was treated in the same manner, the mesocolon was divided, and the cancerous mass was removed entire. This was followed by very free bleeding, which was, however, finally controlled. The seat of the growth was then temporarily packed with sublimate compresses, after which the cavity was irrigated with sterilized salt solution. The sutured small intestines were then replaced in the abdomen, but as it was impossible to suture the large intestine satisfactorily it was brought out of the wound, and a strip of iodoform gauze placed under and around it, the peritoneum being sutured beneath. Recovery was uneventful, and the patient returned to his home about seven weeks after the operation, though a small fistula persisted, through which only gas escaped.

The tumor was about the size of a child's head, and microscopic examination proved it to be cancerous.

In the same paper Kocher reports his results in the treatment by resection of gangrenous strangulated hernia, excluding cases in which general peritonitis was present at the time of the operation.

When carbolic acid was used, and before the principles of antisepsis were thoroughly understood, he performed 12 resections for this condition, with 9 deaths. One of these deaths was due to pulmonary embolism, one to sepsis, and seven to peritonitis.

Two resections were performed with zinc chloride as an antiseptic, one case recovering.

Then came the period of strict antisepsis with corrosive sublimate, with 13 resections and 11 recoveries.

To obtain the best results Kocher advises that the resection should be done through healthy tissue, the portion removed having approximately a wedge shape. Two continuous sutures are used to unite the divided ends of the bowel—a deep suture including a small portion of the mucous coat and a superficial suture through the serous coat only. If the suture does not unite the bowel properly, as in the above reported case, Kocher brings the sutured portion out of the wound and surrounds it with iodoform gauze.

The Cold Bath in Scarlet Fever.—The good effect of cold immersion in severe scarlet fever was well illustrated in a case related by M. DIEULAFOY at a recent meeting of the Paris Hospitals Medical Society. The patient, a girl sixteen years of age, on the sixth day of the fever was attacked by marked nervous symptoms, excitement, insomnia, and suppression of urine—the pulse ranging from 120 to 150, and temperature very high. On the eighth day her condition was very grave, the eruption had disappeared, the temperature was 105.6° F., pulse irregular and intermittent, and the prostration extreme. In spite of the fact that she was menstruating, Dieulafoy advised the cold bath, and after some delay the friends of the patient permitted the measure. She was placed in a bath at 75° F., which caused severe shivering, cyanosis, and coldness of the extremities. But the pulse-rate fell from 150 to 100, and the delirium ceased. At the end of fifteen minutes she was removed from the bath, which was repeated three times during the night, at higher temperatures. This treatment was continued up to the eleventh day, when the body temperature became normal. M. Dieulafoy advocated the bath in all malignant forms of fever, and its good effects in scarlet fever were endorsed by MM. Johel-Renoy and Duponchel, who had obtained similar good results. Dr. Huchard advised caffeine injections for the collapse.—*Lancet*, May 24, 1890.

Unusual Modes of Infection with Syphilis.—DR. R. W. TAYLOR reports a number of cases illustrating the variety of methods by which syphilis may be acquired (*Journal of Cutaneous and Genito-urinary Diseases*, June, 1890). The most singular of the series is the following:

A lady, aged thirty-six, in perfect health, lived with her husband, and with them a lady friend resided as a companion. In July, 1886, the mistress of the household complained of an ulcer on the lower right eyelid near the inner canthus, which gave her great uneasiness and inconvenience by reason of the constant lacrymation. When first seen by Dr. Taylor this lesion presented a characteristic nodular induration and a raw exulcerated surface. The corresponding ante-auricular ganglion was much enlarged, while those of the neck were less hyperplastic, though later they all became markedly enlarged and typically syphilitic. A diagnosis of syphilitic chancre was made at once, but the question of its source was then unanswerable. After much inquiry and questioning it was ascertained that the lady's maid had been suffering from syphilis for some months, and that just prior to the infection of her mistress she had had pharyngeal and labial mucous patches. All possible modes of mediate infection suggested by the case were examined into, and it was finally decided that infection must have occurred by means of a towel, for the servant after a time reluctantly confessed that she had several times wiped her mouth with the "corner of a towel."

The initial lesion on the lady's eye yielded kindly to treatment, and in due time was followed by general secondary manifestations. Under treatment these disappeared, and for about six months the patient passed from observation. Toward the latter part of this period she was very negligent in following the prescribed treatment, and when next seen she was in great mental distress, and told the following story: She had for two or three months suffered from sore mouth and tongue, but had faithfully used a gargle (bichloride, tincture of myrrh, and water) which had been given her. At irregular intervals she had used chewing-gum very freely during the day, and once or twice noticed, on removing it from the mouth, that a little blood adhered to it. On two occasions when she was thus chewing gum she had temporarily placed her bolus on some article of furniture, from which it had been taken by mistake and chewed for some time by her female companion. As she had received stringent instructions as to the prevention of the spread of the disease to her husband and her companion, she was on each of these occasions somewhat troubled in mind and on the alert. For two weeks her companion had complained of a sore just within the lower lip on the right side, which had failed to disappear

under the use of borax, alum, and other domestic remedies. The lady's friend was in total ignorance of the nature of her trouble, but stated that in brushing her teeth a few weeks before she had abraded the lip, so that it was painful, and that the sore thus produced had not healed. Examination revealed a typical indurated chancre of the lower lip and marked submaxillary and cervical adenopathy. In due time roseola and rheumatoid pains ushered in the secondary period of syphilis.

Other cases are reported showing that syphilis may be acquired while making an autopsy on a syphilitic subject; that it may be inoculated by a caustic-holder which has been used in the treatment of syphilitic lesions; and that handkerchiefs, bathing-suits, syringes, adhesive plaster, water-closet seats, pillows, and razors may each be the medium of infection.

The Abortive Treatment of Gonorrhœa.—Two papers were recently read upon this subject at the Society of Practical Medicine of Paris.

DR. MALÉCOT discussed the treatment by injections of nitrate of silver. He regards the prejudice against the employment of silver as unreasonable, if the salt is properly applied, but he considers the strong solutions dangerous, especially if used for several days in succession. They may provoke discharge of blood, and their too energetic action may diminish the subsequent elasticity of the canal. Furthermore, with the piston syringe the sphincter may be forced and the caustic be uselessly injected into the bladder. He therefore recommends the olive-bulb instillator, which is introduced as far as the muscular sphincter. The additional sensation of resistance here felt serves as an indication that the instrument has gone far enough.

The patient first urinates, then the canal is washed out with a feeble boric acid solution, and the instillation made—the first day in strength of 1 to 50, and the following days 1 to 100 or 1 to 150, the solution being retained in the urethra for two or three minutes. The irritant action is of short duration, and affects only the epithelial layer of the mucous membrane. It is recommended to wash out the urethra with some antiseptic solution in the intervals between the acts of urination such as the permanganate of potassium, resorcin, or bichloride, the latter not stronger than 1 to 10,000 or 1 to 20,000.

Dr. Malécot has obtained excellent results from the salicylate of mercury in strength of ¾ grain to 3 ounces of water, at a temperature of about 100° F. It is a strong antiseptic without being painful. Internal treatment is not wholly neglected, sandal oil, copaiva, etc., being given in the belief that they undergo a change in the economy by means of which they become germicidal. He has also followed Dreyfous in the employment of salol in daily doses of 1½ drachm with the same object in view.

Following out this plan, a recent gonorrhœa may often be aborted and without danger. Only violent inflammation of the urethra should cause one to suspend the treatment. In some cases, without known cause, the method fails.

DR. PICARD entered into the question of the efficacy and harmlessness of abortive injections of the nitrate of silver. If we examine into the action of a sufficiently concentrated solution of nitrate of silver we see that it acts upon the mucous membrane of the urethra just as the gonorrhœal virus acts, causing death and desquamation of the superficial epithelium. The difference between their actions, which explains the efficacy of the treatment, is the rapidity with which the silver acts, destroying the epithelium at once, while the virus requires several days to effect the same result. The success of the treatment therefore depends upon the promptness of its application. It should be made when the first symptoms appear—that is to say, before the appearance of pus. In practice it is at the time that the patient feels an itching sensation in the fossa navicularis, and perhaps notices a drop of clear fluid at the meatus, that the treatment must be instituted. A red meatus, with the lips swollen and everted, turgidity of the glans, and great pain, are contra-indications to the employment of the abortive method. If these parts are normal and the pus is not too abundant and thick, the silver may still be used. The solution he recommends is of a strength of 1 to 25 or 1 to 30. The pain occasioned is usually moderate. Twenty-four or thirty-six hours after the first injection, if the discharge persists, a second should be used, provided the parts are neither red nor painful. — *Journal of Cutaneous and Genito-urinary Diseases*, June, 1890.

Capsicum as a Counter-irritant.—DR. HENRY J. BUCK (*Lancet*, May 31, 1890) thinks that capsicum is one of best counter-irritants. He uses an infusion prepared by macerating a handful of the crushed pods in hot water for an hour. The liquid is then strained and bottled for use. The addition of a small amount of Cologne-water will prevent the infusion from decomposing. A piece of lint soaked in this, applied to the skin and covered with gutta-percha tissue, may be left in position for hours without fear of blistering. The application is particularly beneficial in cases of muscular rheumatism, acute torticollis, neuralgia, etc. In cases of "relaxed sore-throat" instant relief is often obtained by painting the uvula and pharynx with the infusion.

A stronger lotion may be prepared, which will produce sufficient irritation if simply painted upon the skin with a camel's-hair brush.

Patients should always be warned to wash their hands immediately after using the lotion, as it is, of course, exceedingly irritating to the eyes.

Potassium Permanganate in Snake-bites.—DR. ARKHANGELSKY states that he has successfully treated many cases of poisonous snake-bites by means of interstitial injections of a one per cent. solution of potassium permanganate, as recommended by Lacerda (*Meditzinskoïe Oborenïe*). Two or three syringefuls of the solution are injected above the bite, the point of the needle being directed toward the wound. At the same time a syringeful of ether is injected in the epigastric region, and brandy or wine, and ammonium carbonate are administered by the mouth. The permanganate injections are used by the author in cases of scorpion and spider stings also. In the latter forms of poisonous wounds this treatment acts more rapidly than any other in dispelling the symptoms.—*Provincial Medical Journal*, June, 1890.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author.

OREXIN.

ONE of the most judiciously conducted investigations recently reported is that of MARTINS (*Deutsche medicinische Wochenschrift*, No. 20, 1890) upon the value of orexin in stimulating the appetite. It will be remembered that Penzoldt introduced this drug, the chemical name of which is dihydrophenylchinazolin, as an agent of great use as a veritable stomachic, promoting appetite and digestion. The value of a medicament which could be depended upon for this purpose needs not to be emphasized. To test the claims made for orexin the studies here commented upon were made. Following the precedent of Rosenbach in that investigator's trials of hypnotic medicaments, Martins took every precaution to exclude the psychic factor which so often misleads in experiments of this nature.

In the first place, in order to prevent the patients from knowing that the state of their appetite was the subject of investigation, they were asked innumerable questions relating to all their organs and sensations, and the "endeavor was made, if possible, to concentrate their attention upon headaches, sleeplessness, or some other indifferent symptom, rather than the one under observation."

In the second place, observations were made upon the effect of pills of althea exactly resembling in size and appearance the orexin pills which were employed. Both kinds of pills were gelatin-coated and the patient was directed to swallow them as quickly as possible, so that no information could be gained through the sense of taste.

Other measures were also employed at the same time, such as ice-bags, mustard plasters, and the like, so that the patient did not know exactly what action was being inquired into. Another method was to give indifferent pills to patients suffering loss of appetite in such a way as to suggest that improvement of the appetite was the object sought. Patients who improved under this treatment were excluded from further observation, while those who did not improve were afterwards given the genuine orexin. In this way Martins was able to assure himself that whatever result was observable was due to the treatment and not to any influence upon the mind of the patient. In twenty-nine cases studied the appetite was improved in five, but not materially; in the other twenty-four the orexin appeared to be without influence upon the appetite. In five other cases in which orexin had appeared to have caused increased appetite, equally favorable results were obtained by the administation of pills which did not contain the drug. So far, then, as Martins's researches go, the predictions of Penzoldt have not been confirmed.

SPECIAL HOSPITALS FOR TUBERCULOSIS.

DURING the past few years the belief that the bacillus tuberculosis is the cause of consumption and not its result, has obtained so firm a hold in the minds of most advanced medical men, that the prevention of consumption by the isolation of persons suffering therefrom has become an important subject for discussion, not only among physicians but amongst those of the laity who are actuated by sufficiently philanthropic motives to be interested in the prevention of disease in their fellow men.

Not only is this true, but tuberculosis affects the rich and poor with such equal frequency and with such fatal effect that every man, woman, and child, in almost every part of the world, is forced, by necessity, to pay attention to its ravages.

Experiments recently carried out under the direction of Professor Koch, of Berlin, which have been supplemented by others performed in other portions of Germany, England, and this country, all show that the mortality of consumption amongst nurses taking care of such patients is greater than amongst a similar class in charge of non-tuberculous inmates

of hospitals. It has also been proved that it is possible to scrape the walls of a room in which a tuberculous patient has lived, and with that dust to produce tuberculosis by inoculation in rabbits, and we are speedily finding that the "white plague" of phthisis is to be prevented by isolation and hygienic measures. Further than this, it is not going too far to express the hope that scientific medicine may eventually crush out this disease as it has already limited the ravages of smallpox by the practice of vaccination.

In this city attention has been called to this subject very recently by the exhaustive and very able paper read before the College of Physicians by Dr. Lawrence Flick, in which he discusses the subject of hospitals for tuberculosis and describes the buildings and methods of administration of the various hospitals of this character which are found in England and on the Continent. He also dwells upon the importance of the establishment of hospitals for consumptives in this country, and we agree with him perfectly in the assertion that physicians and hospital superintendents have no right to place in the same wards with other cases persons suffering from pulmonary tuberculosis.

At the same time so many cases of this disease seek admittance to hospitals, and need medical care in many cases so acutely, that it is practically impossible to exclude them from the general hospitals as long as no special hospitals exist.

In view of these facts, it seems to us that a pressing need exists for the building of an institution of this character, and we can but express the hope that many of the charitably inclined people of this city will remember the necessities of this very large class and provide for them either during their lifetime or in their wills.

EDITORIAL CHANGE IN "THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES."

The Medical News is informed that upon the completion of the July issue, Dr. I. Minis Hays will retire from the editorial chair of the *American Journal of the Medical Sciences*, and that Dr. Edward P. Davis will be his successor. Under the guidance of the Drs. Hays, father and son, for sixty of its seventy years, the *American Journal* has attained a preëminent place among the world's medical periodicals, and has been the medium through which our greatest medical thinkers have laid before the profession their most important contributions. Dr. Davis receives his editorial charge in a position of high esteem both at home and abroad, and brings to his arduous duties the qualifications of ample ability, preparation, and energy. We bespeak for him the hearty support of the profession.

REVIEWS.

The Refraction of the Eye: a Manual for Students. By Gustavus Hartridge, F.R.C.S. Fourth Edition. Philadelphia: P. Blakiston & Co., 1890.

The first edition of Hartridge's little work on refraction appeared in 1884, and was soon exhausted. The fourth edition is enlarged, revised, and better able than its predecessors to fill the want the existence of which has been amply proven. In comparing this with the first edition we note forty-four more pages of reading matter and nine additional illustrations, besides new tables and some excellent plates of the eye-ground characteristic of high grades of myopia. There is also the correction of an error in omitting the words "having previously corrected any ametropia which may exist in his own eyes" (the observer's) which may be found under Retinoscopy, page 65 first edition. Much more space is allotted to the explanation of the use of the plane mirror in retinoscopy, and due credit given to Dr. Edward Jackson, of Philadelphia, for his article in *The American Journal of the Medical Sciences*, April, 1885, on this subject—the author showing his appreciation of this method by quoting the article at some length.

Difference of opinion exists among ophthalmic surgeons in the treatment of hypermetropia, as to how much, if any, latent hypermetropia should be allowed to remain uncorrected. The author advises the correction of the manifest and one-fourth of the latent, and this perhaps is as nearly correct for the average case as an arbitrary rule can be, but in the opinion of the reviewer, this law cannot be safely followed in low or even moderate degrees. The strength of the glass must depend on the power of accommodation, and it is well known that patients of the same age show great variation in this power. Hence it must follow that in order to derive the greatest benefit for the longest time from his glasses, each patient should have the strongest correction that can be comfortably worn, and that as seldom as possible should he be burdened with two sets. Another criticism might justly be made. On page 234 is cited a case of hypermetropic astigmatism, R., L. + 1^{c} ax. 180° = $\frac{6}{VI}$, as developed under atropine. "After the atropine had passsed away, R., L. — 1^{c} ax. 90° = $\frac{6}{VI.}$ This correction was given for constant use." According to the text it can only mean that the minus cylinders were ordered, yet this is incredible, for while vision might be temporarily improved, these glasses must induce tonic spasm of the ciliary muscle, asthenopia, and headache. No mention is made of mydriatics other than atropine except in one instance in a clinical record. The author might properly have included a comparison of atropine, duboisine, homatropine, hyoscyamine, and others.

The work is a valuable one to the student of ophthalmology. He will find in its pages clearly-expressed and well-defined directions which he can follow with safety and profit. The publishers' work is well done. Legible print and good thick paper are used, and no typographical errors are noticed.

DISEASES OF WOMEN AND ABDOMINAL SURGERY. By LAWSON TAIT, F.R.C.S. Edin. and Eng., LL.D. Vol. I. 4to., pp. 540. Philadelphia: Lea Bros. & Co.

THE profession is to be congratulated upon the publication of Mr. Tait's most recent opinions, experiences and results. His preface apologizes for the addition to the mass of medical literature by stating that his chief object has been to offer the results of his own experiences in as condensed form as possible. He also pays a fitting tribute to the ability of our American surgeons—"who have done so much to aid me in what has been accomplished." The present volume treats of the anatomy, physiology and surgical treatment of the uterus, ovaries, urethra, bladder, broad ligaments and Fallopian tubes. Mr. Tait reserves, however, the chapter upon Ovariotomy for Volume II. This volume, as indicated by the "Table of Organs Concerned," following the title-page of Volume I., will also discuss Abdominal Surgery proper, the organs being taken up in the following order: Surgery of the Pelvic Bones; Liver and Gall Bladder; Kidneys, Spleen, and Pancreas; Colon, Rectum, Cæcum, and Small Intestines; and the Breast. The introductory chapter discusses very thoroughly the anatomy of the external organs of generation, and the illustrations, though many of them are old, are well chosen. In speaking of laceration of the cervix and perinæum, Mr. Tait rather upbraids (and we think justly) those who claim that much of woman's ill health is *not* to be attributed to such accidents of parturition, but we cannot agree with the distinguished author in belittling Emmet's operation for torn perinæum in that it makes only a "skin perinæum," for it is just this latter objectionable feature which Emmet obviates. Mr. Tait's operation is well described and the two diagrams are fairly explanatory though his directions for its performance are scarcely sufficient for a beginner. The views formerly held by the author upon extra-uterine pregnancy, as well as his practice and favorable results, we are glad to find are unchanged.

Much of the book is devoted to tubal diseases and many valuable statistical tables are here incorporated. From these we find that in the removal of uterine appendages for salpingitis the author has a fatal result in but 2.5 per cent. of his cases. Mr. Tait does not find that electrolysis, which is being somewhat urged as a cure for uterine growths, is of much use. He says: "If it should prove that in the future uterine myomata can be cured . . . by any means short of a surgical operation, no one will rejoice more thoroughly than I shall. It is by no means clear . . . that the electric current is without harm, whether the diagnosis is correct or not, and it is equally without proof that it is sufficient to produce the effect desired."

The press-work and numerous illustrations are well executed, and many readers will undoubtedly anxiously await the appearance of the last volume.

A NEW MEDICAL DICTIONARY: INCLUDING ALL THE WORDS AND PHRASES USED IN MEDICINE, TOGETHER WITH THEIR PROPER PRONUNCIATIONS AND DEFINITIONS. By GEORGE M. GOULD, B.A., M.D. Philadelphia: P. Blakiston, Son & Co., 1890.

AN analytical review of a dictionary is impossible unless the book has been long used, but an examination of the work of Dr. Gould shows that it has been carefully prepared, is surprisingly complete, and fairly consistent in orthography. We say *fairly* consistent, for, in a few instances, there seems to be some hesitancy in the use of diphthongs; for instance, *peritonitis* is defined *inflammation of the peritoneum*, while *intraperitonæal* is defined *within the peritonæum*. *Epistaxis* is said to be *hemorrhage* from the nose, and on turning to *hemorrhage* we are referred to *hæmorrhage*.

Particular attention has been given to the words added to medical literature within the past few years as a result of the rapid development of the specialities and of bacteriology. In connection with the latter, Massé's invaluable tables of the principal characteristics of the more important bacilli and micrococci are given.

The "make up" of the book would, perhaps, have been better had these tables, as well as the tables of the nerves, bloodvessels and muscles, been relegated to the appendix; indeed, it is questionable if anatomical tables should have any place in a dictionary, for the data can be easily obtained from any text-book on anatomy. However, it is a mere matter of individual preference, whether one would rather look for the origin of a nerve or the insertion of a muscle in his dictionary or in "Gray." The information will be more quickly obtained from the former, but the details will be more complete in the latter.

It is also rather startling to find that the appendix is largely composed of a descriptive list, furnished by another author, of the mineral springs of the United States.

However, no book is exactly to the liking of every buyer, and what to us may seem minor faults, to others may be strong recommendations.

The dictionary, on the whole, is an excellent production. The publishers' work is particularly good, the volume being bound in such a manner that it will remain open at any page desired.

ESSENTIALS OF DISEASES OF THE SKIN, INCLUDING SYPHILODERMATA. ARRANGED IN THE FORM OF QUESTIONS AND ANSWERS, ESPECIALLY PREPARED FOR STUDENTS OF MEDICINE. By HENRY W. STELWAGON, M.D., PH.D. With 74 illustrations. Philadelphia: W. B. Saunders, 1890.

THIS is another one of the series which we have already noticed several times in the columns of THE MEDICAL NEWS, and, without any desire to repeat the praises which we have already sung, we wish to compliment Dr. Stelwagon upon the ease and grace with which he has concentrated a very large amount of information in a comparatively small space. Considering the price and the style of the book the illustrations are unusually good, and we doubt not but that it will rapidly become a favorite among those students who must pass an examination in dermatology before obtaining their degree. Sufficient attention is also paid to treatment to make the

book of value to the ordinary practitioner who does not care to wade laboriously through the larger works upon dermatology, which, of course, are far superior to the one before us as scientific guides.

Saunders's Question Compends: Essentials of Gynecology. By Edwin B. Cragin, M.D. 12mo., pp. 192. Philadelphia: W. B. Saunders, 1890.

The Saunders's Question Compends are already so well known that the one before us requires but few words. Like the others, it will assist the student in acquiring a large number of facts; but we fear facts acquired by this method are easily forgotten. However, if students will have compends, let them be good ones, and the "Essentials of Gynecology," it is safe to say, is one of the best in the series.

CORRESPONDENCE.

LONDON.

Dr. Sansom on "The Rapid Heart." Cystotomy for Tubercular Disease of the Bladder. Optic Atrophy in Tobacco Poisoning. Injuries of the Spinal Cord. Thrombosis of Longitudinal Sinus. Hospital Changes.

To the Editor of The Medical News,

Sir: The Medical Society, which is one of the oldest if not the oldest medical society in London, adheres to the long-standing custom of giving an annual entertainment in the shape of a *conversazione*, beginning with an oration by some prominent member of the profession; this year Dr. Sansom was chosen, and took for his subject "The Rapid Heart." His Lettsomian lectures before this society on valvular diseases of the heart are probably well known to many of your readers. On the present occasion he restricted himself to the consideration of cases in which undue rapidity of the cardiac action was the only morbid phenomenon, and he gave the following list of affections in which this condition is met with: 1. Graves's disease, in which the cardiac involvement is the chief source of danger. 2. The irritable heart of soldiers, noticed and described by Da Costa, one feature of which is that although the pulse-rate is perceptibly quickened the breathing remains normal or nearly so. This often results in cardiac hypertrophy or dilatation, and is peculiarly common in times of great political or social excitement. 3. The rapid heart of osteo-arthritis especially described by Dr. Spender, of Bath. 4. The rapid heart without noticeable morbid conditions, for our knowledge of which we are mainly indebted to Dr. Bristowe. He laid stress upon the fact that the latter cases are not paroxysmal, and that there is often no palpitation, and no marked distress nor discomfort, but that notwithstanding this apparent mildness the condition is serious and even dangerous, for of seven cases recorded by Dr. Bristowe, no less than five proved directly fatal. The pulse-rate in these cases varied from 110 to 260, and in many the onset was attributed to physical or mental overstrain; in others the symptoms developed gradually, and were associated only with vague dyspepsia; restlessness and insomnia were common. His chief recommendation in the way of treatment is the application of the continuous current over the region of the great nerve-centres.

At a recent meeting of the Clinical Society, Mr. W. H. Battle read an account of a case in which the bladder was opened for the cure of tubercular disease. The patient, a girl aged twenty years, came under observation while suffering from cystitis of several months' duration. Under an anæsthetic the urethra was dilated and the finger then detected an ulcerated patch near the base of the bladder, measuring 2 inches by 1½ inches. This was scraped with a Volkmann's spoon; subsequently the interior of the bladder was examined with the aid of the cystoscope and the ulcer was seen to be still present, though smaller. Scraping was again resorted to. Three months later, the improvement having been only temporary, suprapubic cystotomy was performed, the ulcerated portion exposed and scraped, and a solution of chloride of zinc (30 grains to the ounce), was applied to the surface of the ulcer. A catheter was then passed into the bladder through the urethra, the wound was dressed with iodoform and sal alembroth and a drainage-tube put in. The patient continued to make satisfactory progress and left the hospital on the fifty-third day after the operation; she has been seen since and remains well. The scrapings were examined microscopically and showed caseous degeneration of a tubercular deposit, but no bacilli.

Ever since tobacco amblyopia was definitely recognized as a distinct form of disease it has been very generally taught and believed that the smoker has only to give up his tobacco when his optic nerves will in time recover their function. A paper, however, by Mr. Lawford, recently read before the Ophthalmological Society, tends to shake our faith in this comforting dogma. He reported nine cases of optic nerve atrophy, which, in the early stages, closely resembled that due to tobacco poisoning. All the patients were men and smokers, and usually consumed a large quantity of tobacco. Treatment by abstinence from tobacco and the administration of nervine tonics led to no improvement, and in most of the cases the sight became progressively worse. There was gradual failure of vision with central negative scotomata for form and color, and the temporal half of the optic disc showed slight pallor. The chief point in which these cases differed from ordinary cases of tobacco amblyopia was in the peripheral limitation of the field of vision, the field in the latter affection being usually normal. Most of those who took part in the discussion regarded the cases as instances of tobacco poisoning, and Mr. Edgar Browne, who has already done much good work in this direction, pointed out that similar optic nerve disease in non-smokers was not known.

At the recent annual meeting of the Association of Medical Officers of Schools, the subject of the epidemic of influenza was selected for discussion, and Dr. Symes Thompson was invited to open the debate. The chief fact brought out by the discussion was the general unanimity of opinion that the disease is spread by contagion. Another point, perhaps not quite so clearly made out, is the comparative immunity of young children; thus at the Foundling Hospital, out of 317 inmates, 95 were affected; whilst at Haileybury, one of the public schools, 60 per cent. were attacked. All agreed that, apart from complications, keeping the patient in bed is the only

treatment necessary. The epidemic is now virtually at an end in London, but one still hears of stray cases, mostly second attacks, which, by the way, are at least as severe as the original attack.

For years we have been threatened with a commission on the hospitals of London, and at last there is a select committee of the House of Lords at work. The terms of the motion under which the committee was appointed were rather vague, and it is not very easy to see what is expected to be the result of the inquiry. Apparently those who have been loudest in their demands for investigation are by no means unanimous as to what they hope to gain by it, and thus far the evidence tendered and the questions asked do not make the object clearer. That a great deal of harm is done by the indiscriminate way in which hospital letters are given without inquiry as to whether the recipient is a deserving person cannot be doubted, but if the voluntary system is to be continued, and we are assured that no one wishes the hospitals to be placed under State control, it is not easy to see how we are to dispense with governors' letters. The subscribers must have something in return for their money, for the majority of them are by no means actuated solely by motives of charity. The chief complaint is from the general practitioners, who say that the gratuitous treatment in the hospital out-patient rooms deprives them of a number of patients, but it will be very difficult to adjust this undoubted grievance without endangering the facilities for clinical teaching.

An important and practical paper on injuries to the spinal cord was contributed by Mr. Anthony Bowlby at the last meeting of the Royal Medical and Chirurgical Society, subverting some general but erroneous beliefs upon the subject. He had records of eleven cases of complete crushing of the spinal cord in which especial attention had been paid to the condition of the tendon-reflexes. In all of these cases the limbs were quite flaccid, the tendon-reflexes were abolished and ankle clonus and rigidity were absent; in most of the cases the superficial reflexes were also lost, but not in all, and in some cases the superficial reflexes subsequently returned. In three instances where the crushing of the spinal cord was not complete, the reflexes were found increased. Mr. Bowlby draws the inference that when the deep reflexes are abolished there is presumably complete crushing of the spinal cord; that such cases are not amenable to operative interference; and that an operation is likely to be of use only when the deep reflexes are not wholly abolished and when, therefore, the cord is not completely crushed or severed.

In regard to the condition of the superficial reflexes and the date of their return, he said that in a considerable number of cases they did not return at all, and when they did, it might be either almost immediately or not for months. He attached no importance, for diagnostic or prognostic purposes, to the presence or absence of the superficial reflexes. His paper included ten other fatal cases of spinal-cord injury, and he was careful to point out that in all the twenty-one cases there was no compression of the spinal cord by displaced vertebræ or any other condition amenable to surgical treatment. He believed that the crushing of the cord took place at the moment of the injury by the temporary displacement of the bodies of one or more vertebræ, and that the displaced bone was spontaneously restored, so that compression was not kept up. He thought it possible that an injury short of complete crushing of the cord might cause the disappearance of the deep reflexes, but declined to make a dogmatic statement upon the subject.

Dr. Bastian, who a short time ago called attention to the fact that in total transverse lesions of the cord the reflexes were abolished, pointed out that in cases of disease of the spinal cord he had found that where tactile sensibility was abolished, but painful sensations persisted, the reflexes were not abolished.

Dr. Langley Browne, who had seen a good many cases of injury to the spinal cord, thought that in all cases where the reflexes are not wholly abolished the important thing is to prevent movement at the seat of injury, and he recommended the immediate application of a plaster jacket. He narrated some very satisfactory results where this mode of treatment had been adopted.

At the last meeting of the Clinical Society, Mr. Arbuthnot Lane described a case of complete thrombosis of the longitudinal sinus which was diagnosed during life. The patient was a child aged two years, who had a depressed fracture immediately above the lambdoid suture in the vicinity of the groove of the sinus. The depressed bone was partly removed and partly elevated, a vein being ligatured at its entry into the sinus, which, however, sustained no injury. On the second day after the operation convulsive movements appeared, first on one side, then on both; following the movements there was a condition of apparent paralysis, which was at first partial, but soon became general and was accompanied after a time with drowsiness, which soon developed into coma. The child died on the third day after the injury. There was no optic neuritis, from which fact it was inferred that neither lateral sinus was thrombosed; it was supposed that the clotting in the sinus was consequent upon the formation of a clot at the orifice of the vein that was ligatured at the time of the operation. On post-mortem examination thrombosis of the superior longitudinal sinus and of some of the superior cerebral veins was found, and as the oldest part of the clot was considerably in front of the fracture it was thought that it must have been independent of the original injury. Mr. Lane based his diagnosis on the symptoms of cortical irritation with subsequent paralysis and the known injury to a vein during the operation.

An unusual number of changes have taken place on the medical side of some of our hospitals quite recently. In fact, the current medical journals announce vacancies at no less than four. At Guy's Hospital the retirement of the senior physician, Dr. Pavy, has caused Dr. Hale White to become full physician after an unusually short period as assistant physician. He is by far the junior in years of all the full physicians at the metropolitan schools, and has been exceptionally fortunate in obtaining his promotion so rapidly. Dr. Sansom has succeeded Dr. Langdon Down at the London Hospital, and has had much longer to wait for his step, but at this hospital the assistant physicians have the very unusual advantage of having a considerable number of beds at their disposal. At Charing Cross Hospital the unexpected death of Dr. Julius Pollock, after a few days' illness from pleuro-pneumonia, has given Dr. Abercrombie the full physiciancy some years earlier than he would have attained it in the ordinary course of events; whilst a vacancy has also occurred at St. Mary's, by the

very sad suicide of the junior assistant physician, Dr. Walter Pearce. He had hardly been at work long enough to make a name for himself outside of his own hospital, but he was very highly esteemed by all with whom he came in contact. He shot himself a few days ago after seeing his out-patients at the hospital. He had been exceedingly depressed for some time past, and several years ago had had a similar attack, so that those who knew him best, though naturally greatly distressed, were not much surprised at the sad occurrence. At all the metropolitan schools provision is made for the retirement of the seniors either after twenty years on the full staff, as at the London, St. George's, and St. Mary's, or on attaining the age of either sixty or sixty-five years, as at most of the hospitals. It is difficult to say which is the best arrangement—the latter probably suits the juniors best, but it is very hard in some cases, as a man is often kept in the out-patient room until he is long past forty. All are agreed, however, that some retiring scheme is necessary, and, practically, both these plans work pretty well.

VIENNA.

To the Editor of THE MEDICAL NEWS,

SIR: Medical students abroad have the choice of various centres in which to work, each with its peculiar teaching and imparting its peculiar impression. For this reason the smaller places offer distinct advantages; as there the combined influence of the greater schools is felt, while in Vienna and Berlin nothing is recognized which has not first received the stamp of local approbation. In Vienna one hears of what is thought in "Deutschland," but always in contrast to the superior teaching of Vienna. The student who can spend, however, only a short time abroad, who knows what he needs to study, and who can confine himself to the proper number of courses, will find Vienna the best place, because the courses are numerous, conveniently situated, and various.

The clinics of Braun and Chrobak offer more material than those at the Frauen-klinik in Munich, but in other respects are not superior. Neither of these teachers has the energy of Winckel, and neither possesses his earnestness and simplicity of method. Their clinics are, perhaps, more effective because they are more formal, and partake more of the character of clinical lectures. At the Frauen-klinik, where the following method of teaching is carried out more consistently than here, each student is assigned a case, and he is questioned before the class; the latter learn by a natural process; they have the same deficiencies as the man before them, and as he learns they learn with him.

In the clinic of May 7th Chrobak brought before the class a case of vertex presentation complicated by prolapse of the cord, hand, and foot. The child being dead, and the reposition of the prolapsed members impossible, perforation and extraction by the cranioclast were performed. To the students such an operation is of incalculable advantage, especially, as in this case, where the reasons for the operation and the different steps are explained, but to the operator it offers anything but the opportunity for brilliant effect. It is tedious, fatiguing, repulsive, and the student with a limited obstetrical training cannot appreciate the difficulties which embarrass the operator.

The obstetrical wards are under the joint direction of Chrobak and Braun, and the latter, at one of his clinics at the beginning of May, reviewed the work in his department during April. There were three hundred and twenty-one women delivered, with but one death, and in this case the parturient was admitted with fever. Among these cases all the obstetrical operations, excluding the artificial removal of the placenta, were performed. He reported fourteen laparotomies in April, with one death.

The Poliklinik has accepted plans for a new building, to be begun immediately. There are to be three pavilions: one in which the clinics are to be held, a second for a general infirmary, and a third, with fifty beds, for children. There is to be a hydropathic institute and a bath-house for day patients. The present accommodations are limited and inconvenient. The cost of the new klinik is to be half a million florins.

NEW ORLEANS.

To the Editor of THE MEDICAL NEWS,

SIR: It is probably generally known that the greater portion of New Orleans lies below the level of the Mississippi River, and that but a few feet below the street level the soil is quite moist. In consequence of this there are no sewers, excepting a few private ones that are emptied by a steam force-pump. The surface water runs through foul-smelling gutters into more foul-smelling canals, and thence toward Lake Pontchartrain, into which it is emptied by drainage machines. On its course through the gutters the water is contaminated in various ways, and yet it is a common spectacle to see people sprinkling the streets with this foul water.

For flushing purposes, the Auxiliary Sanitary Association has established pumps at various places to force river water directly into the gutters. For obvious reasons artesian wells would be advantageous, and the Association has in vain solicited the public to subscribe the $10,000 necessary to bore the wells. At this stage the Louisiana Lottery Company has tendered the money, and a canvass is being made of the members of the Association regarding the advisability of accepting the gift. The company has also offered the Association $20,000 to expend in the construction of public baths, a long-entertained desire that has seemed impossible of realization, though their usefulness from a hygienic standpoint is unquestioned.

In consequence of the character of the soil, the houses are without cellars, the buildings resting on the ground or elevated a few feet, and they are more or less damp. With houses favoring a lowered vitality—aside from the effects of the climate—and the facility for dissemination of the bacillus tuberculosis that the use of the gutter water to wet the streets affords, it is not surprising that a study of the mortality statistics for the past five years shows that fourteen per cent. of the total mortality among the whites is due to tuberculosis—a death-rate of three per thousand of population. Among the negroes the mortality from this disease is nineteen per cent. of the total mortality, or six per thousand of negro population. The prevalence of the disease among the white population is by some explained by the fact that it is the general custom to employ negress nurses for children.

The absence of sewers, necessitating each house to have privies that are emptied by odorless apparatus, may have much to do with the low mortality from most of the germ diseases, though this immunity is greatly favored by the general employment of cisterns built above the ground, and the use of water from them or from the Mississippi River. Typhoid fever is an infrequent disease; and diphtheria was so until recently, but in the past three years there has been an increase in the annual number of cases—an increase that has been attributed to the influx during the winter months of northern visitors.

The recent enactment of the national quarantine law forbidding the admission of lepers into this country, and the discussion of the subject of leprosy at the conference of State boards of health at Nashville, bring this disease to mind. There is no evidence that leprosy is increasing in this State, and yet there is no law that would allow the isolation of the leper. In the century that the disease has existed in Louisiana no case of contagion is known, and to-day persons so afflicted are living with their families and not subjected to the additional affliction of separation from their friends. These people are liable to travel; and but a short time ago a case of leprosy was discovered in Jackson County, Mississippi, and isolated. He was originally a native of Louisiana. The mortality tables show one or two deaths a year from the disease, a fact that does not indicate an increase in the number of cases. Lepers throughout the State are induced to come to the Charity Hospital for treatment, and many remain there until death.

The Board of Health of Louisiana—and it is also the Board of Health of New Orleans—has just issued its biennial report for 1888 and 1889. It is well illustrated with drawings of the quarantine buildings and of disinfecting apparatus, and affords a clear idea of the means adopted to protect the State and the Mississippi Valley from the invasion of pestilence. The income from quarantine fees is over $50,000 per annum, and the Board has felt justified in making a reduction of about thirty per cent. in the fees for each class of vessels. It is a matter of surprise that the merchants of New Orleans, like those of New York, do not complain of this tax on their commerce, and urge the federal government to continue, without fees, a system that is as beneficial to the interior States as to those employing a quarantine system.

The City Council has just sent to the Legislature a protest against continuing the custom of confining the indigent insane in parish jails, and urges that the city be relieved of the expense of caring for this class, and that the State assume their maintenance in the asylum at Jackson, or elsewhere. As that institution is filled to its utmost capacity, and the State is hardly able to construct new asylums, there is but little hope of an improvement in this matter.

Referring to the charges against Passed Assistant Surgeon Armstrong, in charge of the Marine Hospital here, that were published in THE MEDICAL NEWS of the 7th, the Secretary of the Treasury finds that the 1st, 2d, and 4th (*b* and *c*) charges are sustained; the other charges are not sustained. Dr. Armstrong is to be superseded, to remain as assistant to his successor, and not to have command of a station for a year.

This is a surprise to Dr. Armstrong's friends, who had understood from the Surgeon-General that while Dr. Armstrong was a strict disciplinarian he was not in the wrong in the matter.

Dr. Armstrong feels that so great an injustice has been done him in the matter, that he will resign his commission.

S. T. ARMSTRONG.

CINCINNATI.

To the Editor of THE MEDICAL NEWS.

SIR: The people of Cincinnati realize, more than ever before, the importance of a properly conducted health department. It is not three months since the present Health Officer, Dr. J. W. Prendergast, received his appointment, but in that time he has so completely revolutionized matters under his control as to call forth the highest praise from the public and approval from the Academy of Medicine. The changes have been accomplished, for the most part, by personal activity in matters usually assigned to subordinate officers and assistants.

The first and most important movement was directed against improperly conducted dairies. Many dairies were found in a most appalling condition, and fully ninety per cent. were lacking in cleanliness. In some the cows stood up to the knees in filth. Many of them had not been liberated from their stalls for more than a year, and they were fed chiefly on distillery slop. An existing ordinance forbidding, under penalty, the having or offering for sale "milk from cows that have not been kept upon and had the use of good, wholesome pasturage at least twelve hours in every twenty-four during the months of May, June, July, August, and September of each year," had not been strictly enforced.

Examination of the milk from these dairies revealed, as might be expected, an even more alarming state of affairs. Milk from cows manifestly diseased and condemned, of which there were a considerable number, contained large quantities of blood, pus and filth. In his examinations the Health Officer obtained the assistance of the curators of the Cincinnati Hospital, headed by Dr. Leonard Freeman, Demonstrator of Bacteriology in the Medical College of Ohio, and the examinations were conducted in the laboratory of the hospital.

Eighteen specimens of milk were obtained from sixteen different cows in as many dairies. Five of the specimens contained tubercle bacilli in varying numbers. One sample from a slop-fed cow, which had not been out of her stall for several months, was apparently of ordinarily good quality, and even when examined with the microscope without the use of staining fluids, showed no impurities, but when properly prepared was found to be a veritable culture-soil for the bacillus tuberculosis. One cover-glass preparation contained several clusters of closely crowded bacilli, nearly all of which contained spores, and they were so numerous as to represent almost a pure culture of extraordinary size and thrift.

In the revelations which have been made there has been no attempt to reflect unfavorably on the official career of previous health officers, and no such reflection should be made. The fault lies not with those who have occupied the office, each of whom has been, so far as the writer is informed, a competent and reputable

member of the medical profession; the fault lies with the city government. The growth of the Health Department has long since fallen behind the growth of the city, and the fact has not been sufficiently appreciated. At present the office is but third-rate in rank and salary. With nearly 350,000 inhabitants, Cincinnati should demand that her Health Officer devote his entire time and attention to the duties of the office, and the saving of life and health which would result would amply justify the expense.

The Academy of Medicine will adjourn June 30th until September 1st, for the usual summer vacation.

A microscopical society has recently been formed by a number of the younger members of the profession who are actively engaged in microscopic work. The society has at its head Dr. J. Eichberg, president, and Dr. A. C. Poole, secretary, and will be a branch of the Ohio State Microscopical Society.

The Cincinnati delegation to the American Medical Association was larger than that from any other city, numbering more than twenty.

NEWS ITEMS.

Fiske Fund Prize.—The Trustees of the Fiske Fund Prize of the Rhode Island Medical Society have awarded a prize of $300 to Dr. Edward Martin and Dr. H. A. Hare, of Philadelphia, for an essay on "The Treatment of Wounds and Obstruction of the Intestines," and a prize of $300 to Dr. Philip Coombs Knapp, of Boston, for an essay on "The Pathology, Diagnosis, and Treatment of Intercranial Growths." For 1891 a premium of $300 is offered, under the usual conditions, for the best essay on "The Etiology, Pathology, and Treatment of Diseases of the Hip-joint."

Pennsylvania State Medical Society.—The Pennsylvania State Medical Society held its fortieth annual session in Pittsburgh on June 11th, 12th, and 13th, and these officers were elected for the ensuing year: President, Dr. Alexander Craig, of Bucks; Vice-Presidents: Drs. F. H. Van Valzah, T. McKennan, W. S. Foster, and S. D. Bell, respectively of Mifflin, Washington, Allegheny, and Butler; Treasurer, Dr. George B. Dunmire, of Philadelphia; Permanent Secretaries: Drs. W. B. Atkinson and Charles W. Dulles, of Philadelphia; Recording Secretary, Dr. Israel Cleaver, of Berks. Reading, and the first Tuesday, June 7, 1891, were selected as the place and time for the next meeting. The committee in charge of the legislation for a State Board of Medical Examiners reported and read the names of those who had voted for and against the bill in the last Legislature. It was decided that the presidents of the State and county societies should constitute a legislative committee, "to secure the passage of a medical law that will give protection to the people of this State against incompetent practitioners of medicine." After much discussion, the following resolution was passed: "That it is the sense of this Society that the medical superintendents of our State insane asylums shall be restricted exclusively to the treatment of the insane inmates, and that one or more female physicians should be appointed, whose duty, under the control of the superintendent, shall be to have charge of the female insane patients, and we urge the Legislature to enact such laws as shall make these reforms obligatory." The meeting was a very successful one, over two hundred delegates being present.

Dr. Warburg, the inventor of the "tincture" of antimalarial renown, is said to have reached the age of eighty-six years, and to be in great pecuniary distress. An appeal on his behalf has been published in England.

A Revolt at the Bicetre Asylum.—On May 26th the great Parisian asylum for the insane witnessed the strange sight of a rebellion of its inmates. The rebellion was begun by a maniacal patient bursting the bars of his cell and then releasing forty others. They attacked and drove back their guards, and then proceeded to ransack the quarters of the keepers, after which they kept up the fight quite fiercely until the guards got access to the water-hose and turned it on them; this frightened and cowed the rebels so that they retreated and were one by one returned to their cells.

Dr. Oliver Wendell Holmes has given us a characteristic sentiment in favor of an International Copyright code. He says that literary men are "the soft-handed sons of toil," and further remarks that he cannot see "that a callus on the palm confers any better claim to fair treatment than a furrow in the forehead, and an aching in the brain."

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JUNE 10 TO JUNE 17, 1890.

By direction of the Acting Secretary of War, GEORGE M. STERNBERG, *Major and Surgeon*, will, in addition to his present duties, perform the duties of the Post Surgeon at Fort McHenry, Maryland, during the absence of that officer on leave.

By direction of the Acting Secretary of War, JOHN DE B. W. GARDINER, *Captain and Assistant Surgeon*, having been found incapacitated for active service by an Army Retiring Board, will proceed to his home.—Par. 21, *S. O. 135, A. G. O., Washington*, June 10, 1890.

CRAMPTON, L. W., *Captain and Assistant Surgeon.*—Is granted leave of absence for one month, to take effect the 15th instant.—Par. 5, *S. O. 75, Department of the Missouri, St. Louis, Mo.*, June 9, 1890.

APPEL, AARON H., *Captain and Assistant Surgeon* (Fort D. A. Russell, Wyoming).—Is granted leave of absence for one month, to take effect on or about June 15, 1890, with permission to apply, through Headquarters Division of the Missouri, for an extension of one month.—Par. 4, *S. O. 42, Headquarters Department of the Platte, Omaha, Neb.*, June 10, 1890.

ORIGINAL LECTURES.

ENUCLEATION OF GOITRE.

A Clinical Lecture
delivered at the Jefferson Medical College Hospital,
March 22, 1890.

BY W. W. KEEN, M.D.,
PROFESSOR OF SURGERY.

GENTLEMEN: I shall show you to-day a case of goitre in a woman with the following history: She is thirty years of age, an American by birth. Six years ago she noticed that breathing after exertion became difficult, and three months later she discovered a slight swelling in the neck. This swelling has increased in size only gradually, except for two or three months after each of her two labors, when the increase was quite rapid. This statement is in consonance with the fact that in many women there is increased fulness of the thyroid gland after maternity. The tumor is not painful. The urine is straw-colored and contains a doubtful trace of sugar, some pavement epithelium, but no albumin.

The following measurements have been taken: Circumference of the neck 16¼ inches. The horizontal arc of the tumor, from side to side, is 7¾ inches, subtending a chord of 4¼ inches. The horizontal arc from the middle line to the right border is 4½ inches; from the middle line to the left border 3¼ inches. The vertical arc is 6 inches; its chord 3¼ inches. The tumor feels distinctly cystic and resilient, but it is not markedly lobulated. The larynx has been examined by Dr. Jones and the vocal cords found to be normal, and there is no paralysis. I should add that it is through the courtesy of Dr. Hearn that I have the opportunity of showing you this patient.

There are three kinds of goitre: First, we have exophthalmic goitre, which heretofore has been a non-surgical affection, and is accompanied with enlargement of the heart, rapid pulse and protuberance of the eyeballs. This form has been successfully operated on recently, but the number of cases is too small to generalize from. Second, we have parenchymatous goitre, in which the gland tissue proper of the organ is involved. This makes a hard dense fibrous structure. Third, we have the form which I think is present in this case—a cystic goitre, which is really a fibro-adenoma with one or more cysts. In addition to these goitres, properly so called, we have the various cancerous enlargements of the gland, which are necessarily more serious than those which I have mentioned.

The diagnosis of goitre is usually easily made, but the variety is not always so readily determined before operation.

The medical treatment of goitre is unsatisfactory. Sorbefacient and irritant ointments and internal remedies have given practically but little result. In the surgical treatment of this affection several methods have been employed. The first method that I shall allude to is that of injection, either of the ordinary tincture of iodine, or as proposed by Sir Morell Mackenzie, of the tincture of the chloride of iron, the object being to convert the enlargement into an abscess. I do not believe in either of these methods, especially since the splendid results of operations which have been reported by Socin and others. In the light of these reports, I think that it is useless to talk of the injection of any fluid into these tumors. It is a procedure attended with danger of septic infection, and is painful, tedious, and uncertain in its results.

Of operative procedures proper, there are three. The first is evacuation. In some cases, especially of large immovable masses, this will do a great deal of good. It consists in opening the various loculi, whether cystic or solid, and peeling out their contents. The second method, and the one which I shall try in this case, is enucleation. It consists in cutting down to the cyst itself and enucleating it as we would any other cystic growth. This method has been advocated especially by Socin, of Switzerland, and his cases have been reported by Keser, his assistant. The third method is extirpation, which is the most dangerous of all, both as concerns its immediate and subsequent results. In 1871 Dr. Green, of Portland, Maine, reported six cases of this kind, and it surprised the surgical world that he was able to report so many. Since that time, and more especially in the last few years, a revolution has taken place in the surgery of the thyroid gland. Billroth has reported a large number of cases in which he has had remarkable results. It has remained for Kocher, of Switzerland, to give the most extraordinary figures. In a paper published in the *Correspondenzblatt für Schweizer Aerzte*, January, 1889, he reports 250 cases of extirpation. His results are astonishing. Of the 250 cases 25 were cases of cancer. Of this number 4 died, a mortality of 17 per cent. Of the remaining 225 non-cancerous cases, 223 recovered and only 2 died, a mortality of only 0.8 per cent. Socin in 59 cases of evacuation and enucleation had only one death. This occurred a short time after operation and was due to hæmorrhage. You can imagine how great the hæmorrhage was, when I tell you that during the operation 170 ligatures were employed. Years ago I saw a case of goitre operated on in this city in which the hæmorrhage was enormous, and the patient died three days afterward.

I have here some drawings from Kocher's paper published in Langenbeck's *Archiv* for 1880. The incision which he recommends in extirpation is an angular one, vertical in the median line and then extending outward over the larger portion of the growth. If necessary, this can be converted into a Y-shaped incision by an oblique cut on the opposite side. In operating it is the veins which give by far the greatest trouble. In this first in-

cision the external jugular will probably not be interfered with, but the anterior jugular, another vein called by Kocher the oblique jugular, and the anterior communicating branch will be cut. These are to be tied with double ligatures and the vein divided between them. We next come to the deeper vessels. We have a superior communicating vein going from the superior thyroid vein of one side to that of the other. There is also a deep anterior communication connecting the deep thyroid veins of each side. There is not only a superior thyroid, but also an accessory superior thyroid. In the same way there is an inferior thyroid and an accessory inferior thyroid. Then we have, what is very common, a still lower thyroid vein, the vena thyroidea ima, with an accessory vein to it. These veins are to be divided methodically. The order in which the three superficial veins are tied makes little difference. The fourth vessel to be tied is the superior thyroid; fifth, the accessory superior thyroid; sixth, the superior communicating; seventh, the thyroidea ima; eighth, its accessory; ninth, the inferior thyroid; tenth, its accessory; and eleventh, the inferior communicating.

But there are also arteries as well as veins which require attention. It is principally at the inferior thyroid that trouble is apt to be met with. This is because of its relation with the recurrent laryngeal nerve. The inferior thyroid, as you know, arises from the thyroid axis, goes behind the carotid and the sympathetic nerve, having in front of it the superior ganglion of the sympathetic, from which goes the cardiac nerve. The artery then goes behind the recurrent laryngeal nerve and passing under the tumor toward the middle line, finally plunges into the gland. In tying this artery there is danger of wounding the sympathetic or the recurrent laryngeal nerves. If the latter is destroyed it produces paralysis of the vocal cord of that side, but does not necessitate tracheotomy. If both are injured it becomes necessary to do tracheotomy, as the glottis closes.

The only way to avoid this injury to the nerve is *to isolate absolutely* the vessel before it is tied. In goitre this artery not seldom becomes as large as the carotid.

Another difficulty is that the recurrent laryngeal nerve is very tightly adherent to the gland on its posterior surface in the groove between the œsophagus and trachea. If the gland is drawn over to one side, the nerve may be pulled into a loop and injured, causing paralysis of the vocal cord. It is important to keep close to the tumor at this point.

I have here some statistics taken from Keser's paper, published in 1887. The number of cases operated on was 59. Of these, 5 underwent total extirpation, 17 partial extirpation and 37 enucleation. It was found that in 9 of the partial extirpations, enucleation could have been performed. The ages of the 59 patients varied between twelve and seventy years. There was only one death. In 11 partial extirpations, the histories of which were followed, there was return in 5. In 21 enucleations there was return in only 3.

The dangers of extirpation are immediate (as from hæmorrhage) and remote. The remote dangers are important. These dangers have been explained by the experiments of Horsley. In cases of atrophy or destruction of the thyroid gland its function is, of course, abolished. The function of this gland seems to be a two-fold one. It presides in some obscure way over the nutrition of the mucous tissues of the body, and in the second place it largely controls the genesis of the blood. The complete extirpation of the gland is liable to be followed by great anæmia and a condition which is called myxœdema or cachexia strumipriva. In this curious condition the body becomes bloated, the eyelids hang in folds, the face is like that of a person dropsical from Bright's disease, but the exudation is not soft but hard, and results from the development of mucous tissue. After a time, the hair drops out and mental changes occur, finally resulting in crétinism. This is often seen in Switzerland in connection with goitre. In these cases the speech is slow and faulty, mental operations become sluggish, albumin appears in the urine, and finally death closes the scene. Another curious occasional result is that peculiar muscular tremor known as tetany. Myxœdema and tetany are not apt to occur in those cases in which a portion of the gland is allowed to remain. This fact has led to enucleation of the goitre in preference to extirpation of the whole gland, and lately to the recommendation by some that a part of the gland should be transplanted. This has been suggested by Schiff and Kocher, and has recently received the approval of Horsley. The operation consists in taking a part of the normal thyroid gland of some animal, as a sheep, and transplanting it into some part of the body before operation, as, for instance, into the abdominal cavity. The results of these operations have not yet been published, but, as I have stated, they have received the approval of so able a surgeon and experimenter as Horsley, which is a great point in their favor.

In this case I propose, if possible, to do enucleation and not extirpation. In enucleation we avoid two of the dangers of extirpation, the immediate danger of injury to the recurrent laryngeal nerve and the remote danger of myxœdema or tetany. Here a large portion of the left lobe appears to be in good condition, and I shall try to preserve it.

In some cases it is necessary to do tracheotomy, but always avoid it if possible, for the moment you open the trachea you have a septic wound, as all the air entering and passing from the lungs passes over the wound.

You observe the peculiar breathing which the patient shows, and also the fact that she does not take ether well. I first make my incision through the skin and ligate all the veins that appear. The layer of gland tissue which overlies the cyst in these cases may be very thin or it may be as thick as one-half or three-fourths of an inch. I shall cut through this tissue until I reach the cyst. I now come to what I think is the cyst wall. I ligate the veins that appear on its surface, tying every vessel that would be apt to bleed. I now find, however, that it is not the cyst wall, but glandular tissue, almost one-fourth of an inch of which I must cut through before I reach the cyst. On opening this, a quantity of dark-colored fluid is discharged. It is easily seen by those who are near that the cyst-wall can be readily distinguished from the gland tissue. The cyst, as you see, is separated and removed without difficulty, with but little bleeding. There is quite free hæmorrhage from one rather large vessel at the bottom of the cavity, but this is now controlled after some little trouble. I shall not close the wound until satisfied that every bleeding vessel

is tied. The number of ligatures used by Socin varied between twenty-four and sixty. In this case I have used thirty-seven. I have not at all interfered with the left lobe of the gland, which, however, is only slightly enlarged. As there is no further bleeding I apply deep catgut sutures to bring together first the cyst wall, then the muscles, and lastly the skin, by superficial sutures of silk, inserting a rubber drainage-tube and also a bundle of horsehair. The wound is then dressed in the ordinary manner.

NOTE.—The patient had had a troublesome cough for some days before the operation. This was very markedly increased immediately after the operation. She was also uncontrollably restless, and so displaced the dressing that the wound was exposed and became infected within twenty-four hours; moderate suppuration and considerable fever followed, the temperature rising to 104.2°. For six days she was seriously ill. The sutures in the vertical incision were removed, the wound washed out with bichloride solution and ample drainage secured. Alcohol was freely given. She then began to improve; in ten days the temperature became normal, and she left the hospital, after three weeks, entirely recovered.

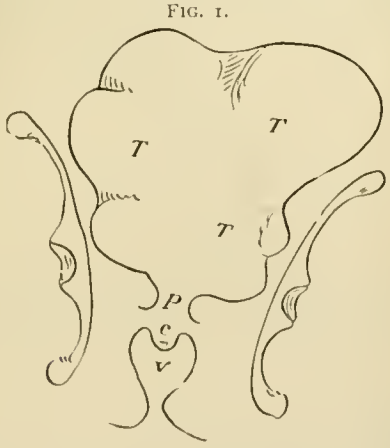
SUPRA-VAGINAL HYSTERECTOMY.

Hysteromyomectomy with Suspension of the Stump in the Lower Angle of the Abdominal Incision.

BY HOWARD A. KELLY, M.D.,
GYNECOLOGIST TO THE JOHNS HOPKINS HOSPITAL, BALTIMORE.

THE method here proposed[1] is limited to cases conceded to be most favorable for operation—those in which there naturally exists a pedicle, or in which it is possible to form a pedicle below the tumor masses. I do not wish to consider atypical cases, in which total ablation of the uterus (panhysterectomy) is called for, or those in which the uterus

FIG. 1.

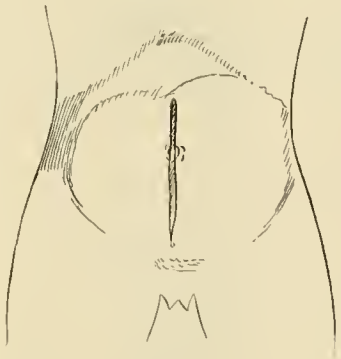


T T T, tumor. *P*, pedicle. *V*, vagina in section.

from fundus to cervix is a mass of fibroid tumors. I also purposely avoid the important question as to the best method of forming a pedicle when the broad ligament is choked with fibroid tumors. Fig. 1 is a generic representation of the class under discussion.

I have adopted in these cases an original method combining the advantages and eliminating many of the dangers of Hegar's and Schröder's methods—the ordinary extra- and intra-peritoneal methods.

FIG. 2



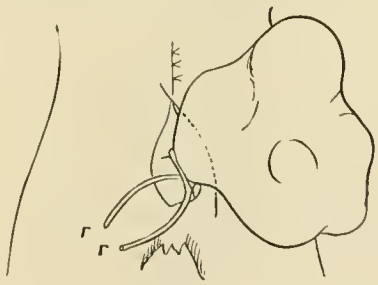
The operation consists of seven steps, as follows:

First. A long incision in the linea alba (Fig. 2) for the delivery of the myomatous uterus.

Second. The elevation of the tumor until the pedicle is brought into view for treatment by tying the broad ligament structures, or for enucleation of tumors from the broad ligament until a pedicle is formed, when the rubber ligature is applied and tied tightly, controlling the circulation. (Fig. 3.)

Third. The tumor is cut away from one to two inches above the rubber ligature (Fig. 4), by first

FIG. 3.



Tumor delivered. *r r*, rubber ligature in place and ready to be drawn tight. Dotted line shows the incision through the peritoneum.

splitting the peritoneum and then cupping out the upper face of the stump, cutting with each stroke down toward the vaginal canal.

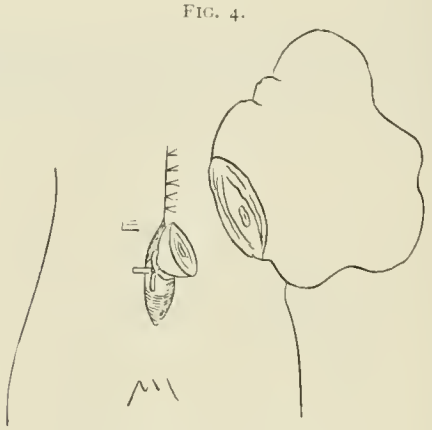
The cervical canal must next be carefully dissected out and its site well cauterized.

Fourth. This consists in the closure of the raw face of the stump by uniting the opposite sides by means of a continuous buried suture of catgut as seen in Figs. 5 and 6. Fig. 5 represents the appearance

[1] See American Journal of Obstetrics, April, 1889.

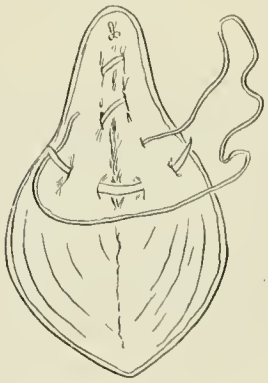
seen upon looking down on the stump from above, Fig. 6 being a vertical section through the cervix.

Fig. 4.



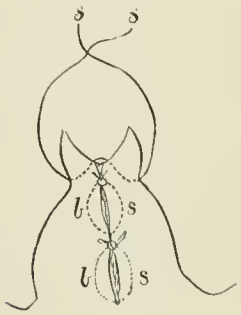
Tumor separated from pedicle.

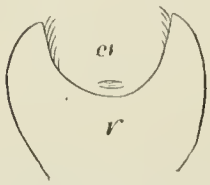
Fig. 5.



Method of closing upper raw surface of stump by means of a continuous buried suture.

Fig. 6.



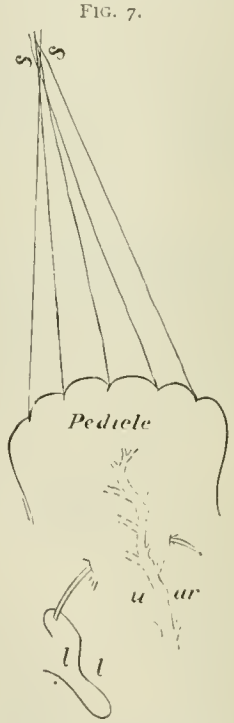


Stump united up to last row of interrupted surface-sutures, *S.S.* *b s*, last rows of buried sutures. *V*, vagina. *c v*, vaginal cervix.

The last row of sutures, which brings the peritoneal surfaces into apposition, is of interrupted silk sutures, with the long ends left uncut, for a purpose to be described later. All of these sutures, buried and superficial, must be applied with the view of controlling the circulation as well as securing approximation. They must, therefore, be drawn tight, and must encircle any vessels in view.

Fifth. After the surface of the stump has thus been closed and there remains nothing of the wound but the linear union of the peritoneal surfaces, the rubber ligature is cut away, and the lips of the wound are carefully observed. If there is any persistent oozing the nearest uterine artery must be ligated. This is accomplished by grasping the long ligatures and pulling the stump to the right or left, exposing the site of the left or right artery. A stout needle armed with a catgut ligature is then swept boldly through the side of the stump, well below the sutured area (Fig. 7) and tied, thus cut-

Fig. 7.



Ligation of left uterine artery. Pedicle is pulled toward the right by means of the long interrupted silk sutures *S S*, while the needle carrying ligature is passed under the uterine artery.

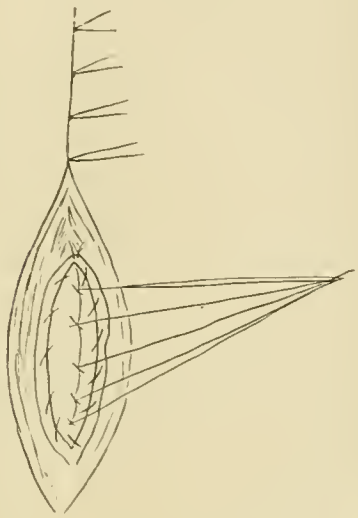
ting off all communication between the artery and the stump.

Both arteries may be treated in this way without any danger of destroying the vitality of the stump. If, however, there should be no flow of blood from the closed lips of the stump, the fifth step may be omitted.

Sixth. The abdominal incision is closed down to

the stump, putting in a drainage-tube, if needed, well above the stump. Following this the parietal peritoneum of the abdominal incision is united to the peritoneal coat of the stump, below the lips of the stump, by means of a continuous catgut or silk ligature (Fig. 8); and in this way the stump is separated from the peritoneal cavity.

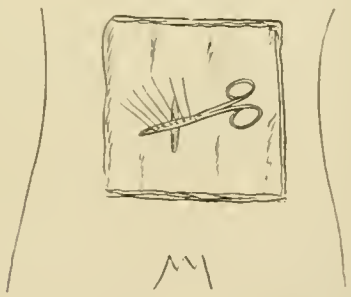
FIG. 8.



Showing union of the peritoneal surface of the stump to the parietal peritoneum.

Seventh. The wound is dressed with some dry antiseptic powder, or simply packed under the edges of the skin, around the suspended stump, with antiseptic gauze. Finally, a large square of gauze, six or eight folds in thickness, with a small slit in it, is prepared, and the long ligatures which unite the peritoneal lips of the stump are pulled through the slit. These are lifted well up, and grasped by a pair of long Keith's forceps laid horizontally on the body (Fig. 9).

FIG. 9.



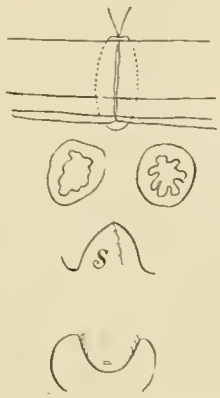
Dressing applied. Interrupted sutures of the surface of stump are brought through a hole in the gauze and grasped by forceps.

This dressing serves effectually to keep the stump from pulling back into the abdomen, and the operator has at all times full control of it at a moment's notice in case of accident. This gauze can be changed as often as soiled. Once every two or three days is usually sufficient. The silk sutures uniting the peritoneal lips of the wound finally either come away or are cut loose and pulled out in about ten days.

The small pit which is thus left in the lower angle of the abdominal wound over the stump rapidly fills by granulation.

This method has distinct advantages over internal or external methods commonly in use. It is better than dropping the stump back among the intestines (Fig. 10). By the new method hæmorrhage is not

FIG. 10.

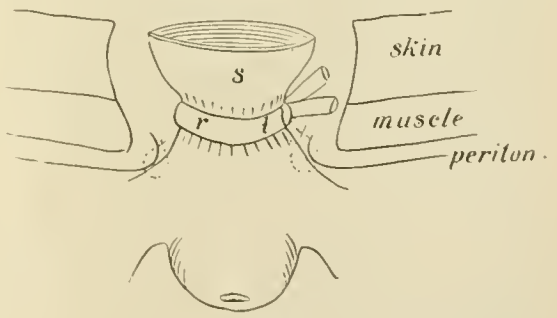


Intra-peritoneal treatment. Stump *S* dropped back into peritoneal cavity and abdominal walls closed above.

dangerous, being at all times under control. The danger of sepsis is also removed, a danger to which large numbers of cases have succumbed after the intra-peritoneal treatment of the stump.

It is better than the common external method (Fig. 11), because, in the first place, it is there

FIG. 11.



Extra-peritoneal treatment of stump *S*, which sloughs off at the rubber ligature *r l*. The union of the peritoneum of the stump to that of the abdominal walls is shown by the dotted circles.

necessary to elevate even a short pedicle far enough to attach the parietal peritoneum *below the rubber ligature*. By my method the attachment is higher, and the method is, therefore, better for short pedicles, doing away with a traction which is often excessive.

Again, when the rubber ligature is left on, it is impossible to limit the depth of the slough which takes place as the distal end drops off, and it will readily be granted on general principles that a method which constricts any part of the body, and waits for it to drop off by sloughing is a coarse and unscientific means of performing an amputation.

THE PROPRIETY OF THE REMOVAL OF THE APPENDIX VERMIFORMIS DURING THE INTERVALS OF RECURRENT ATTACKS OF APPENDICITIS.[1]

By FREDERIC S. DENNIS, M.D.,
VISITING SURGEON TO BELLEVUE AND TO ST. VINCENT'S HOSPITALS, NEW YORK.

The question propounded in the title of this paper is a new one in surgery. Its solution cannot be made at once. The entire subject must first be considered in the light of aseptic surgery, and, having discussed the question from that point of view, the operation must be examined into as to its propriety in certain cases. A definite answer must be postponed until new data and recent clinical experience have afforded us more reliable information from which to judge the expediency of such an important surgical procedure. The propriety of excision of the appendix can be discussed, however, from a theoretical point of view, and reference can also be made to the few reported cases, and from such data some knowledge can be obtained which will at least throw light upon this hitherto unexplored field of operative surgery. The entire subject of iliac inflammations is fraught with great interest from many points of view. However attractive these inflammations may appear, the discussion in this paper is restricted to one single question in regard to the whole subject, and that is, Is the surgeon justified in excising the appendix after recovery from one or many attacks? The question of removal of the appendix during an interval of quiescence cannot be answered dogmatically. I shall endeavor to demonstrate that the operation as routine treatment in all recurrent cases is unsurgical, and that only in rare cases is it indicated.

With the view to simplifying the subject it seems pertinent to classify these inflammatory attacks; because all inflammations in this region are not identical, either in etiology, in the anatomical part involved, or in the termination.

The opinion has recently been advanced that all of these conditions are dependent upon a primary pathological change in the appendix, and that all the subsequent changes are secondary to an affection of the appendix. For my own part I cannot endorse this view. I have observed many cases that certainly ran a course very similar to typical appendicitis, and yet the cæcum or the pericæcal region were the parts involved, and the appendix was normal. I shall have occasion to refer again to these cases. If the view is accepted that all these changes are secondary to a primary appendicitis, then certainly it must be admitted that this one region forms an exception to the laws governing inflammations in other parts. This belief would imply that there is a part or section of the alimentary canal that enjoys an immunity from primary inflammatory changes, and that there is a limited area of connective tissue in the right iliac region which is free from initial inflammations, and that there is a restricted zone of peritoneum exempt from a peritonitis except as secondary to an appendicitis. Surely this view is not tenable, and clinical experience clearly points to the conclusion that there is no exception here to the laws governing inflammations in general; but that each part, and every structure, and all varieties of tissue may become the seat of an inflammation independent of an appendicitis. To refer now to a classification of these inflammations. They may, for convenience, be divided into—

1. Typhlitis.
1. Perityphlitis.
3. Appendicitis.
4. Peri-appendicitis.

These different inflammations may merge into one another if no surgical treatment intervenes; but the separate conditions may exist independently, and each may run its course without necessarily involving the other. By a typhlitis is meant an acute or subacute inflammation of one of the several coats of the cæcum. This form may possibly extend to the adjacent tissues. The lesion consists of a catarrhal or ulcerative inflammation, and begins in the mucous membrane. This variety of inflammation is dependent upon fæcal impaction, a septic diarrhœa, a corrosive poison, or an ulcerative process.

There are some surgeons who deny the existence of a localized inflammation of the cæcum. I am confident that I have seen several cases of this kind. The proof of this statement becomes apparent by an examination of two specimens which I have, showing well-marked ulceration of the mucous membrane of the cæcum, and these changes are entirely independent of any trouble with the appendix. Dr. Janeway informs me that he has recently seen three cases of localized cæcal inflammation. These cases certainly establish the clinical fact which is denied by some surgeons, that a local inflammation in the right iliac region can exist independent of appendicitis.

The case reported by Mr. Pepper, of London, is another proof of local cæcal inflammation. The vaginal injection of a 1 : 2000 bichloride of mer-

[1] Read before the American Surgical Association, May 14, 1890.

cury solution caused extensive ulceration of the cæcum. The patient died, and the autopsy revealed the fact that the ulceration was limited to the cæcum.

Toxic enteritis may chiefly, if not entirely, involve the cæcum, and after the administration of antimony as well as of arsenic this phenomenon has followed. I have cured a case of extensive ulceration, of eleven years' standing, of the cæcum and ascending colon, by copious injection high into the colon, using as strong a solution of bichloride as the circumstances permitted. After eleven years of septic diarrhœa and hæmorrhage this patient was entirely cured of his cæcal and colon ulceration.

The second variety, viz., perityphlitis, is that form of inflammation which involves the areolar tissue in the vicinity of the cæcum. This leads to suppuration and may exist independent of any change in the appendix. These cases are observed following traumatism, as in sprains of the psoas muscle, or from some pathological condition in the ilium, sacrum, or vertebræ. I have seen these cases occur after violent athletic exercise; one case occurred after swimming, a second after jumping, and a third after lifting heavy weights. These abscesses go on to free suppuration, are situated in a kind of tissue prone to break down after an injury, are not subject to perforation, but generally point toward the periphery of the body.

The third variety, appendicitis, means an inflammation of the vermiform appendix, and is identical with a typical typhlitis, only that it is more serious in its consequences, owing to the anatomical formation of the part; but the causes which give origin to the change are, in many respects, similar.

The fourth variety, viz., peri-appendicitis, is not so clearly defined as is perityphlitis, because this variety is undoubtedly secondary to an appendicitis. The small amount of areolar tissue about the tip of the appendix is not exposed to the same injuries as the more abundant quantity about the cæcum.

The question of removing the appendix during the quiescent period would therefore involve the last two conditions, viz., an appendicitis or a peri-appendicitis.

It is, then, with an appendicitis or a peri-appendicitis that this question of removal of the organ during an interval of attack concerns us at the present time.

In discussing the operation the first question that naturally arises is, What proportion of cases of appendicitis are recurrent? It is with this percentage of cases that the question of removal of the appendix arises. There are no definite statistics upon this most important point. Fitz, in his scholarly article, has found in the examination of 257 cases of appendicitis that 28 of the cases were recurrent. This would place the number at about 11 per cent. In other words, 89 per cent. of the cases of appendicitis are solitary and 11 per cent. are multiple. The proportion is about the same in regard to typhlitis and perityphlitis as regards solitary and multiple attacks.

A second question now arises, viz., In the 11 per cent. of cases in which a relapse occurs, what is the termination? If all the 11 per cent. of cases of relapsing appendicitis terminated fatally then the question of excision of the appendix is easy to answer. It is obvious that if all these patients died during one of the recurrent attacks excision of the appendix should be attempted after the first or second attack; because the removal of the appendix would be the only salvation open to these unfortunate individuals. Happily death is not the only termination for this 11 per cent. of cases.

They may terminate in:

1. Resolution.
2. Formation of pus and evacuation of abscess.
3. Perforation and general peritonitis.

It is not known how many of these cases of relapsing appendicitis terminate in resolution. Unfortunately there are no statistics upon this point.

Nearly all of the authorities, however, are in accord with the general statement that a majority of the cases undergo resolution, and that only exceptionally perforation occurs.

The second way in which an appendicitis may terminate is by the formation of pus and the evacuation of the abscess, either spontaneously or by surgical interference. In regard to the chances of recovery offered by an early operation, it has been shown that there are fifty per cent. more recoveries following operations before the eighth day of the disease than after the eighth day, and that the mortality is only eight and one-half per cent. in those cases operated upon before the eighth day. If now the operation of incision is performed during the second or third day of the disease in these relapsing cases, the rate of mortality is lessened to such a degree (as shown by a study of Weir's, Bull's, and McBurney's cases) that the mortality is comparatively insignificant.

If now out of the eleven per cent. of cases of relapsing appendicitis there are deducted first those cases which terminate by resolution, and second, those cases which recover by early incision, it is obvious that only a small part of the eleven per cent. of cases are exposed to the remaining source of danger, viz., perforation and general peritonitis.

The whole question of removal of the appendix, therefore, practically has reference only to those cases in which a general peritonitis, the result of a perforation, is likely to arise. It is under these circumstances that death follows, and the excision of the appendix is the only measure that will remove

this cause of almost certain death. The line of argument thus pursued brings us face to face with the clinical fact that removal of the appendix is to be considered only as a means to protect a patient in the future from death by a peritonitis the result of a perforation. If it can now be shown that in the extreme emergency of a general peritonitis a laparotomy can save a patient, then the removal of the appendix during a quiescent period is deprived in a great measure of the only argument that can be claimed for its performance. Simple reference to the cases of Krönlein, Morton, Weir, Sands, McBurney, and others demonstrates that perforation does not necessarily preclude all possibility of recovery, which is the great argument in defence of removal of the appendix during the period of quiescence. The same line of argument may be carried even further, and it can be shown that perforation may occur and no laparotomy be performed, with still a possible chance for recovery. A proof of this statement may be found by a reference to the following cases.

Dr. Markoe reports the case of a child who had symptoms of general peritonitis upon the second day of an attack. A month later this child died from some other disease and the autopsy showed that perforation of the appendix had occurred, and that adhesions of the intestine had taken place. Dr. Biggs made an autopsy and found the evidences of a previous perforation of the appendix from sloughing. The appendix was found encysted in an old circumscribed peritoneal abscess.

A case is mentioned by Shaw where an abscess was formed in the scrotum from a perforated hernial appendix, and Thurman records a similar case.

Dr. Cabot reports a case where an inch of a previously perforated appendix was found in an abscess in the groin some eighteen months after an attack of appendicitis.

Ballou and Pooley each report a case where the appendix had sloughed and the patients recovered. Many other cases might be cited to show that even if perforation of the appendix has occurred it is not necessarily a fatal lesion.

Dr. Janeway made an autopsy on a patient who died some time after an attack of appendicitis. The appendix had been the seat of ulceration and perforation; but it had formed adhesions by inflammation to the surrounding tissues and no gas had escaped into the general peritoneal cavity, and as far as the perforation was concerned, the patient lived. It is an illustration of the clinical fact that a circumscribed peritonitis may shut off the appendix from the general peritoneal cavity and that even perforation may occur and not be a fatal lesion.

The best of all proofs that perforation of the appendix may occur and the patient survive such an attack, is found in a case in which an autopsy was made ten years after an attack of appendicitis. It was ascertained that the appendix had been perforated during the attack and that it had been accompanied with abscess and suppuration. Dr. Biggs, who made the autopsy, found that the tip of the appendix had sloughed from its base, to which it was still held by an impervious cord. The entire mass, including the base and apex, with the filiform connection between the two separated parts, was embedded in a mass of inflammatory new-formation tissue, which was adherent to the kidney and to the liver. This patient for ten years had no trouble with his appendix, and no one ever suspected the nature of his previous attack of illness.

If now I have made the thread of my argument clear, it is obvious that excision of the appendix has to do with only about 11 per cent. of the cases of appendicitis, for 89 per cent. of the cases are not relapsing, and therefore do not belong to the class of cases in which removal is indicated. Of the 11 per cent. a majority recover; because perforation is the exception rather than the rule. Some undergo suppuration and heal. Of the few cases exposed to the danger of perforation and general peritonitis some recover, as is shown by a reference to the cases just mentioned.

It is now pertinent to consider in detail the real arguments against removing the appendix during a quiescent period in the few cases where the attacks have been recurrent. The arguments which I would respectfully submit against this operation of excision during a quiescent period in relapsing cases are as follows:

1. The danger to human life.
2. The difficulties of a positive diagnosis.
3. The development of ventral hernia.
4. The lack of conclusive evidence that excision of the appendix is attended with permanent relief.
5. The result of relapsing attacks may afford an immunity from danger in the future.

1. *The danger to human life* is an argument which confronts the conscientious surgeon. Opening the abdomen for the purpose of finding the appendix vermiformis is certainly attended with risk to life. That risk increases in accordance with the amount of pathological change that has taken place. I must dissent from the view held by Morton, who speaks of this procedure as a "comparatively trivial operation at a time and under conditions when prompt and permanent relief and recovery can almost invariably be secured." The same opinion is also expressed by Senn, who writes: "Excision of the appendix in cases of simple uncomplicated appendicitis is one of the easiest and safest of all intra-abdominal operations." Such statements are misleading. In May, 1887, I excised the appendix, on

account of a stab-wound, with no difficulty as regards finding it; but to remove it and to invert the edges and to introduce sutures and to close hermetically the opening into the cæcum is a delicate operation which requires nicety of *technique*. It is by no means to be considered a trivial procedure, and upon the result of the operative work of the surgeon depends the life of the patient. The giving way of a stitch or the sloughing of a small shred exposes the patient to imminent peril. One bubble of intestinal gas is sufficient to infect the whole peritoneum, and such a catastrophe will in all probability lead to a fatal termination. The possibilities of hæmorrhage, of purulent œdema, of septic peritonitis, of suppression of urine, and of surgical shock must not be overlooked. These are the dangers to which a patient is subjected in the ordinary cases; but when, from recurrent attacks, adhesions have formed, the connective tissue has undergone pathological changes, the cæcum has become dilated, and the anatomical relations are disturbed, excision of the appendix becomes a serious operation. Surgeons have attempted to find an analogy between removal of the appendix and of the ovary. This comparison causes a tendency to attach too little importance to the excision of the appendix. It must be borne in mind that the vermiform is an integral part of the alimentary canal; it often is adherent to the large and important bloodvessels, it may be buried under the cæcum, it may be firmly imbedded in inflammatory exudation, the tearing of which may result in a rent in the intestine or ureter, and the sewing up of which requires time and skill. Not so with the ovary, for here the oozing is easily controlled, and if a pus cavity is found the cavity can be easily washed out and rendered aseptic. For these reasons the excision of the appendix cannot be looked upon in any light other than that of an operation attended with considerable risk to human life.

The operation of removal of the appendix during an interval between the attacks has been attended with a death-rate the precise percentage of which cannot be at present ascertained, because a report of all the cases has not yet appeared in print. It is safe to state, however, that the death-rate is higher than that of early incision on the second or third day of an attack. This one argument alone deprives the operation of its greatest advantage. Thus far, in dealing with this subject the ability to find and to remove the appendix has been assumed; but a most serious aspect of this question is the failure to find the appendix after the abdomen has been opened, or, owing to extensive adhesions, an inability to remove the organ. Recently I was present at an operation for the purpose of excision of the appendix. The laparotomy was performed upon the patient during the quiescent stage, and although the surgeon was one of the most skilful operators and one of the best anatomists, he was unable to find the appendix after a long and tedious search. The abandonment of this operation was wise and prudent. and I mention this clinical fact to impress the point that the operation is, of necessity, attended with great danger where a prolonged search must be made with the peritoneal cavity opened and the intestine exposed. When an operation becomes necessary it should be performed early during an attack, and at the same time removing, if necessary, the appendix. It is the proper line of treatment. It is quite another thing after an attack has passed and in the quiescent stage to attempt an excision. In the former case it is indicated to save life, in the latter case it is fraught with great danger to avoid a possible future attack, from which the patient may even easily recover.

2. *The difficulties of a positive diagnosis.*—No surgeon who has seen many cases of abdominal surgery can overlook the fact that the diagnosis is often fraught with the greatest difficulties and with much uncertainty. The more cases examined the more real becomes this fact. It is often impossible to arrive at a positive and clear diagnosis as to the real condition that has given rise to the attacks. The most skilled diagnosticians and the most experienced surgeons have made errors in diagnosis as regards lesions in this region. It is only necessary to review the list of diseases that already have been mistaken for appendicitis in order to estimate the weight of this argument against excision of the appendix during a quiescent period.

Among the conditions that have been mistaken for appendicitis may be mentioned the following: General or circumscribed peritonitis, pelvic peritonitis, renal, biliary, and intestinal colic, ovarian and lumbo-abdominal neuralgia, intestinal obstruction, floating kidney, pyelitis, cæcitis, internal strangulation, psoas abscess, pelvic cellulitis, rupture of the serratus magnus muscle, suppurative adenitis, typhoid, tubercular and stercoral ulcers, caries of ilium and of vertebræ, morbus coxarius, suppuration in the retro-peritoneal and mesenteric glands, traumatic rupture of intestine and right ureter, rupture of the bladder and of the gall-bladder, rupture of an aneurism in the broad ligament, sprain of the iliacus and psoas muscles, salpingitis of the right tube, abscess of liver, tubal pregnancy, typhlitis and perityphlitis.

This list does not embrace nearly all the conditions which eminent men in the profession have frankly acknowledged to have mistaken for appendicitis, or *vice versa*. The list, however, is of sufficient size to impress the important point that errors in diagnosis may occur, and that a laparotomy for

excision of the appendix may be performed and the real pathological condition which the operation is intended to relieve be other than a diseased appendix. Finally, it is significant that in some of the cases in which the appendix has been removed during the quiescent period no change sufficient to cause trouble could be found in the appendix. Within a month I have examined a specimen showing a perforation of the cæcum where appendicitis was diagnosed. If this patient had survived the attack and the appendix had been removed the operation would have been of no avail, for the lesion was situated in the cæcum.

3. *The development of ventral hernia.*—This interesting observation has been made by Dr. Bull, whose brilliant work in abdominal surgery is of world-wide reputation and entitles his opinion to the highest respect.

This condition is not likely to follow the early incision which is made during an attack to allow pus to escape, because the incision under these circumstances is very small, whereas, in a laparotomy for excision of the appendix during the interval of attacks, the length of the incision is from four to five inches. Several cases of ventral hernia following operations for removal of the appendix have been reported. The special situation of this incision and the peculiar character of the parts divided, and the tendency of the wound to gape, render the development of hernia a most serious complication. There is no doubt that this condition can give rise to strangulation, and even if strangulation does not follow, the presence of the ventral hernia is a source of great discomfort and annoyance to a patient.

4. *The lack of conclusive evidence that the excision of the appendix is attended with permanent relief.*—Time is the crucial test to settle this important point. The cases that have been published bear witness to the fact that the operation has been performed, but the period of time is too short to base any conclusions as to the ultimate result. If the excision has been performed in a case where the appendix alone was involved, the result may be satisfactory as regards the appendix; the pathological process, however, which established the lesion in the appendix may subsequently develop in the cæcum and changes similar to the original attack may then ensue. If the appendix has been removed when the lesion is in the cæcum the relief does not follow.

To what extent the operation will afford immunity in the future is still a question *sub judice*. There is positive evidence that recurrent attacks may terminate in a final one with recovery, and the patient enjoy years of immunity. He may never have any return of the trouble. I know of one patient residing in a southern State who has had fourteen consecutive attacks of appendicitis; but during the past five years has never had the slightest indication of any disturbance. These fourteen attacks occurred during a period of a few years, and the patient was able to trace the cause of the attacks to the use of cathartics and to a peculiar diet. Since he has abandoned cathartics and has lived upon a meat and gluten diet he has never had the slightest indication of trouble. His appendix may be so situated as to never develop another attack. An attempt to excise his appendix might be attended with a fatal issue.

5. *A condition following relapsing attacks may afford immunity from danger in the future.*—I feel certain that some surgeons will dissent from this view; but I shall endeavor to prove the correctness of the statement from pathological material and from clinical data. One great mistake that surgeons commit in discussing this subject is to consider all cases of appendicitis doomed to immediate death. Investigation and observations are made at the time of a contemplated incision to avert perforation, consequently the subject is viewed from very narrow limits. I believe that often a single attack from which recovery follows places the appendix in such a position that no further harm can result to the patient. For example, I have four microscopical specimens showing that the appendix in a cross-section has become completely obliterated as a result of appendicitis, and that instead of the normal duct with its narrow lumen filled with glairy mucus an impervious cord exists. This change is the result of a previous inflammatory process, as is seen by an examination of the tissue. I know of other cases where the same condition is present. If this is true in regard to a single attack, why may not the last of recurrent attacks place the appendix in this same condition? An appendix, then, that is an impervious cord becomes so by inflammatory processes, and I fail to find a report of an autopsy where the patient died from an attack of appendicitis and in which the appendix was an impervious cord.

These cases of obliterated appendices are found incidentally, and upon microscopical examination the fact is revealed that the cords are the result of a previous attack of appendicitis. But the impervious cord is not the only condition that may afford immunity to a patient. For example, I have specimens showing some interesting conditions resulting from appendicitis. One specimen shows that the duct was embedded in a dense stratum of inflammatory new-formation behind and to the outside of the cæcum, and entirely shut off from the general peritoneal cavity. A perforation had previously taken place. A small foreign body was lodged in a circumscribed cyst cavity. In another case an

autopsy was made upon a patient who had died suddenly from heart disease, and the appendix was found buried in a mass of areolar tissue continuous with a dense band of tissue adherent to a cicatrix upon the skin. This mass of tissue in which was embedded the appendix with a cicatrix denoting a slough was behind the cæcum and the peritoneum. Several years previous this patient had suffered from an attack of appendicitis; perforation had followed and the appendix was placed in a position never again to give rise to any trouble. The condition of perforation was not diagnosed at the time of the attack and the patient never suffered ill consequences from the new position of the appendix. I have also another specimen of an appendix which was situated behind the cæcum and adherent to it. A perforation of it would have been extra-peritoneal, and in that case the danger of a purulent peritonitis would have been avoided. I believe that exceptionally a few of these cases of abscess connected with the appendix are outside of the general peritoneal cavity; but, of course, the large majority of them are intra-peritoneal. Any attempt to excise an appendix during the quiescent period under the circumstances just mentioned would be attended with very great danger, whereas no trouble would ever arise from the condition of the parts.

I know of three cases where the appendix had become adherent to the wall of the cæcum and perforation had occurred through the adherent surfaces directly into the lumen of the cæcum. The escape of pus *per rectum* is the proof offered in these cases of typical appendicitis. The patients recovered and the appendices in their present condition of adhesion with the cæci will probably never give rise to mischief.

To recapitulate, it seems from an examination of the clinical facts and of the pathological material, and from a careful study of the reported cases of appendicitis that excision of the appendix pertains to only eleven per cent. of all the cases of appendicitis. Of these cases represented by eleven per cent. many undergo resolution, some terminate by abscess opening spontaneously or by early incision, while a few are exposed to the dangers of perforation and general peritonitis. Excision of the appendix is suggested as a preventive measure in the small percentage of cases of relapsing appendicitis in which perforation is feared. It has, however, been clearly proved by my specimens that even perforation and general peritonitis are not in all cases fatal complications.

So, then, if those cases of perforation in which recovery follows—and they are more frequent than has been supposed—are deducted from all the cases of perforation, there are left but a few concerning which the question of the propriety of excision of the appendix would arise. If, now, it is remembered that an incision on the second or third day during the attack in relapsing cases, is attended with most brilliant results, showing a mortality of only a small percentage, is it not wise to observe conservatism and decline to excise the appendix during a quiescent period, when its death-rate is higher than the death-rate of early incision upon the second day? The results which Dr. Willard Parker obtained by operating during the second week after adhesions had formed were brilliant, considering the high death-rate previous to his suggestion. The improvement upon Dr. Parker's operation by early incision upon the second or third day has left but little to be desired in the management of these cases during an attack. Are not, then, a patient's chances for life better after an incision upon the second or third day during an attack than they are after a laparotomy performed during the quiescent period, with the view of removing an appendix which may not be found, and if found cannot be safely removed. Does not such an operation expose the patient to a greater peril than the management of a future attack by early incision?

In conclusion the clinical fact must not be lost sight of that the last attack from which the patient suffered, may have placed his appendix in a position that precludes the possibility of a future attack. From a consideration of these facts it seems wise to condemn the operation of excision of the appendix during the quiescent period as routine practice. Some special reasons should exist to justify the operation—reasons that do *not* exist in the majority of cases of relapsing appendicitis. That occasionally a case may be presented in which excision of the appendix is indicated, I do not deny, but as routine practice in all cases of relapsing appendicitis it is a measure fraught with greater danger than incision and removal upon the second or even the first day of a recurring attack. If this very early incision, as suggested by Sands and practised in several cases by McBurney and others, is resorted to in these relapsing cases, the question of excision of the appendix will arise only in connection with an early attack. If relapsing cases are operated upon at the onset of the trouble the prognosis is better than in those in which later incision is employed. It is one of those operations of expediency which should never be performed, even in a case preëminently suitable, without a thorough examination of the heart, lungs, and kidneys, for under no circumstances, with organic disease, should so bold an operation be resorted to unless the patient is confronted during an attack by death itself. To excise during an interval between recurring attacks in a patient suffering from any organic disease is ex-

posing that patient to a certainty of death, while conservatism might result in a prolongation of human life, during which time no other attack may arise. If an attack should develop, the early operation upon the first or second day in a relapsing case might offer a prospect of recovery that would be more favorable than was at first supposed. At all events, this line of practice does not expose the patient to the danger of death before he is confronted with it, and then it is not too late to expect an escape by a resort to the new and early operation of incision and excision before serious changes have developed that might place the patient's life in jeopardy.

A CLINICAL HISTORY OF TWENTY-TWO CASES OF FILARIA SANGUINIS HOMINIS,

Seen in Charleston, S. C., from 1886 to May, 1890.

By P. G. De SAUSSURE, M.D.,
of Charleston, S. C.

My excuse for this paper is that it deals with a disease scarcely known eighteen years ago, and still but imperfectly understood.

Whether or not filaria have just appeared in Charleston I am not prepared to say, but the case-book of the City Hospital shows that in 1882 or '83 Dr. J. J. Edwards, then a student of medicine, together with several members of the house-staff of the hospital, looked for filaria in the blood of a chyluric patient; and that in 1884 Drs. Edwards and W. D. Bratton examined again and again the blood of a chyluric pregnant woman for filaria, but with negative results. In 1886 Dr. John Guitéras gave the subject a new start, this time with success.

The arduous duties of a large dispensary practice leave me little time and less energy with which to make original research, nevertheless at the end of this article I have set down some facts noted while studying the subject.

Case I.—A mulatto woman aged about forty. At the time filaria were first found (1886) she was a patient of Dr. Edwards, but had sought treatment of many doctors. She was born in Charleston, S. C., lived in Augusta, Ga., five years, but removed to her birth-place and has lived there ever since. Has had for the last ten years chyluria, with vague lumbar pains, occasional diarrhœa, and during the last three years an irregular fever with chills. In 1884 or 1885 I treated her for lymphangitis of the vessels and glands of the left leg. After some weeks the inflammation seemed to settle in the popliteal space, for in that place I opened an abscess. The pus was not peculiar, but the healing process was slow. During this attack the patient was unable to follow her vocation, that of a seamstress, but before and since she has been able to work; I have lost sight of her for the last two years. This, then, was the first case in which living filaria were found, and the examination of her blood was suggested by Dr. Guitéras.

Case II.—A patient of Dr. Edwards. A negro aged nineteen or twenty years. Born and brought up in Charleston, S. C., in the vicinity of which he has spent all of his life. He has spent two or three months of several summers at Mt. Pleasant, a summer resort for Charlestonians, just across the bay. By occupation he was a house-servant. He sought Dr. Edwards's advice for the relief of rapidly developed chylocele which the patient thought was due to traumatism. Dr. Edwards submitted to me some of the fluid drawn from the scrotum and in it I found dead filaria; two nights afterward living filaria were discovered in his blood. Drs. Edwards and Guitéras thought he then had beginning elephantiasis of the scrotum. Shortly after this a mitral regurgitant murmur and dropsy presented themselves. The murmur and ascites increased and the patient died, apparently from heart failure. No post-mortem was allowed.

Case III.—John G. A nearly pure negro, aged sixty-five, born and brought up in Charleston, S. C., which he claims as his residence, though he has been for months at a time on a rice plantation in South Carolina, at Flat Rock, N. C., and at Newport, R. I. By occupation he is a valet and house-servant. Had perfect health up to 1882, when, following some exertion, he had lumbar pains and hæmato-chyluria, and it was for this that he sought a doctor's advice. In 1883 he came under my care and a careful examination of his urine revealed dead filaria (not then recognized as such), blood, pus and mucous corpuscles, with epithelium from bladder and kidney. A diagnosis of pyuria was made and under tonics and astringents the patient improved, the hæmato-chyluria, lumbar pains and slight diarrhœa returning at intervals, until the fall of 1884, when once more he presented himself for treatment, having then headache, a heart murmur and a swelling of the right side of his neck resembling a unilateral goitre. He again improved under treatment. In 1886, after seeing the filaria in Cases I. and II., I recognized that the objects seen in this patient's urine in 1883 were filaria, so I examined his blood, and found living filaria. In 1889 the patient was once more under treatment for dyspnœa, palpitation of the heart, and persistent headache. In April of that year ascites developed, but under digitalis and iron the patient was relieved. During this attack the patient's heart was embarrassed, but exactly what the trouble was I am unable to make out. The abnormal sounds could not be classified. For the last half year the patient has been able to go about, but any undue exertion distresses his heart and brings on an attack of hæmato-chyluria.

Case IV.—Mulatto man aged sixty-five, by trade a carpenter, born in Charleston, S. C., which place has been his home, but he, like most of the patients reported, has from time to time lived in other parts of the State. His health was perfect up to seven years ago, when he had his first attack of hæmato-chyluria, which was preceded by lumbar pains, abdominal colic, and dysentery. His medical attendant diagnosed cholera morbus. In 1887, when he

came under my care, his blood was examined and filaria found.

CASE V.—Allen, a negress, aged forty-two, born in South Carolina. Has lived in Charleston for the last twenty years, but is not clear as to her previous residence. By occupation a cook. Has suffered from chyluria for five years. No other trouble until three years ago, when she had back-ache, colic and slight dysentery, but did not stop working. Filaria found in the blood in 1886. She is a widow, has had several children, only one of whom is living. She does not know of what her husband or children died. Looking for some hereditary influence, I asked that her child should come to the office.

CASE VI.—Allen's son, a lad aged eighteen years, born and brought up in Charleston. Is an epileptic, but otherwise is in excellent health. No pains nor chyluria. Blood examined in 1887 and filaria found. The filaria do not seem to give this patient any trouble. Bromides control his convulsions more or less.

CASE VII.—Mr. B., thirty-three years old, born in Charleston. Is now a constable, but has followed different occupations, one of which carried him for several months to Nassau, where he had "fever" during the late war. In 1870 he had his first attack of chyluria. Between 1870 and 1880 he had a peculiar inflammation of the glands of the groin. He says his physician could do nothing with them, and that finally an abscess formed. Since 1887 with his chyluria he has lumbar pains and some dysentery. Filaria were found in 1887. He does not know if they had previously been looked for.

I think this patient is mistaken in regard to his age, which I would say is about forty-three.

CASE VIII.—Mr. Y., aged about twenty-seven, born in Charleston, S. C., where he has spent all of his life. On account of a diseased hip-joint he has never been able to do much manual labor, though he has been a great deal about the shipping. Excepting hip disease he enjoyed perfect health until four years ago, when, following a liberal meal at a picnic, he was seized with cholera morbus. From then until now he has been subject to attacks of dysentery with abdominal pains. Examined for and found filaria in 1888.

CASE IX.—White female, aged thirty-five; born and raised in Charleston, though she has visited for two or three months on various plantations in the vicinity of Charleston. She is married, and at the time of first observation in 1887 had one child. Her health was good until the latter part of her first pregnancy, when she began to suffer with chyluria and severe pains in the lumbar region. The urine was white until after labor, when it became natural and remained so until the eighth month of her second pregnancy, when the urine became white again. I saw her for the first time at this period and found chyluria and rectal tenesmus. The urine contained vesicular masses large and small, the former about one and one-half inches long by one inch broad. These vesicles were entirely new to me and I can only describe them as looking like egg albumin enclosed in a fine membrane, the whole being in color and transparency like uncoagulated albumin. Sometimes they would be arrested in the urethra and pass only after long bearing-down efforts. I examined several of the masses, for they could be handled, though soft and compressible, but I could make nothing out of them. Once I thought I had a Bilharzia ovum, but of this I am not sure. I can only say that the vesicles and what I saw in one of them under the microscope were new to me. In this patient's blood filaria were found a few hours before labor, as well as the night before. Immediately after labor none were found either in blood from the cord or in that drawn from her finger. Examination of the blood and milk on the following day was also negative and no filaria were found in the child's blood. After some weeks chyluria disappeared, but filaria were again found in the mother's blood (child's blood was always negative). Patient became disgusted with so many examinations and I lost sight of her until 1890, when once more she consulted me and I found that she had been confined again in 1889. She said that she had had no trouble during pregnancy, but this I doubt, and think she made the statement to keep my needle out of her baby, to whom I had been summoned to relieve it of dysentery. The whole family—father, mother, and three children—were examined, and I got negative results and my discharge. The child has since died under the care of another physician. The certificate of death shows entero-colitis as the cause.

This case is particularly interesting, for the discharges from the four-months-old infant were identical in appearance with those of the other patients suffering from chyluria and dysentery.

CASE X.—Mr. G., aged fifty-seven, born in Ireland, has lived in Charleston for the last 35 years. He has been a wanderer and is a "jack of all trades." Since 1875 he has been much of the time in hospital, complaining of vague pains. In 1887 he applied for relief of lymph scrotum and enlarged groin glands. Filaria found in blood glands, which were removed, but were not adult filaria.

CASE XI.—S., aged fifty-eight, born and brought up in Charleston. Present occupation that of a house-cleaner, but like most negroes, has turned his hand to everything, and I must say of him as I have of others, that he claims Charleston as his residence, but acknowledges visits to other places; for instance, he was in Savannah, Ga., for four months. He sought relief in 1888 for chyluria of several months' standing, with lumbar pains and dysentery. Filaria found, and from eye measurement I would say that they were larger than the average. This patient had, during the month preceding his coming to me, an irregular fever with chills; no enlarged glands present.

CASE XII.—J., aged fifty-five, born in South Carolina. Resided for last ten years in Charleston; before that in different parts of the State, with visits of months' duration to North Carolina and Georgia. His work at times has been loading and unloading vessels. Has had chylocele for four years. This

rapidly growing larger, he applied for treatment in 1889. Blood examined and filaria found. On being told that an operation would have to be performed he left, and I have no further history.

Case XIII. (Should have been reported amongst cases found in 1886.)—A negress, one hundred years old, born in Africa. Was brought over to South Carolina in a slave-ship.

With the exception of four years, she has lived in Charleston. Called to attend her in 1886 for a cold abscess, pointing just over the scapula. Her age prevented her from giving much of a history. Thinking that her birth-place gave her a right to filaria, I examined her blood and found them. She was sent to the hospital, where the abscess was opened, but nothing peculiar was noted about the pus. She has since become insane, and has been for the last three years in an asylum. The assistant physician writes, May 10th, that "she has occasional chyluria, but no glandular swellings, and, in fact, is remarkably well." Filaria were found two weeks previously.

Case XIV.—Mr. J., aged forty-five, patient of Dr. J. L. Dawson, Jr., who gives the following history: Birth-place and residence Charleston, S. C., but has lived in Florida, Georgia, and North Carolina. Has had chyluria for years. An attack is always preceded by lumbar pains. Is married and the father of several children, all of whom are healthy. This patient's occupation for the last few years has been that of a book-keeper to a large fruit firm, and from time to time he drinks water on vessels from Cuba and the West Indies. Had chyluria before this, however. Filaria found in 1888.

Case XV.—Mr. M., aged thirty-two, lawyer, a patient of Dr. Kinloch's; birth-place and residence Charleston, S. C. Filaria found in blood by Dr. Kinloch in 1887; subsequently in urine and blood by Dr. Guitéras. Chyluria is the only symptom that he presents.

Case XVI.—Mrs. B., aged fifty-two; born in Germany, but has lived in Charleston, where she came direct from Germany thirty years ago. By occupation a cook. Has had chyluria for the last eight years, but no other symptoms, save lumbar pains. Filaria found in 1887. Has one child, a boy, born since her arrival in this country. The boy's blood gives negative results.

Case XVII.—M., male, aged about sixty years; born in South Carolina. Lives now in Charleston, but has lived in different parts of the State. In good health until several months ago, when he began to have trouble with his urine, which he describes as muddy and streaked with blood. Applied for treatment of cystitis. Dr. Edwards thought that the disease might be caused by stone, but the sound gave negative results, so we determined to look for filaria, which were found in his blood in 1890. This patient complains of great muscular weakness.

Case XVIII.—Mrs. F., aged twenty-six, a patient of Dr. Manning Simons. Born and raised in Charleston. Is married and has two children. Has had chyluria for fourteen years. Has also had irregular fever with chills, and enlargement of the lymphatics of left leg and arm. None of these have ever suppurated, and the patient is able to go about attending to all of her household duties. Filaria found in 1890.

Case XIX.—Sallie, aged forty-five, patient of Dr. D. Ryans. Born in South Carolina, lives in Charleston now, but gives no clear history of her birth-place or residence before she came to Charleston. Gives no account of the duration of chyluria, which is her only trouble. Is married and the mother of several children. Filaria found in 1890.

Case XX.—Frank, aged forty-five, patient of Dr. Ryans. No history, save that he was born in South Carolina and has lived in Charleston for many years. Applied for relief from chyluria, which he says he has had for years. Filaria found in 1890.

Case XXI.—Martha R., aged forty-eight; born in South Carolina; residence for last twenty-six years, Charleston. Health good until seven months ago, when she had an attack of hæmaturia, consequent upon gravel, her physician thought. Since then she has suffered from palpitation of the heart and dyspnœa. Three weeks ago œdema of the lower extremities appeared. On May 13, 1890, presented herself for treatment. Filaria found.

Case XXII.—Gibbes, aged sixty, born in South Carolina; residence for last thirty-six years, Charleston. Health perfect until six months ago, when he had an attack of palpitation of the heart with dyspnœa; this has grown rapidly worse for the last month. Œdema of feet and lower extremities now. Filaria found, May, 1890.

Tabulating the cases, I find that the disease was distributed as follows: 9 colored males, 6 colored females; 5 white males, and 2 white females. Of the 22 cases 16 were in married people; all of whom had children. In over one-half of the cases filaria were searched for in children of the married, in husbands or wives, or in friends and bed-fellows of the single ones; and yet but in a single instance did I find two cases in the same house (Cases V. and VI.). In the child of Case IX. I think, if the search could have been carefully carried on, filaria would have been found.

As to the social conditions of the patients, 15 were colored, 7 white; of the latter only three can be said to be in high life. All of the others, black and white, belong to the lower and middle classes. Why this difference? Is it from abode or diet? The houses of our domestics and laborers are very similar to those of the same classes elsewhere.

In reference to the diet and water, the former is that of the working-class in other cities, only that here they eat a great deal of fresh fish—in fact, during the summer months fish of some sort takes the place of meat. As to the drinking-water, I differ absolutely from Dr. Guitéras, for he considers it mainly cistern, and I know from a ten-years' practice amongst the lower classes that it is mainly

pump or artesian, and exceptionally cistern water. Sometimes, for a short period just after rain-storms, the poor have barrel water, but the supply soon runs out, and they go back to the pumps and artesian wells. A word about the barrel water, which is rain-water caught in barrels and casks open to dust and dirt, and one can always find with the microscope many living things in the water. The same is true of the artesian water, which, though it comes from wells 1800 to 1900 feet deep, is, before being served, stored in an open reservoir, which, to the best of my knowledge and belief, is bricked halfway down the sides, but only puddled at the bottom. I am not enough of a microscopist to say to what class the animals found belong, but know this, that with the microscope I have spent hours seeing them fight and destroy each other. The better class of Charlestonians drink cistern water. As to mosquitoes, I think they are as common in the homes of the rich as in those of the poor.

Diagnosis of the disease can alone be made with the microscope, for by reference to the table attached to this paper we find that chylocele, chyluria, lymph-legs, and glandular enlargements are frequently found, yet examinations of the blood may fail to show filaria. Again, we find filaria without any of these disturbances (Cases VI., VII., X., XXI., and XXII.).

There is no pathognomonic symptom. Sometimes we have fever and chills, at other times neither. The disease, as a rule, does not appear to prevent the patients from working. Cases II. and III. are exceptions, and some of the other patients were for a time disabled, but returned to their duties, and the filaria were still found when looked for. The chyluria is intermittent, and in no case that I have seen was it always present; and I would state further, that during its presence a given specimen of blood would not show more filaria than another specimen examined when chyluria was absent. In but two cases have I ever failed to find filaria after having once seen them (Cases VIII. and IX.). In Case III. his residence for three months at Flat Rock, N. C. (at an elevation of 2000 feet above the sea-level), always reduced the number of filaria, but after being in Charleston for eight months they became numerous again. Would they entirely disappear if he remained in the mountains?

To show the impossibility of making a diagnosis without the microscope, I would state that during the last three years I have examined three cases of chylocele with negative results (blood of two, fluid of one). Six cases of chyluria and one of hæmatochyluria have also given negative results, though one of these may yet prove to be a case of filaria, for it occurs in a patient who is a printer, and as yet I have not been able to examine him at the end of his work, which is about 5 A.M. Five cases of elephantiasis of the leg have been under observation, but no filaria were found.

Learning from our veterinary surgeon, Dr. Benjamin McGinnis, Jr., that filaria were very common in the dogs of Charleston, with his and Mr. L. W. Bacaise's assistance I made some observations on the disease in the dog, and I found that the embryo filaria in man and dog are identical—those of the man being possibly a little larger and their movement more active and strong. Very early in the investigation I was surprised to find that in the dog the embryo filaria could be found at any time of the day or night. In man it is different for I have been able to find them in the day but twice, once at 10 A.M. in the negress from Africa (Case XIII.), and once at 5 P.M. (summer) in John G. (Case III.)

Carrying the investigation still further, I examined fleas from filarial dogs, but got negative results until the morning of May 14th, when I found two filaria in the body of a flea which was taken from a diseased dog. This observation will, I hope, be confirmed, for it may throw considerable light on the mode of infection. I had purposed to make some examinations on the puppies of an infected bitch, but time has been wanting. I therefore would suggest that anyone interested in the subject may, by such examinations, clear up the question of heredity.

In the dog the disease causes death from ascites, which seems to be in consequence of the adult filaria collecting in the heart, a condition that we found in five post-mortems.

It is worthy of remark that in the one case of death occurring in a patient known to be afflicted with filaria, the cause of death was "dropsy with heart failure"—no post-mortem was allowed, so the presence of the adult filaria in the heart was not proven. It is suspicious that Cases II., III., XXI., XXII., should have heart murmur and dropsy.[1]

A REPORT OF TWO CASES OF STRICTURE OF THE URETHRA AND CHRONIC PROSTATITIS PRESENTING INTERESTING REFLEX SYMPTOMS.[2]

BY THOMAS R. NEILSON, M.D.,

INSTRUCTOR IN GENITO-URINARY DISEASES IN THE UNIVERSITY OF PENNSYLVANIA, SURGEON TO THE EPISCOPAL HOSPITAL AND TO ST. CHRISTOPHER'S HOSPITAL FOR CHILDREN, ETC., PHILADELPHIA.

THE two cases which I have the pleasure of reporting in this paper have seemed to me to possess sufficient interest to warrant their being recorded,

[1] I would beg to return to Dr. Louis R. Staudenmayer, of Charleston, my thanks for his help in making microscopic examinations and preparing this paper.

[2] Read before the Philadelphia County Medical Society, May 28, 1890.

because of the marked and peculiar symptoms associated with the disease of the urinary outlet present in each.

Case I.—Mr. ——, a well-developed, athletic young gentleman, twenty-four years of age, came to my office in December last, giving me the following history: About a year previously he had had what seems to have been an attack of subacute urethritis, following an exposure. For this he used, by advice, a strong solution of sulphate of zinc as an injection, with the result of aggravating the symptoms to a considerable degree. Later in the attack a catheter, which entered the canal with great difficulty, was passed, and again the symptoms were for a time increased. Gradually the discharge and other symptoms subsided, but never entirely disappeared. At the time of his first visit to me he complained of frequently recurring attacks of scalding on micturition, accompanied with a purulent or muco-purulent discharge, worse after defæcation, and with an annoying itching just within the meatus. At times this itching was felt over the glans penis, the scrotum, and in both groins. In addition, a sharp pain, neuralgic in character, was felt just below the umbilicus, coming at irregular intervals, lasting for a few moments, and then suddenly disappearing. Simultaneously with the occurrence of this pain, a tickling sensation in the throat was felt, and a short, laryngeal cough was provoked.

The patient had observed that friction over the umbilical region, such as that occasioned by using a towel after bathing, would aggravate the itching in the anterior portion of the urethra when it was present, or produce it when it was not noticed. In addition to the urethral trouble, the patient suffered slightly from internal hæmorrhoids, and when these were congested, during constipation, the itching in the urethra was slightly increased.

Upon examination, I found the circumference of the penis to be three and three-quarters inches, the meatus very small, only 12 (F.) calibre, and the anterior portion of the urethra excessively sensitive to the small-sized rubber bougie which could be introduced into the orifice.

The first step in the treatment consisted in the division of the meatus, so that it would easily admit a No. 34 sound. Being then able to further explore the urethra, I discovered a stricture of 26 calibre at two and three-quarter inches from the meatus, and a gleety condition in the bulbous portion. The whole canal, especially the posterior portion, was extremely tender, and a characteristic prostatic discharge was brought out on the shoulder of the bulbous explorer. Subsequent treatment consisted in passing at regular intervals full-sized steel sounds, the use of hot sitz baths, and the local employment of a sedative and astringent lotion for the itching of the scrotum and groins. After the sounds had been passed a few times the tenderness of the urethra disappeared, micturition was of course much improved (owing to the enlargement of the constricted meatus), the itching sensation in the urethra was no longer observed, and the pain near the umbilicus and the tickling in the throat ceased. It is interesting to note that at first, during the employment of the sounds, the latter symptoms were always aggravated for a short time after each visit.

By the first of April the patient considered himself well, but a little later, after taking a heavy cold and being indiscreet in his diet, the prostatic trouble was excited again, being manifested by a mucous discharge from the urethra while at stool, and a return of the itching near the meatus, but less intense than formerly. Under treatment this condition has again subsided, and the patient is now practically well.

Case II.—Mr. ——, also a private patient, a gentleman twenty-three years of age, having the history of an attack of gonorrhœa, complicated by prostato-cystitis, three years before he first consulted me, which was at the beginning of this year. The symptoms present were a slight gleety discharge, and burning pain on micturition and occasionally during the intervals. Whenever this pain was present there was also felt a similar pain on the inner border of the left foot near the first metatarso-phalangeal joint, and extending to the ball of the great toe. Friction of the glans penis by contact with the clothing produced the painful sensation, both in the urethra and in the foot; and, conversely, rubbing the foot upon a carpet or rug, or warming it before a fire, would excite the sensation in the urethra.

Examination showed: Circumference of penis three and a half inches, a stricture of 24 calibre at two and a half inches, and a highly sensitive condition of the urethra, most marked in the posterior portion, from which the discharge of chronic prostatitis was obtained by the explorer. I advised internal urethrotomy for the stricture, but my patient would not consent, preferring to trust to the less certain method of gradual dilatation. Prescribing a mixture of the bromide of potassium, tincture of hyoscyamus, and camphor water, for the purpose of reducing the abnormal sensitiveness of the urethra, I began the treatment with sounds, and, as the condition of the urethra improved, the painful sensations, both in that canal and in the foot, became less frequent and less intense, and had nearly disappeared when an attack of illness necessitated the discontinuance of the treatment. After recovering from this attack my patient left the city, by the advice of his physician, and on his return, recently, tells me that he again has his old sensations, and has decided to submit to the operation of internal urethrotomy.

Remarks.—The existence of pain or other morbid sensation in association with or arising from stricture of the urethra, cannot, of course, be considered exceptional. All authorities upon the subject of stricture mention among its symptoms (exclusive of those at the seat of the lesion or lesions) pain in the perineum, the hypogastrium (when cystitis is present), the small of the back, the loins, the testes and groins, and sometimes extending down the thighs. Sensory disturbances at more remote situations are certainly exceptional.

A case similar to the second here reported was described by Sir Benjamin Brodie, in his "Lectures Illustrative of Certain Nervous Affections" (*Dunglison's American Medical Library:* "Medical and Surgical Monographs," Phila., 1838, p. 38). The case was that of a gentleman who consulted him on account of a pain in the instep, so severe as to make him lame. Incidentally, the existence of a stricture was discovered, and its dilatation was followed by the relief of the pain.

I have not been able to find any reference to a case resembling the first one of this paper, certainly not so far as the throat symptoms are concerned.

MEDICAL PROGRESS.

Quinine and Sulphur in the Treatment of Diphtheria.—According to the *Provincial Medical Journal*, DR. BURGHARDT employs equal parts of quinine and flowers of sulphur in the local treatment of diphtheria. The powder is blown upon the false membrane, after which, if the disease is in the pharynx, the patient is not permitted to swallow anything for an hour and a half. As a prophylactic measure the powder is also insufflated into the nasal cavities, even when these parts are not infected. Of the thirty three cases treated in this manner by Burghardt all recovered, and in none was the powder applied oftener than twice daily. Internally he prescribed the tincture of the chloride of iron. In addition, the patients were bathed with vinegar, and were given wine, brandy, and milk.

Therapeutics of Green Coffee.—DR. LAUDARABILCO recommends an infusion of green coffee in the treatment of gout, gravel, nephritic colic, and migraine (*Journal de Médicine de Paris*). The following varieties of coffee are used: Martinique, one-half; Mocha and Bourbon, of each, one-fourth. At night six drachms of the mixture are placed in a glass of water and macerated about twelve hours. The contents are then stirred and strained, and the clear liquid drunk without sugar, and while the stomach is empty. Food may be taken soon after. The results are said to be extremely good.—*Provincial Medical Journal*, June, 1890.

Thallin in Typhoid Fever.—DR. FRANZ SCHMID has published an inaugural dissertation on the treatment of typhoid fever with thallin, his observations being made upon twenty-five cases. The drug was administered in doses varying from ¾ grain to 3 grains every hour. The author draws the following conclusions:

1. In the above-mentioned doses thallin has an excellent antipyretic action in typhoid fever of moderate severity. In severe cases it is not very effective. In the former cases it has a good effect on cerebral symptoms.

2. The drug does not cause collapse nor renal irritation, and it is without disagreeable effects on the heart and lungs.

3. It seems to reduce the mortality of typhoid fever, but has no appreciable effect upon the duration of the disease.

4. The thallin treatment is of as much value as the hydropathic treatment, and is, of course, less annoying to the patient.

In the *Correspondenzblatt für Schweizer Aerzte*, No. 9, 1890, Ruetimeyer writes that he has never seen collapse following the use of thallin, even when given in much larger doses than those of Schmid, and that even in severe forms of the disease it has a good effect on cerebral symptoms.—*Provincial Medical Journal*, June 2, 1890.

Prescription for Eczema in Children.—The following prescriptions for eczema in children are quoted in the *Annals of Gynecology and Pædiatry:*

1. R.—Bismuth subnitrate . 4 drachms.
   Zinc oxide . . . 1 drachm.
   Carbolic acid . . ½ drachm.
   White vaseline . . 2 ounces.—M.

2. R.—Bismuth subnitrate . 2 drachms.
   Zinc oxide . . . ½ drachm.
   Glycerin . . . 1½ drachm.
   Carbolic acid . . 20 minims.
   White vaseline . . 6 drachms.—M.

The latter is a very elegant and soothing ointment.

If there is much stinging and irritation the following lotion will be found valuable:

R.—Bismuth subnitrate . 1 drachm.
Glycerin . . . 4 drachms.
Carbolic acid . . 12 minims.
Rose-water to make . 1 ounce.—M.

Shake, and apply with a soft brush.

Cancer of the Pancreas; Extirpation; Recovery.—A successful extirpation of a primary cancer of the pancreas is reported by PROFESSOR RUGGE, of Bologna (*Medicinische-chirurgische Rundschau*, April 15, 1890). The patient, a woman of fifty years, came to Rugge's clinic in August, 1889, complaining of constant gastric pain, anorexia, and obstinate constipation. The pain began in the epigastrium, spreading from there to other parts of the abdomen. Physical examination revealed a tumor in the neighborhood of the transverse colon in the left hypochondrium and surrounding the umbilicus. The tumor was rather irregular in shape, felt firm on pressure, and measured about ten inches in length and four inches in width. The author made the diagnosis of probable retro-peritoneal sarcoma.

The patient insisting on the removal of the tumor, operation was undertaken on September 4th. The removal was rendered extremely difficult by the softness and fragility of the growth and numerous adhesions. Finally, extirpation was accomplished and the growth was found to be the pathologically changed pancreas, which the microscope proved was carcinomatous.

Healing of the wound was most rapid, and the general condition of the patient improved from day to day, and notwithstanding the fact that she desired and received a mixed diet, digestive disturbances diminished and finally disappeared. The author thinks that this remarkable case shows that after total extirpation of the pancreas other glands perform its functions, particularly Brunner's glands and Lieberkühn's follicles.

CODEIN.

ACCORDING to LOEWENMEYER (*Deutsche medicinische Wochenschrift*, No. 20, 1890), codein is very little employed in Germany, notwithstanding the encomiums which it receives from physicians elsewhere and especially from the French.

He therefore recently instituted an extensive series of observations in Jacobson's service at the Jewish Hospital in Berlin. Some five thousand doses of the drug were given to about four hundred patients, some of whom took it for weeks, and others for months; yet in no case did he observe any untoward results. He therefore recommends its use in place of morphine, rating it as a narcotic of somewhat lesser intensity than the latter, but on the whole superior, because of its freedom from danger. He especially endorses Dr. Lauder Brunton's assertion of the peculiar applicability of codein to the relief of painful affections of the abdomen. Gastralgia, colic, and the various visceral neuralgias seemed peculiarly amenable to its influence. The patients had long periods of respite from pain. They found sleep, and when, after a certain time, new exacerbations occurred, the medicament in the same dose as at first still exerted the same favorable influence.

Far more important than the relief of functional disturbance, however, in which the psychic factor may be presumed to have more or less influence, is the possibility of relieving the pain dependent upon organic disease, gastric cancer, cancer of the liver, cancer of the intestine, etc. While morphine was effective in ninety out of one hundred cases of this nature, codein succeeded in only sixty.

The question as to the indications for one or the other of these drugs is quite difficult to answer. Excluding idiosyncrasies, Loewenmeyer is disposed to think that attacks of pain of great intensity, occurring in paroxysms, are not likely to be favorably influenced by codein, but are alleviated by morphine. This was particularly noticeable in hepatic colic and in renal colic. He would also consider it a mistake to administer codein in cases of gout or of circumscribed inflammation of the peritoneum, in which large doses of opium act so happily in preventing extension of the inflammatory process. After the acute symptoms have subsided, however, codein is useful in controlling the remaining pains.

Incomparably more favorable than in any affection heretofore mentioned, is the action of codein in diseases of the thoracic viscera, and particularly of the organs of respiration. This was especially notable in cases of phthisis, alike for its influence upon the cough, for relief of pain, and for modifying acute bronchitic or pneumonitic exacerbations. Good results were likewise evident in some cases of bronchial asthma. The drug was also administered in some cases of severe cardiac lesions in which morphine had previously been employed, and without seeming to produce any toxic effect. On the other hand, it was of little avail either in organic or functional nervous affections. As a hypnotic, however, it acted readily, nor did it seem to have a tendency to produce an unfortunate habit, such as follows the continued use of morphine.

While Loewenmeyer cannot agree with the opinion that codein is useful in the direct treatment of the morphine habit, he looks upon it as a prophylactic, inasmuch as by its substitution for morphine the contraction of the habit may be avoided.

We have called attention to this careful study of an important drug, because we believe that in America, too, its use might be profitably increased. Our experience tallies closely with that of Loewenmeyer so far as reported—an important omission in the report being its use in diabetes mellitus—and the concluding observation of that author is one to which great heed should be given. Many unfortunate cases of morphine habit have been due to un-

guarded prescription of the drug, or too long continued resort to it, by physicians. It is much easier to avert contraction of the habit than to cure it. Therefore, if codein be applicable at all in cases where an opium alkaloid is indicated for anything more than occasional use, it should be preferred. We are inclined to go still further than Loewenmeyer and to urge caution and reluctance in the use even of codein for prolonged periods. Let continuous resort to any drug of this nature be only adopted after careful deliberation, as an absolute necessity, and with the safeguard, to both patient and physician, of a consultation.

CORRESPONDENCE.

FIVE CASES OF PTOMAINE POISONING.

To the Editor of THE MEDICAL NEWS,

SIR: I take the liberty of presenting these cases, which to me were of considerable interest, to my colleagues in the medical profession for their consideration. I think that the report may perhaps assist us in finding the etiology of some of those most serious and painful conditions which we so often meet with, and where the cause is somewhat obscure.

I had been practising for some time in the mining regions near Charleston, S. C., a dangerously malarial section, and while there had seen some of the most desperate and malignant forms of malarial affections, such as malignant malarial dysenteries, paralyses, and congestions, and so was not in a condition to be surprised by anything I met with. However, on Monday, in the latter part of April, 1890, I met with a series of five cases which specially attracted my attention after the death of two of them. On the previous Friday evening there had been a beef and a hog killed, the meat of which was sold in the local market on Saturday; it had not been kept on ice, but the weather was pleasant, not hot. My patients ate some of this meat Saturday afternoon and again on Sunday morning—four women and one man. One of the women at about eleven o'clock Sunday morning was taken with apparently a violent attack of cholera morbus, in which condition she remained until I saw her early on Monday morning. Another of the women was attacked in the same way at about 1 o'clock Monday afternoon; she had eaten some of the pork. The other three were attacked in a similar way during Monday.

The meat had appeared to be perfectly fresh and very nice, so that when I inquired as to whether they had eaten anything which might have caused the trouble, they did not mention the meat. The first two women I found in the following condition: Lying with the knees drawn up and suffering great pain, paroxysmal in character, abdomen distended, tympanitic and painful on pressure, countenance anxious, great nervous excitement, temperature 101°, pulse rapid, bowels constipated, no history of a chill or any previous debility. I considered this condition as cholera morbus, although there had been but one slight attack of vomiting and no purging, so I gave a large enema of warm water and soap, thinking that I would clear the bowels of the irritating substance. The enema acted well and brought away large quantities of fæcal matter. I then gave a hypodermic injection of one-half grain of morphine, ordered hot stupes to be applied over the abdomen constantly, and one-quarter grain of morphine to be given every three hours until relieved.

On calling next morning I found that my patients had had little or no relief, and that a dysenteric discharge had set in, temperature 102°, pulse rapid and compressible. Thinking this to be dysentery following cholera morbus I gave ipecacuanha, opium, and bismuth-subnitrate; also quinine, five grains, three times a day. But the condition continued to grow worse and by night my patients were in collapse, and died the next morning (Wednesday).

Of the other three, the man recovered on the above-mentioned treatment, although he went through a troublesome and severe attack of dysentery. On Tuesday it was suggested to me that perhaps the meat was the cause of the trouble, and the idea struck me as being a likely one and suggested ptomaines. I immediately put the other two women on the following treatment: To one, after washing out the lower bowel with solution of bichloride of mercury 1 : 3000, I gave bichloride of mercury one-sixteenth grain every four hours; she recovered rapidly. To the other I gave tincture of chloride of iron, 20 drops every four hours, also an enema of the bichloride of mercury solution; she recovered, but slowly.

On examining into the histories of these cases I found that all of them had eaten either the pork or the beef. The man's case was milder than the others, which fact, I think, was due to the beef eaten by him having been parboiled before being roasted, which he states was the case. I have also been informed that numbers of others had dysentery after eating meat, on several occasions previous to this. Finding that a considerable amount of distemper existed among the hogs, cows, and horses, I concluded that perhaps, the animals being in an unhealthy condition, putrefactive changes set in rapidly, and, although being only incipient—for the meat seemed fresh—ptomaines were formed, and that my patients were suffering from poisoning from this product.

Now in the section where I have been practising for a year fresh meat could only be had once a week—on Saturday—and I found, on looking over my cases of dysentery for the year—and a great number of them there were—that most of them were in the spring and summer, and that frequently fresh meat had been eaten a day or so before, and that when such was the case the onset of the disease was similar to that of the above-mentioned cases, varying in severity, due sometimes to the mode of cooking and again to the quantity eaten; although there were not many deaths, I must confess my treatment of that disease with ipecacuanha, etc., was not satisfactory.

The theory I wish to endorse is that as dysentery, cholera morbus, cholera infantum, etc., are most common in the summer months, in hot and filthy quarters, and in the tropics, and that as the summer months and warm climates are the conditions most apt to convert albuminoid substances into ptomaines, may not ptomaines,

more frequently than we generally suppose, be the cause of these affections? And that, if such be the case, could not a more satisfactory treatment than the present be formulated? There was a condition in my cases which I failed to make much mention of above, which, I think, goes to strengthen the ptomaine theory. It was the great nervous excitement, which appeared to me to be due to the absorption into the blood of a virulent septic poison; for the local intestinal conditions I did not consider severe enough to cause it; also the collapse I considered due to this cause.

I did not make an autopsy of either of these bodies or examine the discharges chemically, but I feel convinced that they were cases of ptomaine poisoning, and that the above-mentioned diseases are frequently caused by this product.

W. Mazyck Memminger, M.D.
Charleston, S. C.

NEWS ITEMS.

The next meeting of the Fifth District Branch of the New York State Medical Association will be the eighth special meeting, to be held in Kingston, Ulster county, New York, on Tuesday, July 22, 1890. A large attendance is desired.

The 17th annual session of the Mississippi Valley Medical Association will be held at Louisville, Kentucky, October 8, 9, and 10, 1890. The medical profession is respectfully invited to attend. The meeting promises to be of great social and scientific interest, as the profession of Louisville are doing their utmost to make it a success. Ladies accompanying physicians will be made especially welcome. Gentlemen wishing to read papers will please send titles as soon as possible to the secretary, Dr. E. S. McKee, 57 W. Seventh street, Cincinnati. The American Rhinological Association will also meet in Louisville October 6, 7, and 8, 1890.

A Medical Bishop.—The Right Reverend Henry Callaway, Bishop of Saint John's, Caffraria, South Africa, who died March 26th, was a regularly qualified practitioner of medicine and surgery, his M.D. degree having been granted by the King's College, Aberdeen, in 1853. He was in his seventy-third year at the time of his decease.

Dr. Virchow has recently been on a brief visit to Hissarlik, where his old friend Schliemann is still engaged in explorations. On his return, while passing through Constantinople, he was made the recipient of marked attentions by the Medical Society of that city. He addressed the Society in response to remarks by the President, Dr. Stekulis, saying that there was a manifest and happy awakening in many parts of the Orient, of which he himself had been a witness, and the scientific world was destined to be the gainer by the contributions of countries that had hitherto been receivers only, and giving out nothing of value.

Professor Nussbaum Pensioned.—Dr. von Nussbaum, it is announced, will be awarded a pension by his government in consideration of his distinguished services in surgery. He has been invalided on account of a severe attack of influenza, about six months ago, which has left him partially paralyzed and nearly blind.

The University of Halle now has its Hygienic Institute, with suitable lecture-hall and laboratories. Professor Renk has been appointed to be its director.

Obituary.—The death of Dr. Francesco Scalzi, at Rome, is the subject of memorial mention in the *British Medical Journal*. Professor Scalzi was the most eminent authority in materia medica, in Italy, of his generation. He established, in 1876, the first and the best, in Italy, Institute for Experimental Pharmacology and Toxicology. He was a distinguished lecturer and teacher, an editor, the writer of 112 publications on various subjects, a hospital physician, a sanitarian, and a public official. He was fluent, eloquent, fertile, and withal blessed with a sound judgment. He was in his 70th year.

Large Russian Surgical Fees.—Dr. Sklifissowsky, of Moscow, having been called to Odessa to operate upon a case of hip-disease, was presented with an honorarium of 11,000 roubles, or the value of £1,222. This is, for Russia, an enormous fee, and the surgeon, with remarkable generosity, passed it over untouched to the University of Odessa, to found a medical scholarship. He also was called upon, incidentally to his other consultations, to operate upon a cancer of the breast, for which he received 2000 roubles. These large fees are for the elect only, the average Russian medical man being very poorly paid.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JUNE 17 TO JUNE 23, 1890.

By direction of the Secretary of War, leave of absence for six months, to take effect when, in the opinion of his department commander, his services can be spared, is granted William O. Owen, Jr., *Captain and Assistant Surgeon.*—Par. 12, *S. O. 139, A. G. O.*, June 14, 1890.

By direction of the Secretary of War, Eugene L. Swift, *First Lieutenant and Assistant Surgeon*, is relieved from duty at Fort Spokane, Washington, and will report in person to the commanding officer at Fort McDowell, Arizona, for duty at that station, relieving Marlborough C. Wyeth, Captain and Assistant Surgeon, who, on being thus relieved, will proceed to Fort McIntosh, Texas, and report in person to the commanding officer thereof for duty at that station. The officers named will also report by letter, upon their arrival at their new stations, to their respective department commanders.—Par. 10, *S. O. 140, A. G. O.*, June 16, 1890.

By direction of the Secretary of War, leave of absence for two months, to take effect July 1, 1890, is granted Charles B. Byrne, *Captain and Assistant Surgeon.*—Par. 13, *S. O. 141, Headquarters of the Army, A. G. O.*, June 17, 1890.

By direction of the Secretary of War, leave of absence for four months, to take effect upon the final abandonment of Fort Maginnis, Mont., is granted to William W. Gray, *Captain and Assistant Surgeon.*—Par. 14, *S. O. 141, Headquarters of the Army, A. G. O.*, June 17, 1890.

By direction of the Secretary of War, Samuel M. Horton, *Major and Surgeon*, will visit the encampment of the Maine Volunteer Militia, at Augusta, Maine, during the period of its encampment, June 30 to July 4, 1890, inclusive, for the purpose of instructing the medical department thereof in its duties in camp, and on the completion of this duty will return to his proper station.—Par. 5, *S. O. 143, Adjutant-General's Office, Washington, D. C.*, June 19, 1890.

Taylor, Marcus E., *Captain and Assistant Surgeon.*—Is hereby granted leave of absence for one month, on surgeon's certificate of disability, with permision to go beyond the limits of this Division, and to apply for an extension of five months.—Par. 1, *S. O. 45, Division of the Pacific, San Francisco, Cal.*, June 13, 1890.

INDEX.

ABBOT, climato-therapy, 67
Abdominal section, flushing of peritoneum after, 148
surgery, drainage in, 271
retrospect of, Price, 646
tumor, removal of, 189
viscera, transposition of, 541
Abducens paralysis, 236
Abscess complicating uterine fibroid, Davis, 559
of cornea, Hansell, 252
of liver, diagnosis of adhesions in, 197, 208
Accommodation, theory of, 354
Acid, trichloracetic, in nasal diseases, 541
Acne, boric acid and alcohol in treatment of, 66
prescription for, 346
treatment of, 286
Acute pancreatitis, 127
Adhesions in hepatic abscess, diagnosis of, 197
Adirondack sanitarium, statistics of, 405
Adulterations with terra alba, 187
Advertising of proprietary medicines, 488
Albuminuria in the apparently healthy, Washburn, 356
significance of, 481
Alcohol and tobacco headache, prescription for, 231
in patent medicines, 267
use of, during lactation, 486
Alopecia areata, Duhring, 353
Alvarenga prize, 188
American Medical Association, proceedings of, 570
Surgical Association, proceedings of, 547
Ammonium bromide fumes in asthma, 655
picrate in malaria, 258
Amputation in a diabetic subject, Sharpless, 393
of "tapiroid" cervix, Goodell, 493
Amylene hydrate in epilepsy, 70
Amyloid tissues, method of staining, 128
Anæmia, arsenic and mercury in, 347
Anæsthesia with bromide of ethyl, 512
with cocaine, 398
in litholapaxy, 287
Anæsthetics, 209
Anal eczema, treatment of, 101
fissure, 222
fistula, case of, 427
in phthisis, 563
non-operative treatment of, 258
Analgesic properties of exalgine, 314
Anastomosis, intestinal, 185
Anencephalic monster, 634
Anatomical material, scarcity of, Roberts, 68
Aneurism of aorta, MacDonnell, 161
Angina pectoris, false, 181
Anomalous diverticulum from ileum, 146
Anthelmintic, rhubarb as an, 257
Antidote to snake poison, 52, 55
Antifebrin, the dose of, 287
Antimony in inflammation, 398
Antipyrine and spirit of nitrous ether, 405
in sea-sickness, 80
in whooping-cough, 126
Antiseptic gauze, Lister's new, 147
irrigation of knee, Weir, 125
midwifery, Lusk, 581
paste, 654
properties of calcium iodate, 370
surgery, 154
treatment of erysipelas, 128
of gastro-enteritis, 287
of urethritis, White, 637
of vaccination, 233, 541
Anus, imperforate, case of, 626
Aorta, aneurism of, 161
Aphonia, hysterical, treatment of, 201
Appendicitis, 549, 605
quiescent, laparotomy for, 226
Appendix vermiformis, perforation of, 174
removal of, Dennis, 698
Arhythmia, cardiac, 387
Aristol, a substitute for iodoform, 205
Army, examinations for vacancies in, 188
Arsenic as a cause of multiple neuritis, 102
in treatment of anæmia, 347
Arthritis, tubercular, iodoform in treatment of, 126.
Arthrotomy of elbow-joint, 69
Artificial infant-feeding, a reform in, 290
Aseptic catgut, 398
sponges, method of preparing, 19
urethral instruments, 656
Ashhurst, hospital notes, 255
Asphyxiation in infants, method of treating, 186, 287
Aspiration of knee-joint, 309
Association of American Physicians, proceedings of, 547, 564
of Medical Editors, 579
Asthma as a neurosis, Carpenter, 13
oil-silk jacket in treatment of, 415
thyroid, 594
treatment of, 49, 233, 371
with ammonium bromide fumes, 655
Astragalus, removal of for equino varus, 23
Asylums for insane in New York, 108
Atropine instilled into eye, hallucinations from, 369
poisoning, 79
Aulde, antipyrine and spirit of nitrous ether, 405
Auscultatory percussion, 49
Axis-traction forceps, Hoffman, 659

BACILLUS coli communis, relations to Eberth's bacillus, 315
Bacteriological examinations at autopsies, 379
Baldness, treatment of, 49
Baldy, ectopic gestation, case of, 169
electricity in pelvic disease, 302, 661
Balanitis from calomel, 288
Bandages of magnesia-isinglass, 511
Barr, intermittent fever, case of, 677
Beaver, peritoneal adhesions in hepatic abscess, 197
Beck, legal aspects of vivisection, 280
Belladonna, glycerite of, 205
Belt, hallucinations from atropine, 369
Benzoate of bismuth in treatment of chancroids, 180
Bichloride of mercury in anæmia, 347
in dysentery, 347
Bigelow, gynecological electro-therapeutics, 499
Biliary colic, salicylate of sodium in, 456
Billings, J. S., vital and medical statistics, 1
Biniodide of mercury in scarlatina, 232
Bi-polar faradization in gynecology, Smith, 93
Bismuth benzoate in treatment of chancroids, 180
subnitrate, incompatibilities of, 182
Bladder, fibroid tumors of, 593
irritable, prescription for, 682
villous tumors of, 244
Blepharitis, management of, 143
Blindness, hysterical, in males, 33
Blood corpuscles effects of heat on, 399, 435
pressures, extreme, 58
syphilitic, effects of mercury on, 535
Boiled milk, nutritive value of, 100
Bone, implantation of, 125
Boric acid and alcohol in treatment of acne, Post, 66
Bougies weighted with mercury, 655
Bozeman, irrigating catheter, 320
Brain surgery, a failure in, 134
Bright's disease, general treatment of, 456
Bridge, appendicitis, 549
Broad ligament, varicose veins in, 538
Bromide of ethyl anæsthesia, 512
of rubidium in epilepsy, 72
Bronchitis eucalyptus in, 561
chronic treatment of, 654
prescription for, 682
Brower, types of insanity, 412
Bryonia alba as a hæmostatic, 512
Brush, Cheyne-Stokes respiration, 592
Buboes, treatment of, 47, 233
Buckmaster, treatment of fibro-myomata by electricity, 91
Bulkley, dangers of syphilis in dentistry, 449
Bullous dermatosis, case of, 630
Burns, treatment of, 71, 182, 370
Busey, oil-silk jacket in the treatment of asthma, 415

CÆSAREAN section, case of, 333
post-mortem, substitute for, 561
technique of, 480
Caffeone, 476
Calcium iodate as an antiseptic, 370
Calculus, vesical, in boys, 530
large, 596
Calf pepsin, 17
Calomel as a cause of balanitis, 288
in phthisis, 182
vaporized, inhalations of, in croup, 455
Camphoric acid in night-sweats, 481
Cannabis indica poisoning, Glover, 478
therapeutics of 429
Cancer of intestine, triple resection for, 682
mammary, extirpation of, 628
pyloric, gastro-enterostomy for, 112
rectal, colotomy for, 31
secondary, suppuration in, 515

Cancer, uterine, method of treating, 63
Capsicum as a counter-irritant, 684
in pneumonia, 313
Capsules, quinine, short-weight, 487
Carbolic acid gangrene, 385, 519
injections in tetanus, 542
Carbonic acid in treatment of phthisis, 372
Carbuncles and furuncles, treatment of with iodine, 209
Cardiac arhythmia, etc., treatment of, Patton, 387
affections of menopause, 371
Caries of teeth, prevention of, 206
Carpenter, asthma as a neurosis, 13
Cartilage, loose in knee-joint, removal of, 427
Cartwright lectures, 1
Casselberry, hysterical aphonia, treatment of, 201
Castration, double, 479
Catalpa speciosa, Schneck, 624
Cataphoresis in treatment of syphilitic growths, 675
Cataract operations, Pipino, 554
Catarrh of stomach, treatment of, 231, 233
Catarrhal fever, 133
Catgut, method of rendering aseptic, 398
Catheter, self-exhausting irrigating, 320
Catheterization, dangers of, 456
Cauda equina, lesions of, 217
Caustic paste, formula for, 208
Cautery in treatment of epilepsy, 232
Cerebro-spinal meningitis, iodoform in, 372
Cerna, cases treated with iodol, 241
Cervical paraplegia from dislocation, 236
Cervix, "tapiroid," amputation of, 493
detachment of during labor, Hirst, 653
Chancres, difficulties in diagnosis of, 631
of breast, 632
Chancroids, bismuth benzoate in, 180
Chapped hands, prescription for, 370, 682
Chilblains, prevention of, 231
treatment of, 429
Chloral, administration of, in convulsions, 49
suppositories of, 50
Chloralamid, effects of, 47, 595
Chloroform, after-effects of, 429
cause of death from, 190
Chlorosis, treatment of, 103, 314, 682
Choice of methods in treatment of uterine cancer, Jackson, 63
Cheyne-Stokes respiration, 589, 592
Chorea, etc., ocular treatment of, 52
sulphonal in, 275
Chronic osteomyelitis, operations for, 211
prostatitis, treatment of, 150
rheumatic sore throat, Ingals, 266
Cinchonidine salicylate, 442

Sensory and motor reinforcement, 297
Sharp, Tait's operation, etc., 41
Sharpless, amputation in a diabetic, 393
Shimwell, intestinal surgery, 389
Shock, secondary consequences of, 444
Skene, electricity in treatment of fibromata, 99
Skin-grafting, Thiersch's method, 427
Sloughing of gastrocnemius in diabetes, 393
Smith, A. H., gastric ulcer, 526
Smith, A. L., faradization in gynecology, 93
Smith, J. L., treatment of tuberculosis, 163
Snake-poison and its antidote, 52, 55, 684
Sodium salicylate for biliary colic, 456
in pruritus, 224
in typhoid fever, 478
Solvents for fæces, 250
Somnal, effects of, 47
South Carolina Medical Society, 159
Sozoiodol in treatment of burns, 71
Spears, sodium salicylate in typhoid fever, 478
Spinal tumor complicating labor, J. S. Miller, 340
Spina bifida, excision of, 479
Spinous processes, removal of, 210
Spiritus etherus nitrosi, combination of, with antipyrine, 405
Subclavian artery, ligation of, 678
Splint, Hodgen's, 506
Sponges, method of rendering aseptic, 19
Staining of amyloid tissues, 128
Stamm, gastro-enterostomy for pyloric obstruction, 112
Starr, reflex neuroses, 299
Statistics, vital and medical, 1
Sternum, resection of, 257
"Stevens's operation," report on, 52
Stomach, catarrh of, treatment of, 231, 233
Street noises, 544
Stricture, electrolysis in treatment of, 74
Strictures of urethra, case of, 427
of rectum, intestinal obstruction, colotomy, Kelsey, 437
congenital, 222
traumatic urethral, treatment of, 125
with reflex symptoms, 707
Strophanthus, 627
in infantile diseases, 232
Sulphonal in chorea, Jeffries, 275
disadvantages of, 233
formula for, 206
Sulphur in treatment of diphtheria, 150, 255
Summer complaint, 512
Sunflower in treatment of malaria, 283
Suppositories of chloral, 50
Suppuration in secondary carcinoma, 515
Suprapubic cystotomy, McGuire, 522
Vander Veer, 224
Surgery, antiseptic, 154
iodoform in, 180
of brain, case of, with failure, 134
of intestines, 389
Surgical dressing, naphthol camphor as a, 47
treatment of hepatic abscess, 208
of tubercular peritonitis, 150
Suspension splint, Hodgen's, 506
Suturing an intra-capsular fracture of femur, 126
Sweating of the feet, 19, 50
Sweet spirit of nitre, combination of, with antipyrine, 405
Sycosis, treatment of, 345
Symptomatic hæmorrhage, treatment of, 151
Synovitis of knee, irrigation in treatment of, 125
Syphilis, dangers of, in dentistry, 449
diagnosis of, 148
during pregnancy, 680
iodol in, 511
local manifestations of, 396
modes of infection, 683
papular and ulcerating, 393
quinine in treatment of, 47
Taylor, 229
thymolate of mercury in, 285
Syphilitics, blood of, effects of mercury on, 535

TABES dorsalis, treatment of, 72
laryngeal crisis in, pathology, 236
Tachycardia, paroxysmal, 440
Tait's operation, plea for conservatism in employment of, 41
Tamponing uterus for post-partum hæmorrhage, 206
"Tapiroid" cervix, amputation of, 493
Tariff on books, 432
Tartar emetic in inflammations, 398
Taylor, hospital notes, 283, 393
syphilis, scabies and eczema, lecture on, 229
Teeth, caries of, prevention, 206
Tenotomy scissors, 184
Terra alba, adulterations with, 187
Terpine hydrate and salol in "colds," 147
Tetanus in infants, cases of, Fussell, 145
injections of carbolic acid in, 542
treatment of with paraldehyde, 101
Thallin in typhoid fever, 709
Therapeutic oxygen, Wallian, 533
Therapeutics of digitalis, Wood, 109
Thiersch's method of skin-grafting, 427
Thompson, tumors of frontal lobe, 586
Throat, inflammation of, ichthyol ointment in, 178
Thymolate of mercury, hypodermically, in syphilis, 285
Thyroid-asthma, 504
grafting in myxœdema, 596

Thyroid tumors, extirpation of, 150
Tincture of capsicum in alcoholic pneumonia, 313
Tinea circinata, Duhring, 353
hydronaphthol in, treatment of, 18
tonsurans, 127, 393
Tobacco and alcohol headache, prescription for, 231
Todd, secondary consequences of shock, 444
Tonsillitis, treatment of, 19
Tonsillotomy, hæmorrhage after, 231
Toothache, prescription for relief of, 102
Tooth-wash, antiseptic, 287
Torticollis as a cause of scoliosis, Young, 204
Trachea, foreign bodies in, 286
Tracheotomy *versus* intubation, 102
Training schools for nurses, 399, 404
Transposition of abdominal viscera, 541
Traumatic dislocation of lens, etc., Harlan, 354
Traumatism as a cause of insanity, 101
Trephining, cases of, 155
for extra-dural hæmorrhage, Deaver, 176
for epilepsy, Hoegh, 253
Keen, 381, 479
Trichinæ in swine, 101
Trichloracetic acid in nasal disease, 541
Tri-State Sanitary Convention, 186
Trudeau, contagiousness of influenza, 185
Tubercular abscess, Keen, 467
arthritis, iodoform in treatment of, 126
laryngitis as a cause of globus hystericus, 430, 481
peritonitis, case of, 562
surgical treatment of, 150
ulceration of intestine, Gibney, 306
Tuberculosis, general, in hip-disease, 306
in the light of modern research, 402
local excision of, 562
Peruvian balsam in, 511
pulmonary, prescription for, 346
treatment of, 163
Tuholske, gastro-enterostomy and pylorectomy, 503
Tumor of abdomen, anomalous, 189
Tumors of bladder, 244
of brain, 586
of thyroid, extirpation of, 150
Turpentine in typhoid fever, Wood, 243
Tympanum, collodion in disease of, 314
Typhoid fever, 616
at Cumberland, Md., 401, 403
drinking water in relation to, Vaughan, 641
etiology of, 315
immersion in treatment of, 480
sodium salicylate in treatment of, 478
thallin in treatment of, 709
turpentine in treatment of, 243
Tyson, influenza, 133

ULCER, gastric, Smith, 526
Unna's medicated gelatins, 396
treatment of tinea, 127
Uræmia with Cheyne-Stokes respiration, Downs, 589
Urethral fever, prevention of, 345, 397
stricture, cases of, 427
implantation of mucous membrane in, 125
treatment by electrolysis, 74
with reflex symptoms, 707
Urethritis, antiseptic treatment of, 637
Urethroscope, incandescent lamp, Deaver, 667
Urethrotomy, external, 69
Uric acid diathesis, treatment of, 180
eruptions, 631
Urine, incontinence of, in children, 596
influence of massage on, 49
retention of, 431
Urobilinuria, significance of, 127
Uterine cancer, treatment of, 63
expression, delivery by, 183
hæmorrhage, hydrastinin in, 395
Uterus, tamponing the, for post-partum hæmorrhage, 206

VACCINATION, antiseptic 541
complicated by gangrene, 631
of newborn infants, 398
Vander Veer, suprapubic cystotomy, 224
Vanneman, influenza, 45
Varicose veins, excision of, 179
in broad ligament, Hirst, 538
treatment, by injection, 511
of vulva, 563
Vaughan, examination of drinking water, 641
Venereal diseases, evolution of, 156
Veratrum viride and digitalis in treatment of pneumonia, 57
Vermiform appendix, perforation of, etc., 174
Vesical calculus in boys, treatment of, 530
Villous tumors of bladder, Jones, 244
Visual accommodation, 354
Vital and medical statistics, 1
statistics of New York for 1889, 492
"Vita nuova," analysis of, 28
Vivisection, legal aspects of, 280
value of, etc, 259
Vomiting, iodine in treatment of, 231
of pregnancy, menthol in, 100

WAKEFULNESS of neurasthenia, etc., Daly, 360
Wallian, oxygen, 533
Warfield, carbolic acid gangrene, 385
Warts, removal of, by electricity, 346
Washburn, albuminuria, 356
Water, bacteriological, etc., examination of, 379, 641
Weil's disease, 47
Weir, hospital notes, 179
Wharton, colotomy for rectal cancer, 31
White, antiseptic treatment of anterior urethritis, 637
electrical execution, 458
vesical calculus in male children, 530
Whooping-cough, antipyrine in, 126
oubain in, 562
resorcin in treatment of, 48, 268
Willard, operative treatment of hip-disease, 361
Winslow, suppurative peritonitis, etc., 174
"Wolf in sheep's clothing," 458
Women, education of, higher, 75, 77
Wood and Hare, cause of death from chloroform, 190
Wood, H. C., treatment of pneumonia, 57
therapeutics of digitalis, 109
turpentine in typhoid fever, 243
Woodbury, calf-pepsin, 17
cataphoresis in treatment of sypilitic growths, 675
Wool, test for purity of, 482
Wyman, a failure in brain surgery, 134

YOUNG, torticollis as a cause of scoliosis, 204

ZINC chloride in endometritis, 594
